B. JET POWER EFFECTS ON PITCHING MOMENT

This section presents a method from references 1, 3, and 4 for estimating the subsonic jet power effects on pitching moment. The method presented here for estimating the supersonic jet power effects is based on approximate methods developed for the Datcom. Since the power effects on pitching-moment characteristics are primarily a result of the increments in lift due to jet effects, part B of Section 4.6.1 is directly applicable to this section, and the reader is referred to that discussion for a general description of the fundamental phenomena.

DATCOM METHOD

The Datcom method estimates the power-on pitching-moment curves, based on power-off pitching-moment curves, as a function of angle of attack, thrust coefficient, and lift coefficient.

This method analyzes the increments of pitching-moment coefficient due to jet power effects in the following order:

1. Offset of the thrust axis from the origin of the axes
2. Normal force acting at the engine inlet
3. Interference effects

After the above lift increments for a given angle of attack have been calculated, the accumulated total is then applied to the power-off pitching-moment curve to obtain a point on the power-on pitching-moment curve. After several points have been generated (by considering several angles of

attack), the linear section of the power-on pitching-moment curve is obtained for a given thrust coefficient. (Refer to figure 4.6-13b for geometrical definitions.)

All increments of pitching-moment coefficients are nondimensionalized with respect to the product of wing area and wing MAC. Their moment center is at the quarter-chord of the wing MAC.

Step 1. Calculate the increment in pitching-moment coefficient for each engine due to an offset of the thrust axis from the origin of the axes by

$$\left(\Delta C_m\right)_T = \frac{T_c' z_T}{\bar{c}} \qquad 4.6.3\text{-a}$$

where the thrust coefficient is a given or chosen quantity. For multiple-engine configurations the total pitching-moment component is found by summing the single components due to each engine.

Step 2. Calculate the increment in pitching-moment coefficient due to the normal force at the engine inlet as follows:

a. Calculate the inclination of the thrust axis to the oncoming stream α_j at the engine inlet, given by equation 4.6.1-x, i.e.,

$$\alpha_j = \alpha_T + \epsilon_u$$

where the upwash ahead of the wing ϵ_u is obtained from equation 4.6.1-m, i.e.,

$$\epsilon_u = \frac{\partial \epsilon_u}{\partial \alpha} \left(\alpha_W - \alpha_0\right)$$

and the upwash gradient $\partial \epsilon_u / \partial \alpha$ at the engine inlet may be obtained in Section 4.4.1.

b. Calculate the incremental pitching-moment coefficient per engine by

$$\left(\Delta C_m\right)_{N_j} = \frac{2 A_I x_I \sin \alpha_j}{S_W \bar{c}} \qquad 4.6.3\text{-n}$$

where A_I is the inlet duct area. For multiple-engine configurations the total pitching-moment component is found by summing the single components due to each engine.

Step 3. Calculate the increment in pitching-moment coefficient due to the jet interference effects at the horizontal tail or other surface by

$$\left(\Delta C_m\right)_\epsilon = \left(\Delta C_L\right)_\epsilon \frac{x}{\bar{c}} \qquad 4.6.3\text{-o}$$

where $\left(\Delta C_L\right)_\epsilon$ is calculated in Section 4.6.1 and where x is the distance from the moment center to the centroid of the affected area, positive ahead of the moment center (in the case of tail-last configurations x corresponds to the negative value of the tail length ℓ_H).

Step 4. Calculate the total incremental change in pitching-moment coefficient due to jet effects by

$$\left(\Delta C_m\right)_{\substack{\text{power}\\ \text{on}}} = \left(\Delta C_m\right)_T + \left(\Delta C_m\right)_{N_j} + \left(\Delta C_m\right)_\epsilon \qquad 4.6.3\text{-p}$$

Sample Problem

The configuration used in this sample problem is the same as that used in the sample problem of Section 4.6.1, paragraph B.

Given:

Engine Parameters:

Outboard Engines (2)

$T_c' = 0.0746$ (per engine) $\quad A_I = 13.64\ ft^2 \quad x_I = 145.2$ in.

$z_T = 53.0$ in. $\quad \alpha_j = 9.87°$ (Section 4.6.1)

Inboard Engines (2)

$T_c' = 0.0746$ (per engine) $\quad A_I = 13.64\ ft^2 \quad x_I = 283.8$ in.

$z_T = 70.8$ in. $\quad \alpha_j = -10.4°$ (Section 4.6.1)

Horizontal-Tail Parameters:

$\left(\Delta C_L\right)_\epsilon = -0.002$ (Section 4.6.1) $\quad \ell_H = 855.0$ in.

Wing Parameters:

$\bar{c} = 272.8$ in. $\quad S_W = 2930\ ft^2$

Compute:

Determine the increment in pitching-moment coefficient due to an offset of the thrust axis from the origin of the axes by

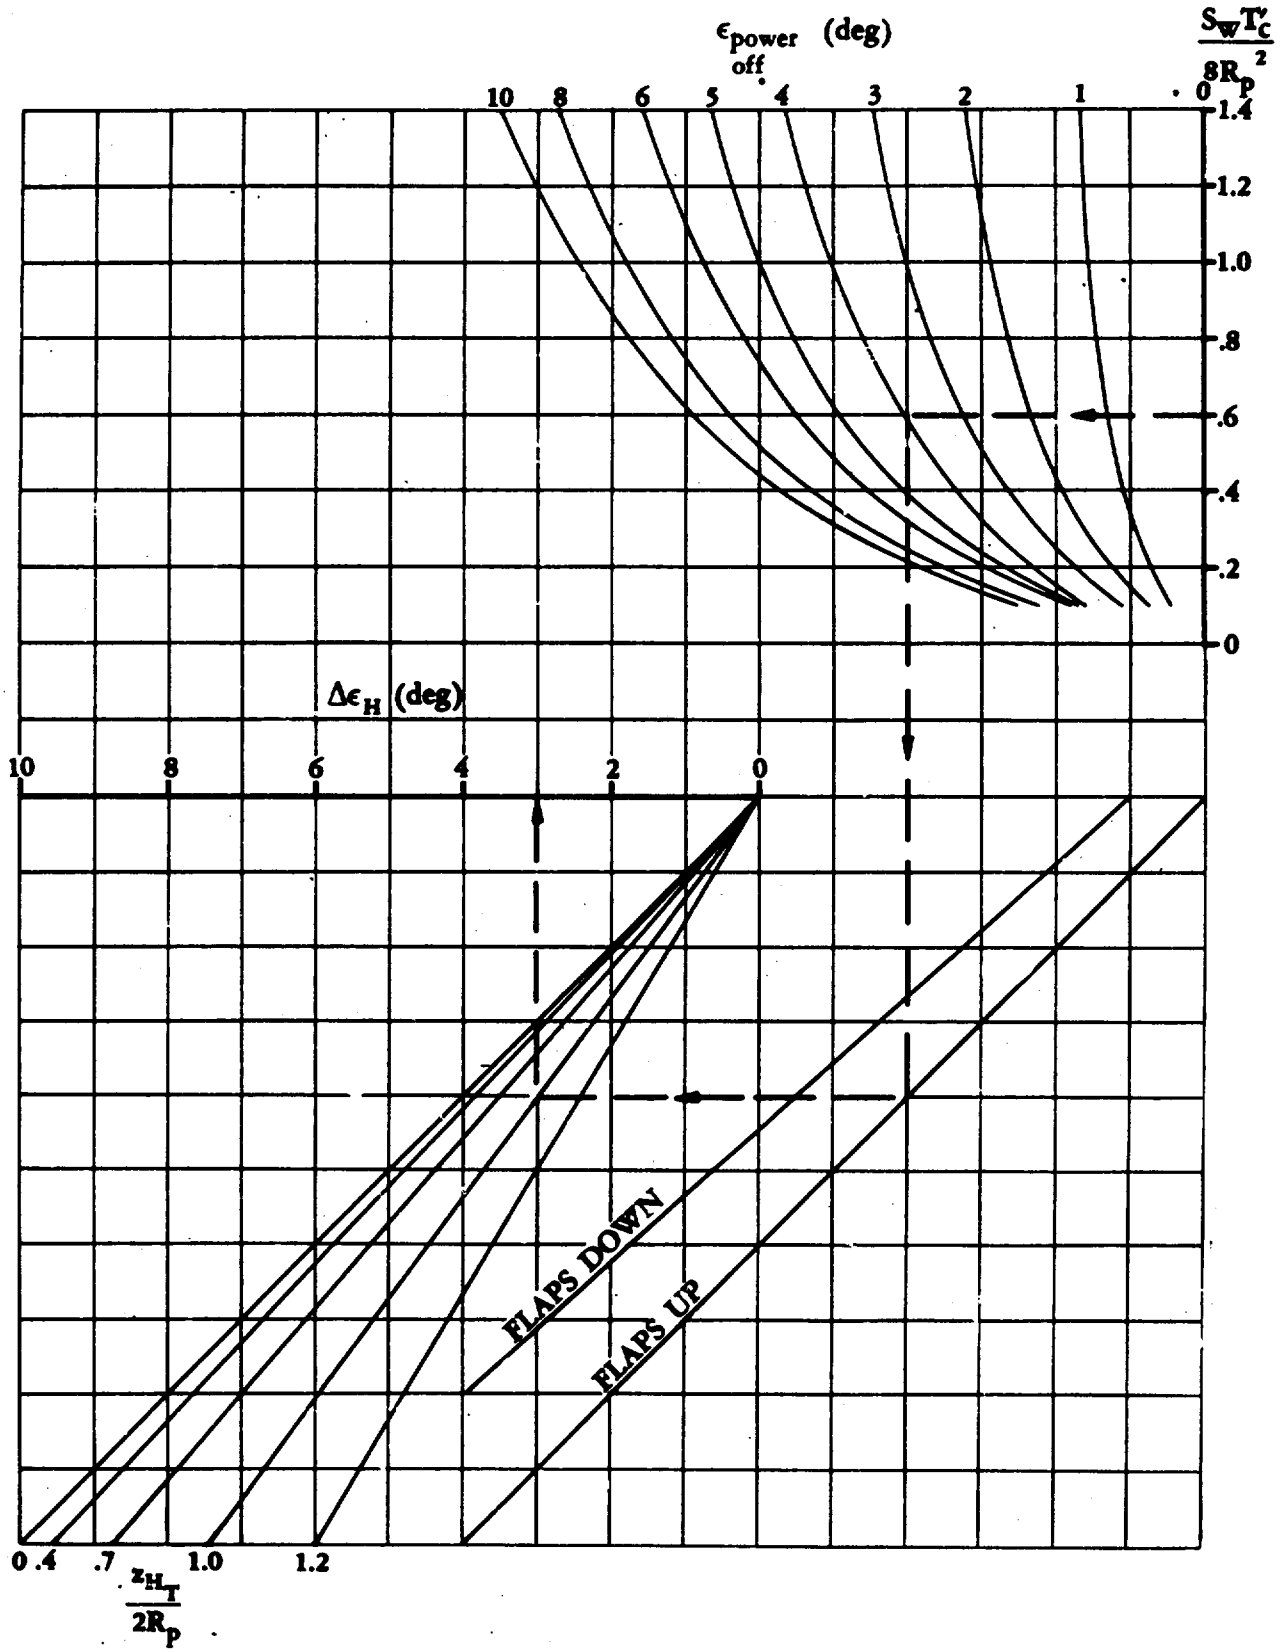

FIGURE 4.6.3-15 INCREMENT IN DOWNWASH DUE TO PROPELLER POWER FOR MULTIENGINE AIRPLANES

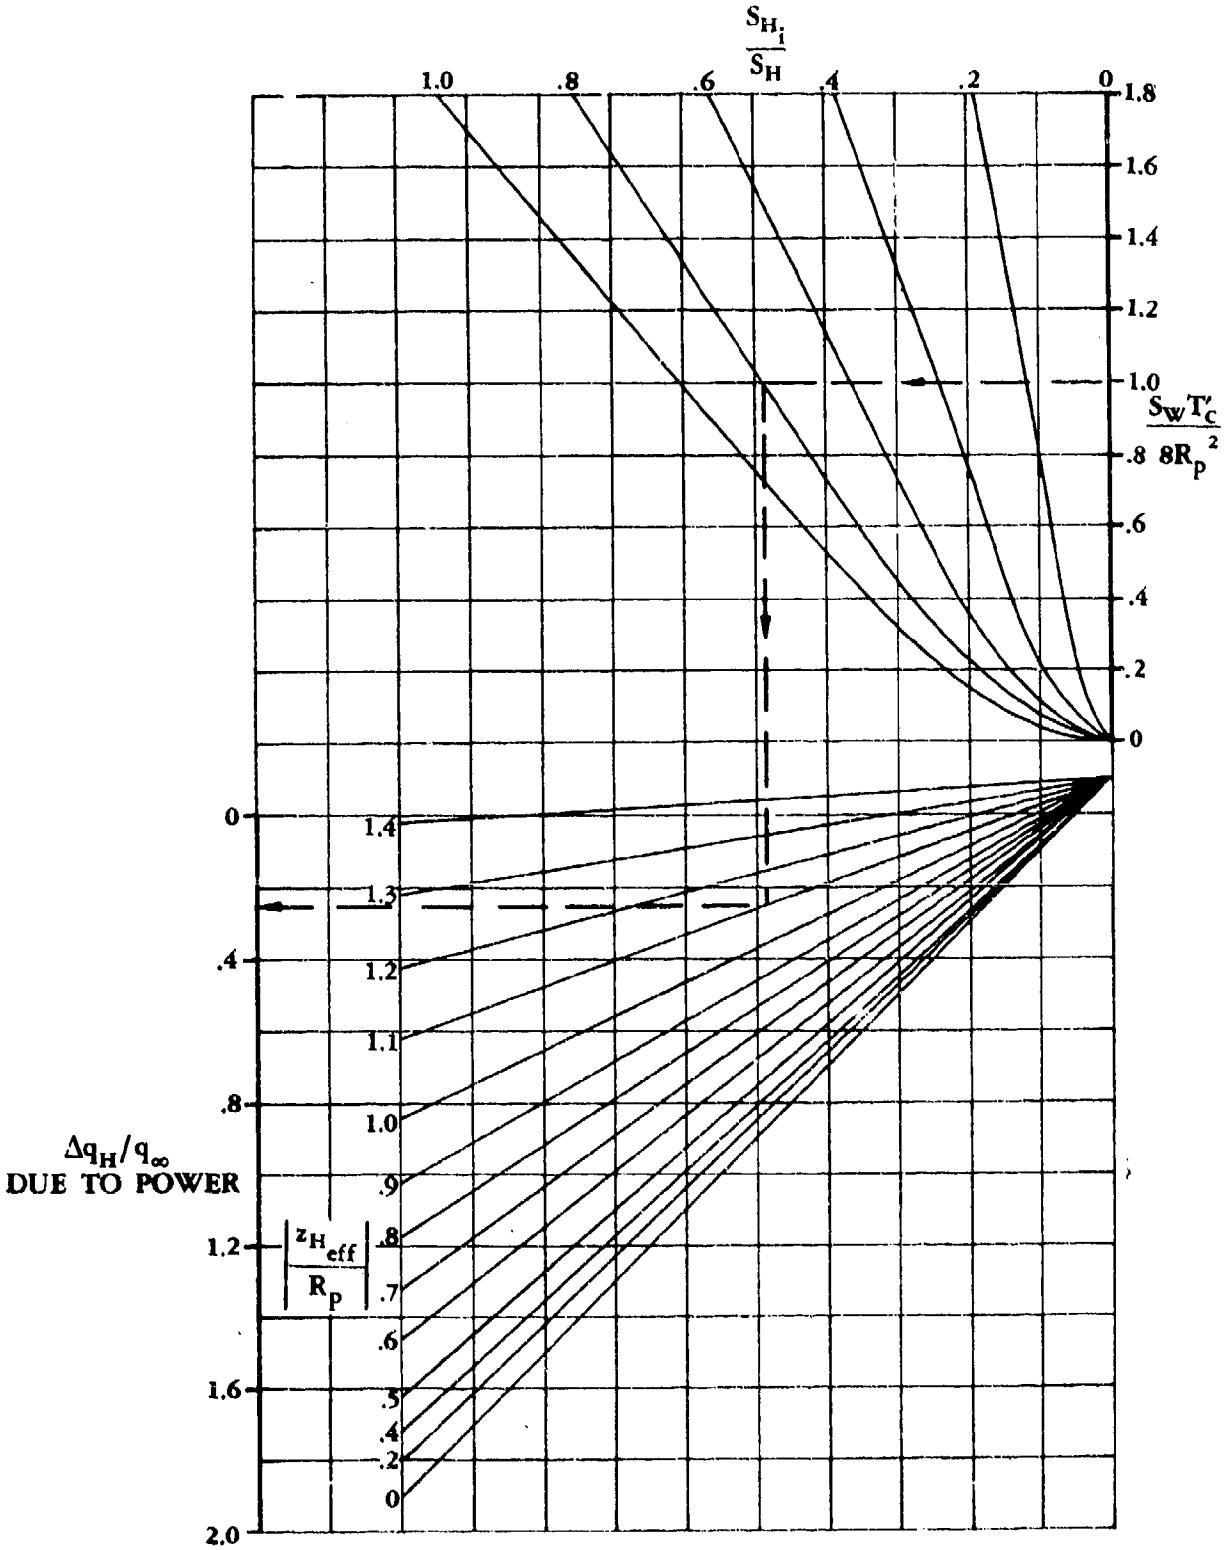

FIGURE 4.6.3-16 EFFECT OF PROPELLER POWER ON DYNAMIC PRESSURE RATIO AT THE HORIZONTAL TAIL

4.6.4 POWER EFFECTS ON DRAG AT ANGLE OF ATTACK

This section presents methods for estimating jet and propeller power effects on the drag of an aircraft. Many of the basic phenomena associated with changes in the drag are discussed in Section 4.6.1, and the reader is referred to that discussion for a more complete description of the fundamental phenomena.

A. PROPELLER POWER EFFECTS ON DRAG

The effects of propeller power on the drag of an airplane require corrections to the zero-lift drag and the lift-dependent drag.

The zero-lift drag is corrected to account for the change in dynamic pressure caused by the propeller slipstream.

The lift-dependent drag of an airplane is affected by propeller power in the following ways:

1. The components of propeller thrust and normal force that are parallel to and have the same direction as the wing lift reduce the wing lift required, thereby reducing the wing drag due to lift.

2. The propeller slipstream modifies the downwash over portions of the wing, thus changing the wing drag due to lift.

3. Propeller thrust is usually assumed to act parallel to the free stream. However, the free-stream component of thrust is really T cos α_T. Therefore, the drag component must include this differential thrust and the propeller normal-force component parallel to the free stream.

DATCOM METHOD

The Datcom method (reference 1) estimates the drag increment due to propeller-thrust effects as a function of angle of attack, thrust coefficient, and propeller normal force.

This method analyzes the increments of drag coefficient due to propeller power effects in the following order:

1. Change in zero-lift drag due to the slipstream dynamic pressure of that portion of the vehicle immersed in the propeller slipstream

2. Change in vehicle drag due to lift as a result of the lift components of propeller thrust and propeller normal force

3. Change in drag due to lift as a result of the change in angle of attack of the wing section immersed in the propeller slipstream

After the above drag increments for a given lift coefficient have been calculated, the accumulated total is then applied to the power-off drag curve to obtain a point on the power-on drag polar. After several points have been generated (by considering several lift coefficients), the power-on drag polar is obtained for a given thrust coefficient.

The above increments in drag can be determined by the following steps. (Reference should be made to figure 4.6-13a for geometric definitions. In all cases the drag increments are based on the wing reference area)

Step 1. Calculate the zero-lift increment of change in drag coefficient due to propeller-power effects as follows:

a. Calculate the increment of skin-friction drag caused by a higher local dynamic pressure on all surface area immersed in the propeller slipstream S_I by

$$\left(\Delta C_{D_0}\right)_s = \frac{1}{S\, q_\infty} \int_{S_I} C_f\, \Delta q_s\, ds \qquad 4.6.4\text{-a}$$

where C_f is the local skin-friction drag coefficient determined by the methods of Sections 4.1.5.1 and 4.2.3.1. By assuming that q_s and C_f are constant over the area wetted by the slipstream, equation 4.6.4-a may be simplified to

$$\left(\Delta C_{D_0}\right)_s = C_f\, \frac{S_I}{S}\, \frac{\Delta q_s}{q_\infty} \qquad 4.6.4\text{-b}$$

where $\Delta q_s/q_\infty$ is determined in Section 4.6.1.

b. Calculate the flap increment of zero-lift drag due to propeller power effects when the wing flaps are extended and are partially or entirely immersed in the propeller slipstream, as follows:

(1) Evaluate the propeller correlation parameter defined as

$$\frac{S_W T_c'}{R_p^2}$$

(2) From figure 4.6.4-12 obtain a value for $T_c' \sqrt{\frac{1+a}{1+2a}}\, \frac{S_W}{S_p}$ as a function of of the propeller correlation parameter.

(3) Obtain a value for the power-off drag increment of the deflected flap $\left(\Delta C_{D_0}\right)_{flap}$ from test data if available or from Section 6.1.7.

(4) Calculate the wing planform area S_{W_f} including and directly forward of the flap area.

(5) Calculate the part of S_{W_f} immersed in the propeller slipstream S_i.

(6) Calculate the flap increment of zero-lift drag by

$$\left[\left(\Delta C_{D_0}\right)_{flaps}\right]_{\substack{power\\on}} = \left(\Delta C_{D_0}\right)^{*}_{flaps}\left(T_c' \sqrt{\frac{1+a}{1+2a}}\ \frac{S_W}{S_p}\right)\left(\frac{S_i}{S_{W_f}}\right) \qquad 4.6.4\text{-c}$$

c. Calculate the total zero-lift increment of drag due to propeller power effects by

$$\left(\Delta C_{D_0}\right)_{\substack{power\\on}} = \left(\Delta C_{D_0}\right)_s + \left[\left(\Delta C_{D_0}\right)_{flaps}\right]_{\substack{power\\on}} \qquad 4.6.4\text{-d}$$

When the flaps are retracted the total zero-lift increment is given by equation 4.6.4-b.

Step 2. Calculate the propeller power effects on drag due to lift as follows:

a. Calculate the propeller normal-force coefficient per engine by

$$C_{N_p} = \left(C_{N_\alpha}\right)_p \frac{\alpha_p}{57.3}\ \frac{S_p}{S_W} \qquad 4.6.4\text{-e}$$

where $\left(C_{N_\alpha}\right)_p$ is obtained from Section 4.6.1.

b. Calculate the angle of attack of the thrust axis α_T measured from the free-stream direction and given by equation 4.6.1-a, i.e.,

$$\alpha_T = \alpha + i_T$$

c. Calculate the thrust coefficient T_c' per engine given by equation 4.6.1-b, i.e.,

$$T_c' = \frac{T}{q_\infty S_W}$$

where the thrust is a given or chosen quantity.

d. Calculate the sum of the propeller lift components by

$$C_{L_p} = T'_c \sin \alpha_T + C_{N_p} \cos \alpha_T \qquad 4.6.4\text{-f}$$

For multiple-engine configurations the total lift component due to propeller forces is found by summing the components due to each engine.

e. Calculate the wing lift coefficient C_L by

$$C_L = \frac{n'W}{q_\infty S_W} \qquad 4.6.4\text{-g}$$

where $n'W$ is the product of load factor and weight.

f. From figure 4.6.4-13a obtain a value for the empirical drag factor K_D as a function of geometry and thrust coefficient.

g. Calculate the wing lift coefficient with power effects C_{L_W} by

$$C_{L_W} = C_L - C_{L_p} \qquad 4.6.4\text{-h}$$

where C_{L_p} is the total lift component due to propeller forces.

h. From figure 4.6.4-13b obtain a value for the ratio of effective downwash to propeller downwash $\bar{\epsilon}/\epsilon_p$ as a function of the propeller correlation parameter and aircraft geometry.

i. Calculate the upwash gradient $\partial\epsilon_p/\partial\alpha_p$ given by equation 4.6.1-j, i.e.,

$$\frac{\partial \epsilon_p}{\partial \alpha_p} = C_1 + C_2 \left(C_{N_\alpha}\right)_p$$

where the constants C_1 and C_2 are obtained from figure 4.6.1-26 as a function of the propeller correlation parameter, and $\left(C_{N_\alpha}\right)_p$ is obtained from Section 4.6.1.

j. Calculate the angle of attack of the propeller plane α_p given by equation 4.6.1-g, i.e.,

$$\alpha_p = \alpha_T + \frac{\partial \epsilon_u}{\partial \alpha} (\alpha_W - \alpha_0)$$

where the upwash gradient $\partial\epsilon_u/\partial\alpha$ at the propeller may be obtained in Section 4.4.1.

k. Calculate the effective downwash over the wing span $\bar{\epsilon}$ by

$$\bar{\epsilon} = \frac{\bar{\epsilon}}{\epsilon_p} \left(\frac{\partial \epsilon_p}{\partial \alpha_p} \right) \alpha_p \qquad 4.6.4\text{-i}$$

l. Calculate the ratio of the power-on induced drag to the power-off induced drag by

$$\frac{\left(C_{D_L}\right)_{\substack{\text{power} \\ \text{on}}}}{\left(C_{D_L}\right)_{\substack{\text{power} \\ \text{off}}}} = \left(\frac{C_{L_W}}{C_L} \right)^2 \left[1 + \frac{\pi^2 A \bar{\epsilon}}{180\, C_{L_W}} \right] + K_D \left[\left(\frac{b}{2R_p} \right) \left(\frac{C_{L_p}}{C_L} \right) \right]^2 \qquad 4.6.4\text{-j}$$

The contribution from the last term in the above equation is generally less than ten percent.

The value for $\left(C_{D_L}\right)_{\substack{\text{power} \\ \text{off}}}$ must be available from wind-tunnel data or may be approximated by the wing-alone value of C_{D_L} obtained by using the method of Section 4.1.5.2.

Step 3. Calculate the total drag of an aircraft including power effects by

$$\left(C_D\right)_{\substack{\text{power} \\ \text{on}}} = \left(C_{D_0}\right)_{\substack{\text{power} \\ \text{on}}} + \left(\Delta C_{D_0}\right)_{\substack{\text{power} \\ \text{on}}} + \left(C_{D_L}\right)_{\substack{\text{power} \\ \text{on}}} \qquad 4.6.4\text{-k}$$

This equation is computed for a range of lift coefficients and thrust coefficients, and the drag-polar curves are constructed. These curves are valid only in the linear-lift region.

Sample Problem

The configuration used in this sample problem is the same as that used in the sample problem for propeller power effects on lift in Section 4.6.1. The quantities listed below are either given or calculated in the sample problem of paragraph A, Section 4.6.1, or assumed.

Given:

Wing Parameters:

$S_W = 380\ ft^2$ $\quad \frac{S_I}{S_W} = 0.309$ $\quad A = 6.23$ $\quad \frac{\Delta q_s}{q_\infty} = 0.394$ $\quad \frac{\partial \epsilon_p}{\partial \alpha_p} = 0.115$

$C_L = 0.523$ $\quad \frac{c_f}{c} = 0.20$ $\quad \delta_f = 30^\circ$ $\quad \frac{S_i}{S_{W_f}} = 0.80$ $\quad b = 48.65\ ft$

Engine Parameters:

$\left(C_{N_\alpha}\right)_p = 0.141$ $\quad i_T = 0$ $\quad \alpha_T = 4°$ $\quad R_p = 6.79$ ft $\quad T_c' = 0.150$

$\alpha_p = 5.14°$ $\quad n = 1$

Additional Parameters:

$\alpha = 4.0°$ $\quad n' = 1.0$ $\quad C_f = 0.0040$ $\quad \left(\Delta C_{D_0}\right)_{flap} = 0.040$

$\left(C_{D_L}\right)_{\substack{power \\ off}} = 0.0160$ $\quad \left(C_{D_0}\right)_{\substack{power \\ off}} = 0.10$

Compute:

Determine the zero-lift increment in drag

$$\left(\Delta C_{D_0}\right)_s = C_f \frac{S_l}{S} \frac{\Delta q_s}{q_\infty} \qquad \text{(equation 4.6.4-b)}$$

$$= (0.0040)\ (0.309)\ (0.394)$$

$$= 0.0005$$

$$\frac{S_W T_c'}{R_p^2} = \frac{(380)\ (0.15)}{(6.79)^2} = 1.236$$

$$T_c' \sqrt{\frac{1+a}{1+2a}} \frac{S_W}{S_p} = 0.25 \qquad \text{(figure 4.6.4-12)}$$

$$\left[\left(\Delta C_{D_0}\right)_{flaps}\right]_{\substack{power \\ on}} = \left(\Delta C_{D_0}\right)_{flaps} \left(T_c' \sqrt{\frac{1+a}{1+2a}} \frac{S_W}{S_p}\right) \left(\frac{S_i}{S_{W_f}}\right)$$

(equation 4.6.4-c)

$$= (0.040)\ (0.25)\ (0.80)$$

$$= 0.0080$$

$$\left(\Delta C_{D_0}\right)_{\substack{\text{power}\\\text{on}}} = \left(\Delta C_{D_0}\right)_s + \left[\left(\Delta C_{D_0}\right)_{\text{flaps}}\right]_{\substack{\text{power}\\\text{on}}} \qquad \text{(equation 4.6.4-d)}$$

$$= 0.0005 + 0.0080$$

$$= 0.0085$$

Determine the effects on drag due to lift

$$C_{N_p} = \left(C_{N_\alpha}\right)_p \frac{\alpha_p}{57.3} \frac{S_p}{S_W} \qquad \text{(equation 4.6.4-e)}$$

$$= (0.141) \left(\frac{5.14}{57.3}\right) \frac{(3.14)\,(6.79)^2}{380}$$

$$= 0.0048$$

$$C_{L_p} = T_c' \sin \alpha_T + C_{N_p} \cos \alpha_T \qquad \text{(equation 4.6.4-f)}$$

$$= (0.150)\,(0.0698) + (0.0048)\,(0.998)$$

$$= 0.0105 + 0.0048$$

$$= 0.0153$$

$K_D = 3.75$ (figure 4.6.4-13a)

$$C_{L_W} = C_L - C_{L_p} \qquad \text{(equation 4.6.4-h)}$$

$$= 0.523 - 0.0153$$

$$= 0.508$$

$$\frac{\bar{\epsilon}}{\epsilon_p} = 0.24 \qquad \text{(figure 4.6.4-13b)}$$

$$\bar{\epsilon} = \frac{\bar{\epsilon}}{\epsilon_p} \left(\frac{\partial \epsilon_p}{\partial \alpha_p}\right) \alpha_p \qquad \text{(equation 4.6.4-i)}$$

$$= (0.24)\,(0.115)\,(5.14^\circ)$$

$$= 0.142^\circ$$

$$\frac{\left(C_{D_L}\right)_{\substack{\text{power}\\ \text{on}}}}{\left(C_{D_L}\right)_{\substack{\text{power}\\ \text{off}}}} = \left(\frac{C_{L_W}}{C_L}\right)^2 \left[1 + \frac{\pi^2 A\bar{\epsilon}}{180\, C_{L_W}}\right] + K_D \left[\left(\frac{b}{2R_p}\right)\left(\frac{C_{L_p}}{C_L}\right)\right]^2$$

(equation 4.6.4-j)

$$= \left(\frac{0.508}{0.523}\right)^2 \left[1 + \frac{(3.14)^2\ (6.23)\ (0.142)}{(180)\ (0.508)}\right] + 3.75 \left[\left(\frac{48.65}{13.58}\right)\ \frac{0.0153}{0.523}\right)\right]^2$$

$$= 0.943\ [1.0954] + 3.75\ [0.01098]$$

$$= 1.074$$

$$\left(C_{D_L}\right)_{\substack{\text{power}\\ \text{on}}} = (1.074)\ (0.016)$$

$$= 0.0172$$

Determine the total drag

$$\left(C_D\right)_{\substack{\text{power}\\ \text{on}}} = \left(C_{D_0}\right)_{\substack{\text{power}\\ \text{off}}} + \left(\Delta C_{D_0}\right)_{\substack{\text{power}\\ \text{on}}} + \left(C_{D_L}\right)_{\substack{\text{power}\\ \text{on}}} \qquad \text{(equation 4.6.4-k)}$$

$$= 0.10 + 0.0085 + 0.0172$$

$$= 0.126$$

B. JET POWER EFFECTS ON DRAG

There are three jet power effects on the drag of an airplane. A jet emanating from the rear of a fuselage or nacelle has large effects on both the afterbody drag and the base drag of the fuselage or nacelle. The remaining two jet power effects on drag can be attributed to the lift force of the jet (the vertical component of the thrust) and the inlet normal force. (See Section 4.6.1, paragraph B, for additional discussion.) These lift forces reduce the wing lift and therefore reduce the wing drag due to lift.

Accurate and rapid procedures for estimating the effects of jets on base and afterbody drag are not available. The large number of internal- and external-flow variables and the large number of geometric variables pertaining to the nozzle and the afterbody prevent the prediction of these effects by the use of either simplified theory or empirical correlation of the available test data. Therefore, no Datcom method for treating jet power effects on base and afterbody drag is given. However, a brief discussion is given from references 2 and 3 presenting the salient aspects of the flow elements. The major portion of the discussion is taken from a method for treating transonic

and supersonic base drag due to jets from reference 3. (The complexity of the method prevents its formulation into a Datcom method.) Curves are presented that indicate the trends of base pressure with some of the significant variables.

DATCOM METHOD

The Datcom method is composed of two parts. The first part presents a discussion of the jet power effects on base and afterbody drag. The second part presents a method for estimating the jet power effects due to the vertical component of thrust and the inlet normal force.

Jet Power Effects on Base and Afterbody Drag

The mathematical expression for base drag in terms of base pressure may be expressed as

$$C_{D_b} = \frac{1}{q_\infty S} \int_{S_b} \int [p_\infty - p_b\,(x, y)]\, dxdy \qquad 4.6.4\text{-}\ell$$

where S_b is the base area and S is the reference area. The base lies in the XY-plane, and the base pressure p_b may vary over the base. For most cases, p_b is almost constant and equation 4.6.4-ℓ reduces to

$$C_{D_b} = \frac{(p_\infty - p_b)\, S_b}{q_\infty S} \qquad 4.6.4\text{-}m$$

A plot of some of the data of reference 2 is given in figure 4.6.4-14 for the model geometry sketched in the upper part of the figure. The base-pressure coefficient is presented as a function of Mach number for three ratios of jet total pressure to ambient pressure. From figure 4.6.4-14 it can be seen that the highest base-drag conditions occur in the transonic regime.

The geometry and initial-flow parameters for an axially symmetric boattailed afterbody with a nozzle are presented in figure 4.6.4-15. Directly behind the base area is a region of low-velocity air at pressure p_b. The free-stream flow expands to this pressure p_b as it passes the end of the afterbody. The expanded free-stream flow mixes with the low-velocity air along a boundary until it encounters flow from the jet. In similar fashion, flow from the jet expands as it passes through the nozzle exit plane. The flow mixes with the low-velocity air at the base along some boundary. When the external and internal flows meet, each must go through a shock wave that (1) turns the flows until they are parallel, and (2) equalizes the pressures of the two flows. The external flow and the flow from the jet then proceed downstream with a mixing zone lying between them. A flow pattern for the above geometrical description is indicated in figure 4.6.4-16 for a supersonic jet and free stream at a ratio of total pressure to ambient pressure greater than 2.35.

The influence of major design parameters on the base-pressure ratio of axially symmetric afterbodies with jets is presented in figures 4.6.4-17 through 4.6.4-21. The influence of free-stream Mach number on afterbody pressure is given in figure 4.6.4-17 for a convergent nozzle with the indicated geometry and pressure conditions. Figures 4.6.4-18a and 4.6.4-18b present the

effects of the ratios of jet total pressure to ambient pressure and of jet diameter to body diameter, respectively, on base pressure. In these two figures the free-stream and exit Mach numbers are constant. For the given free-stream and geometric parameters, divergence of the nozzle significantly increases the base pressure, causing a decrease in base drag. The importance of nozzle divergence angle is shown in figure 4.6.4-19.

The low-speed air at the base of a boattailed afterbody can interact with the boundary layer of the exterior flow. If the jet pressure is sufficiently high, the interaction will increase the pressure in the boundary layer on the rear of the afterbody, decreasing the afterbody drag. Figure 4.6.4-20 presents the probably favorable effects of boattail angle and nozzle divergence angle on both the base pressure and afterbody drag.

The unfavorable effects on base pressure caused by the flaring of an afterbody are presented in figure 4.6.4-21. The flared afterbody is also likely to have more afterbody drag because of its forward-facing slopes.

Jet Power Lift Effects on Drag Due to Lift

The power-on drag due to lift is obtained from the following equation:

$$\left(C_{D_L}\right)_{\substack{\text{power}\\\text{on}}} = \left(C_{D_L}\right)_{\substack{\text{power}\\\text{off}}} \left[\frac{C_L - \left(\Delta C_L\right)_T - \left(\Delta C_L\right)_{N_j}}{C_L}\right]^2 \qquad 4.6.4\text{-n}$$

where C_L is the power-off lift coefficient required for the given flight condition, $\left(C_{D_L}\right)_{\substack{\text{power}\\\text{off}}}$ is the drag due to lift corresponding to C_L obtained by the method of Section 4.1.5.2, $\left(\Delta C_L\right)_T$ and $\left(\Delta C_L\right)_{N_j}$ are found in Section 4.6.1.

Sample Problem

The configuration used in this sample problem is the same as that used in the sample problem of Section 4.6.1, paragraph B.

Given:

$$\left.\begin{array}{ll} C_L = 0.75 & \left(\Delta C_L\right)_T = 0.0446 \\ & \left(\Delta C_L\right)_{N_j} = 0.00655 \end{array}\right\} \text{(Section 4.6.1)}$$

$$\left(C_{D_L}\right)_{\substack{\text{power}\\\text{off}}} = 0.16 \qquad \text{(Section 4.1.5.2)}$$

Compute:

Determine the power-on drag due to lift

$$\left(C_{D_L}\right)_{\substack{\text{power}\\\text{on}}} = \left(C_{D_L}\right)_{\substack{\text{power}\\\text{off}}} \left[\frac{C_L - \left(\Delta C_L\right)_T - \left(\Delta C_L\right)_{N_j}}{C_L}\right]^2 \qquad \text{(equation 4.6.4-n)}$$

$$= 0.16 \left[\frac{0.75 - 0.0446 - 0.00655}{0.75}\right]^2$$

$$= (0.16)\ (0.868)$$

$$= 0.139$$

4.7 GROUND EFFECTS AT ANGLE OF ATTACK

Methods are presented in subsequent sections for estimating ground effects in the linear-lift range on lift, pitching moment, and drag.

In order that the Datcom user may better understand ground effects, a qualitative discussion regarding various aspects of ground effects is presented.

Because of the obvious influence of ground proximity during the takeoff and landing phases, it has been the subject of considerable investigation. However, despite this consideration, an adequate amount of reliable ground-effects data does not appear in the literature. In particular, the prediction of $C_{L_{max}}$, $\alpha_{C_{L_{max}}}$ and pitching moment need additional investigation in ground effects.

The effects of ground proximity generally become measurable at a height above the ground of one wing-[illegible] and increase in magnitude as the height above the ground decreases. Both theoretical and experimental investigations indicate that ground proximity produces an increase in the lift-curve slope, a decrease in drag, and a reduction of nose-up pitching moment for most aircraft planforms in the clean configuration. However, high-lift configurations deviate from this trend in that the ground effect tends to reduce the lift-curve slope (Reference 1).

Wind-tunnel investigation of ground effects has been approached by using the following testing techniques: (1) fixed ground plane, (2) moving-belt ground plane, and (3) an image-model aircraft with respect to a fictitious ground. The fixed ground-plane technique provides the most straightforward approach to simulation. However, this approach does not give a true representation of the phenomena because of the lack of relative motion between the ground plane and the model. This lack of motion permits a boundary-layer build-up on the ground plane that introduces an objectionable component into the simulation. Moving-belt ground-plane simulations eliminate this undesirable feature; however, not all wind tunnels offer this capability. The third testing technique, the image-model approach, has the disadvantage of added cost and complexity of constructing and installing a second model in the tunnel to simulate the mirror image of the test model. Most authorities tend to agree on the relative advantages of these different approaches. As might be expected, results from these different testing techniques do not predict identical results for the same configuration. The lack of agreement between various wind-tunnel results is exemplified in the comparisons presented in References 3 and 4. In addition, these wind-tunnel predictions do not compare favorably with the limited flight-test results of References 3 and 4.

The majority of the theoretical approaches analyzing ground effects employ an image-vortex theory to represent the ground plane. The salient aspects of this theory are discussed below.

The lifting wing is represented theoretically by a bound vortex and two trailing vortices. The effect of a ground plane on this "horseshoe" vortex system is represented by placing a mirror image of the vortex system two ground-plane heights below the vortex system representing the wing. The resulting plane of symmetry satisfies the boundary condition of zero vertical velocity at the ground plane. The two vortex systems (the wing-vortex system and the image-vortex system) and the ground plane are illustrated in Sketches (a), (b), and (c).

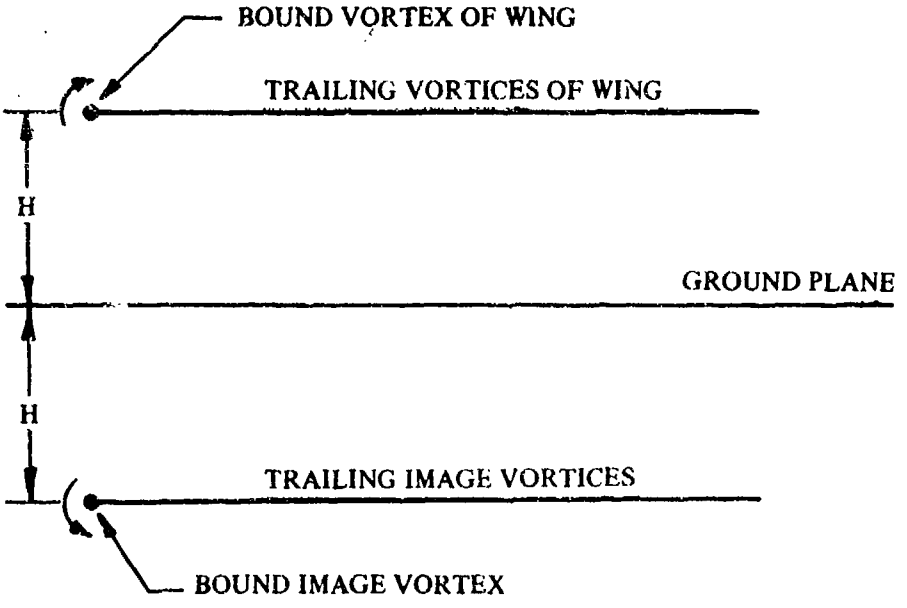
SKETCH (a)

THEORETICAL WING VORTEX SYSTEM, FRONT VIEW



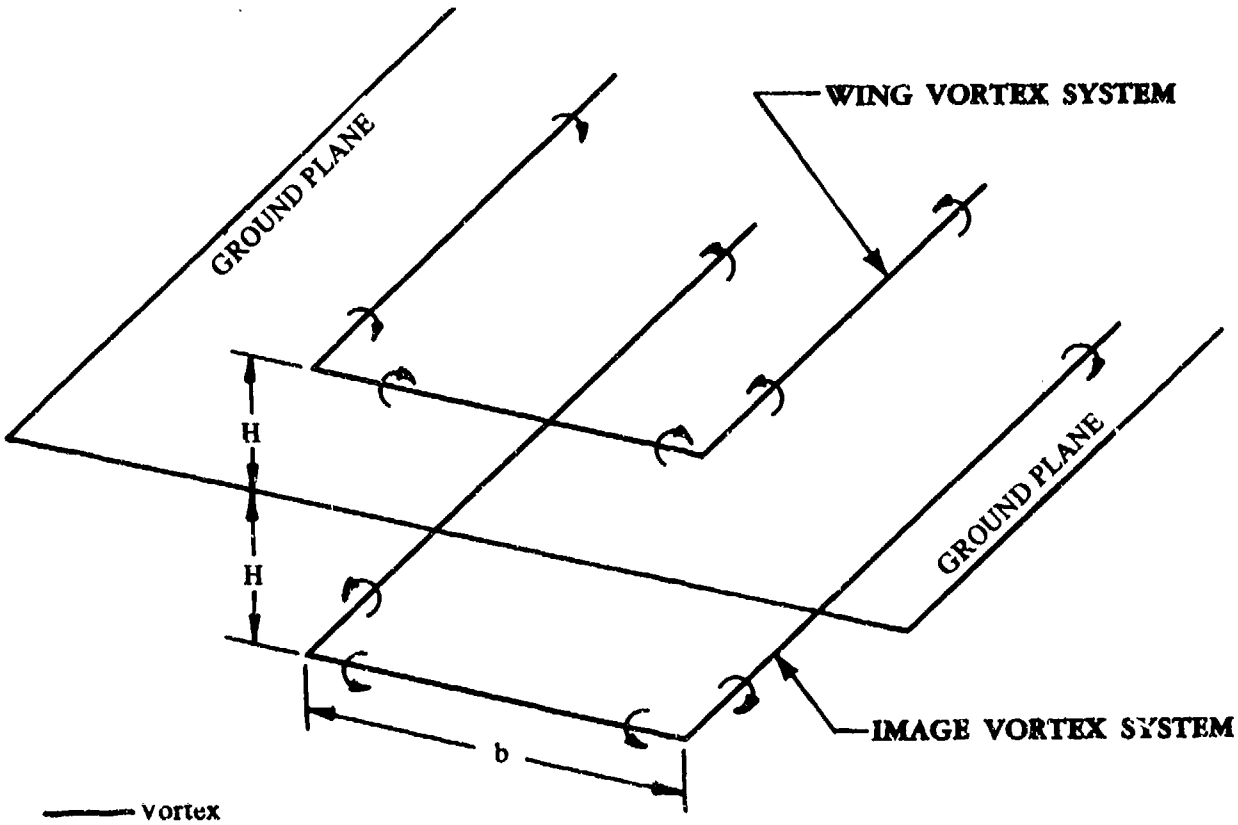
● End view of bound vortices

Trailing vortices

(Arrows indicate direction of circulation)

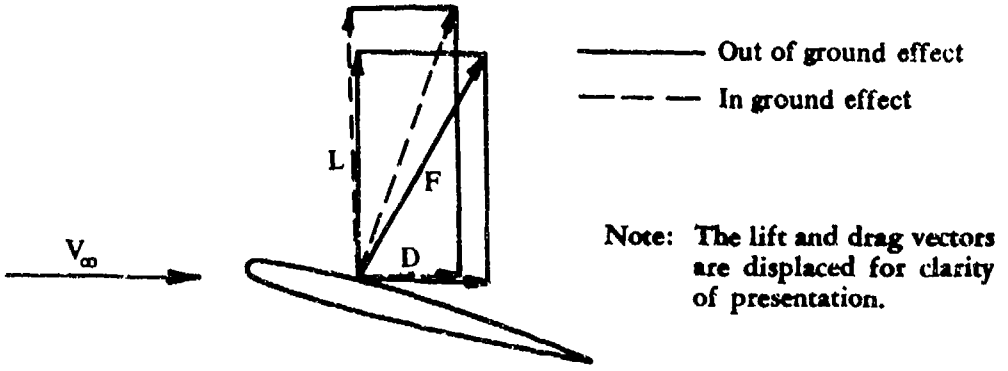
SKETCH (b)

THEORETICAL WING VORTEX SYSTEM, SIDE VIEW

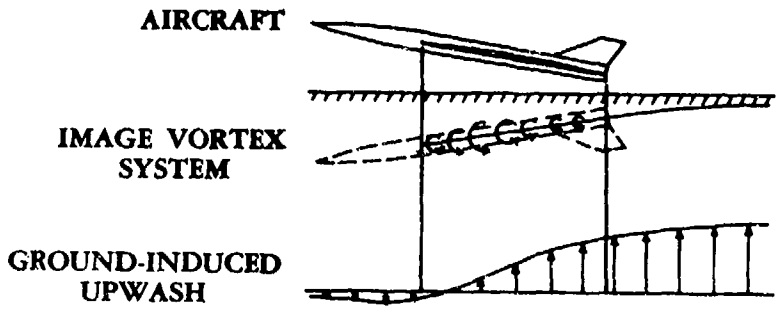


SKETCH (c)

Away from the ground plane, the downwash of the two trailing vortices contributes to the wing drag due to lift by rotating the force vector rearward, as shown in Sketch (d). However, near the ground plane, the trailing vortices of the image vortex system have an upwash component, as shown in Sketch (c) and Sketch (e) (Reference 5). This upwash velocity component reduces the downward rotation of the flow direction caused by the wing trailing vortices, thus decreasing the wing drag due



SKETCH (d)



SKETCH (e)
GROUND-INDUCED UPWASH

to lift. The classical treatment of this effect is given by Wieselsberger in Reference 6. Wieselsberger's approach has been extended in Reference 7 by Tani, Taima, and Simidu to consider the induced effects of the image bound vortex. Both of these approaches are summarized in Reference 8. As indicated in the side view of the vortex system presented as Sketch (b), the bound vortex of the image-vortex system will reduce the longitudinal velocity component at the wing bound vortex, thus modifying the circulation of the wing bound vortex. These effects of the image bound-vortex system become more predominant as the height above the ground is reduced.

Improved theoretical analyses of the effects of ground proximity have been formulated using lifting-surface theory. Because of the general nature of lifting-surface theory, computer programs have been generated to facilitate the computations. Reference 9 presents an example of an image-vortex representation using lifting-surface theory, generalized to apply to a straight-tapered wing in nonviscous flow.

The influence of ground effects on the lateral-control characteristics of aircraft has received consideration in References 10 through 12. Results of Reference 10 suggest that ground effects completely alter the basic lateral characteristics of slender aircraft during the period immediately preceding touchdown. As a result, disturbances in bank angle are drastically attenuated just prior to aircraft touchdown.

The influence of wing-tip fairings and wing-tip end plates is examined in References 13 through 15. The general effect of these wing-tip devices is an increase in lift-curve slope and a reduction in induced drag, which generally results in a significant increase in the lift-drag ratio.

The reader is referred to Reference 16 for a comprehensive literature search and survey of the literature available prior to 1966 in the general field of wings operating in ground effect and related phenomena. Comments are included in this reference regarding some of the papers published, along with sketches of the methods of approach taken by the authors. The bibliography presents sources that consider the problem from the theoretical, experimental, and/or applications points of view. Tables are included that provide a convenient breakdown of the various sources, for a quicker method of locating specific references dealing with an area of special interest to the reader.

A list of pertinent references is included at the end of this section, following a list of notation used in subsequent sections.

NOTATION

A	wing aspect ratio
B	parameter accounting for change in circulation
b_{eff}	effective wing span
b'_f	effective span for increment in load due to flaps
b'_W	effective span for unflapped wing
$\bar{c}$	wing mean aerodynamic chord
C_D	wing drag coefficient, $\frac{\text{drag}}{qS}$
C_{D_L}	drag coefficient due to lift
$\left(\Delta C_{D_L}\right)_G$	increment in drag due to lift in the presence of the ground
$C_{D_{WB}}$	wing-body drag coefficient in absence of ground plane
$\left(C_{D_{WB}}\right)_G$	wing-body drag coefficient in the presence of the ground
C_{D_0}	zero-lift drag coefficient
C_L	wing lift coefficient in absence of ground plane
ΔC_{L_f}	increment in lift coefficient due to flaps in absence of ground plane
$\left(C_{L_f}\right)_{WB}$	wing-body lift coefficient including flap effects, out of ground effect
$\Delta\left(\Delta C_L\right)_{flap}$	empirical factor accounting for flap effects in the presence of the ground
$\left(\Delta C_L\right)_G$	increment in lift coefficient in the presence of the ground
$\left(\Delta C_{L_H}\right)_G$	increment in horizontal-tail lift coefficient in the presence of the ground
$C_{L_{max}}$	maximum lift coefficient, $\frac{\text{maximum lift}}{qS}$

$C_{L_{WB}}$	wing-body lift coefficient in absence of ground plane
$\left(\Delta C_{L_{WB}}\right)_G$	increment in wing-body lift coefficient in the presence of the ground
$\left(C_{L_\alpha}\right)_{WB}$	wing-body lift-curve slope
$\left(\Delta C_m\right)_G$	increase in pitching moment in the presence of the ground
$\left(\Delta C_{m_H}\right)_G$	increase in horizontal-tail pitching moment in the presence of the ground
$\left(\Delta C_{m_{WB}}\right)_G$	increase in wing-body pitching moment in the presence of the ground
$\frac{c_r}{b}$	ratio of wing root chord to wing span
H	height of quarter-chord point of wing mean aerodynamic chord above the ground
H_H	height of quarter-chord point of horizontal-tail mean aerodynamic chord above the ground
h	average height above the ground of the quarter-chord point of wing chord at 75-percent semispan and the three-quarter-chord point of the wing root chord (see sketch on Figure 4.7.1-14)
$h_{c_r/4}$	height of the quarter-chord point of the wing root chord above the ground
K	parameter accounting for effective wing thickness
ℓ_H	distance from moment reference center to the quarter-chord point of horizontal-tail MAC, measured parallel to body center line
$\frac{L}{L_o} - 1$	parameter accounting for effect of image bound vortex on lift
n	distance from wing apex to moment reference center measured in wing mean aerodynamic chords, positive aft
$\frac{q_H}{q_\infty}$	effective dynamic-pressure ratio at horizontal tail
r	parameter accounting for effect of finite span
$\frac{S_H}{S_W}$	ratio of area of horizontal tail to wing area

T	parameter accounting for reduction in longitudinal velocity
$\left(\frac{t}{c}\right)_{max}$	ratio of maximum wing thickness to wing chord
x	parameter accounting for effect of image trailing vortex on lift
Δx	the chordwise distance from the quarter-chord point of the 75-percent-semispan chord to the three-quarter-chord point of the wing root chord, positive when the latter is aft of the former (see Figure 4.7.1-14)
$x_{a.c.}$	distance from the wing apex to the wing-body aerodynamic center, positive for a.c. aft of wing apex
$\Delta\alpha$	increment in angle of attack
$\alpha_{C_{L_{max}}}$	wing angle of attack at maximum lift coefficient
$(\Delta\alpha)_G$	increment in angle of attack at a constant lift coefficient in the presence of the ground
$(\Delta\alpha_H)_G$	increment in angle of attack of the horizontal tail in the presence of the ground
ϵ	downwash angle out of ground effect
$(\Delta\epsilon)_G$	increment in downwash due to ground effect in linear-lift range
$\Lambda_{c/4}$	sweep angle of the wing quarter-chord
σ	Prandtl interference coefficient

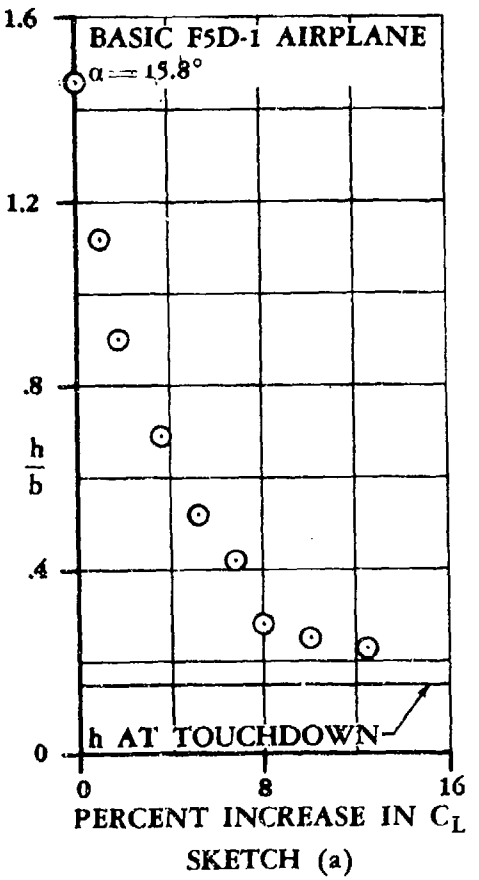
4.7.1 GROUND EFFECTS ON LIFT VARIATION WITH ANGLE OF ATTACK

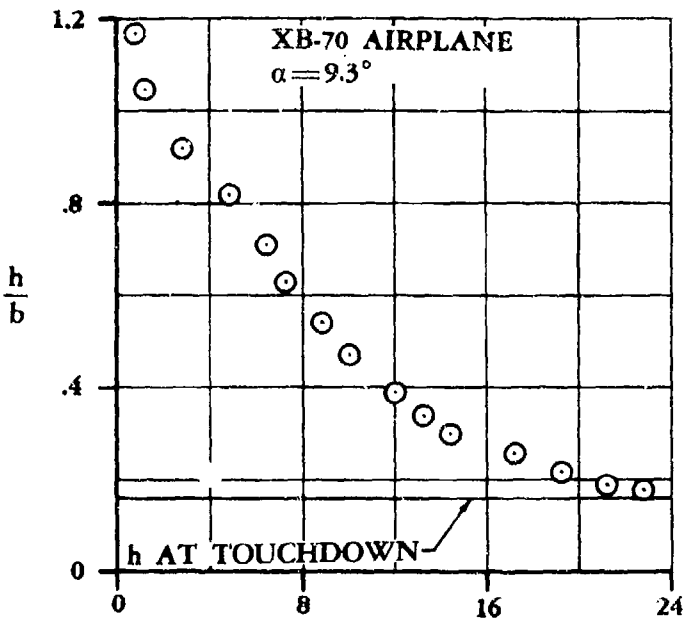
Methods are presented in this section for estimating the ground effects on lift in the linear-lift region. The reader is referred to Section 4.7 for a basic discussion of various aspects of ground effects.

Representation of the ground plane by an image-vortex system (see Sketches (a), (b), and (c) in Section 4.7) enables the ground effects on lift to be identified (Reference 1) as follows: (1) the decrease in longitudinal velocity at the real wing due to the reflected bound vortex, (2) the change in circulation about the real wing due to the reflected bound vortex, (3) the increase in induced upwash at the real wing due to the reflected trailing vortices, and (4) the change in the flow pattern due to the finite thickness of the wing. The first two effects are opposite and approximately equal, while the effects of wing thickness are generally small. As a result, the ground effects on lift can be approximated by considering only the increase in the upwash. This is the approach taken in the classical theoretical treatment of ground effects by Wieselsberger in Reference 2. Wieselsberger's method of approach has been extended in Reference 3 by Tani, Taima, and Simidu to include the induced effects of the reflected bound vortex and of wing thickness.

The increase in aircraft lift due to ground proximity decreases in magnitude as the height above the ground increases. Flight-test data from Reference 4, showing the increase in lift due to ground effects at a constant angle of attack as a function of ground height, are presented in Sketches (a) and (b) for the F5D-1 and XB-70 airplanes, respectively. These trends are representative of the variation of lift due to ground effects that might be expected from similar aircraft.



SKETCH (a)



SKETCH (b)

FLIGHT-TEST GROUND-EFFECT DATA AT A CONSTANT-ANGLE-OF-ATTACK APPROACH

Empirical prediction methods have been formulated for low-aspect-ratio delta configurations in References 5, 6, and 7. However, calculated ground effects using these methods do not compare favorably with the flight-test data of Reference 4. The comparisons indicate an inability to predict accurately the variation of ground effect on lift as the height above the ground is varied.

The ground effects on lift are determined somewhat by the planform of the configuration. For low-aspect-ratio delta configurations, the general trend is a constant increase in C_L due to ground effect, as shown in Sketch (c) (Reference 8). However, transport-type configurations show quite a different trend, as presented in Sketch (d) (Reference 8). This trend is dependent upon the type of high-lift system employed. Computer programs utilizing lifting-surface theory are currently the most favorable means of evaluating the effects of various components of high-lift systems on ground effects.

SKETCH (d)
GROUND EFFECT ON A JET
TRANSPORT CONFIGURATION

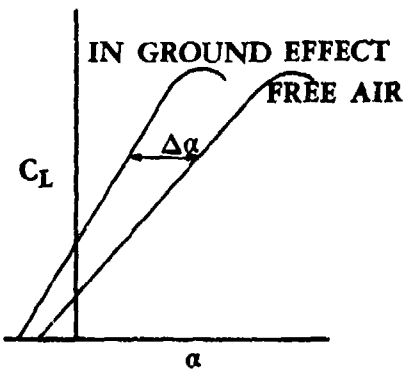
DATCOM METHODS

For most vehicles, calculating the change in lift due to ground effects consists of evaluating two components:

1. the change in wing-body lift
2. the change in tail-body lift due to the effects of downwash

The change in tail-body lift due to the presence of the ground is generally small in comparison to the downwash effects and is neglected in the Datcom methods. For canard-type configurations the change in downwash due to ground effect should be accounted for in the wing contribution.

Both of the Datcom methods presented require the user to construct wing-body and tail-body lift curves in ground effect based on their corresponding free-air lift curves. Equations are given that calculate the change in angle of attack due to ground effect at a constant lift coefficient. The ground-effect lift curves are then constructed by shifting the free-air lift curves at every C_L by the corresponding increment in angle of attack due to ground effect at constant lift coefficients (see Sketch (e)).



SKETCH (e)

Method 1

This method estimates the ground effects on lift in the linear-lift range for a subsonic transport configuration. The method is an extension of the Tani method of References 3 and 4 and includes the effects of taper ratio, sweep-back, dihedral, and flap deflection, while neglecting the effects of wing thickness since they are generally small. The wing-flap effects are valid only for split and slotted flaps as they are accounted for by empirical curves. The first term in Equation 4.7.1-a accounts for the effects of the trailing vortex, the second term for the effects of the bound vortex, and the third term for wing-flap effects. The method does not account for the effects of wing-leading-edge devices.

The change in wing-body angle of attack at a constant lift coefficient due to ground effect with respect to the out-of-ground-effect lift curve is given by

$$(\Delta\alpha)_G = -\left[\frac{9.12}{A} + 7.16\left(\frac{c_r}{b}\right)\right]\left(C_{L_f}\right)_{WB} x - \frac{A}{2\left(C_{L_\alpha}\right)_{WB}}\left(\frac{c_r}{b}\right)\left(\frac{L}{L_o} - 1\right)\left(C_{L_f}\right)_{WB} r$$

$$- \frac{\left(\delta_f/50\right)^2}{\left(C_{L_\alpha}\right)_{WB}} \Delta\left(\Delta C_L\right)_{flap} \quad \text{(per deg)} \qquad 4.7.1\text{-a}$$

where

A	is the wing aspect ratio.
$\frac{c_r}{b}$	is the ratio of wing root chord to wing span.
$\left(C_{L_f}\right)_{WB}$	is the wing-body lift coefficient including flap effects, out of ground effect, obtained from test data or Section 4.3.1 and Section 6.1.4.1.
x	accounts for the effects on lift due to the image trailing vortex and is obtained from Figure 4.7.1-14 as a function of wing geometry and the wing height above the ground.
$\left(C_{L_\alpha}\right)_{WB}$	is the wing-body lift-curve slope, per degree, out of ground effect, obtained from test data or Section 4.3.1.2.
$\frac{L}{L_o} - 1$	accounts for the effects on lift due to the image bound vortex and is obtained from Figure 4.7.1-15 as a function of wing geometry, lift coefficient, and the height of the quarter-chord point of the wing root chord above the ground.
r	accounts for the effect of finite span and is obtained from Figure 4.7.1-16 as a function of wing height above the ground.
$\Delta\left(\Delta C_L\right)_{flap}$	is an empirical factor to account for the effect of flaps and is obtained from Figure 4.7.1-17 as a function of the height of the quarter-chord point of the wing root chord above the ground.

In the linear-lift region, the change in downwash (a decrease) on the tail-body due to ground effects is derived theoretically by representing the ground plane as an image-vortex system. A modification to the method of Reference 9 is given in Reference 10, wherein certain geometric terms are redefined. This modified method is the method presented in the Datcom. The change (a decrease) in tail-body downwash due to ground effects in the linear-lift range is given by

$$(\Delta\epsilon)_G = \epsilon\left[\frac{b_{eff}^2 + 4(H_H - H)^2}{b_{eff}^2 + 4(H_H + H)^2}\right] \qquad 4.7.1\text{-b}$$

where

$(\Delta\epsilon)_G$	is the difference between the downwash in free air and the downwash in ground effect.
ϵ	is the downwash out of ground effect.
H	is the height of $\bar{c}/4$ of the wing above the ground.
H_H	is the height of $\bar{c}/4$ of the horizontal tail above the ground.

b_{eff} is the effective wing span defined as

$$b_{eff} = \frac{C_{L_{WB}} + \Delta C_{L_f}}{\frac{C_{L_{WB}}}{b'_W} + \frac{\Delta C_{L_f}}{b'_f}} \qquad 4.7.1\text{-c}$$

where

$C_{L_{WB}}$ is the wing-body lift coefficient, flaps retracted, out of ground effect, obtained from test data or Section 4.3.1.

ΔC_{L_f} is the change in lift coefficient due to flaps, out of ground effect, obtained from test data or Section 6.1.4.1.

$$b'_W = \left(\frac{b'_W}{b}\right) b \qquad 4.7.1\text{-d}$$

$$b'_f = \left(\frac{b'_f}{b'_W}\right)\left(\frac{b'_W}{b}\right) b \qquad 4.7.1\text{-e}$$

The ratio $\frac{b'_W}{b}$ is given in Figure 4.7.1-18a as a function of taper ratio and aspect ratio, and $\frac{b'_f}{b'_W}$ is given in Figure 4.7.1-18b as a function of the ratio of flap span to wing span.

The horizontal-tail lift curve in ground effect is constructed by shifting the free-air lift curve at every C_L by the corresponding $-(\Delta\epsilon)_G$, i.e.,

$$(\Delta\alpha_H)_G = -(\Delta\epsilon)_G \qquad 4.7.1\text{-f}$$

Method 2

This method estimates the ground effects on wing-body lift in the linear-lift range for all configurations not included in Method 1. The method is Tani's method from References 3 and 11, modified to include the effects of dihedral. The change in wing-body angle of attack due to ground effects with respect to the out-of-ground-effect lift curve is given by

$$(\Delta\alpha)_G = -18.24 \frac{\left(C_{L_f}\right)_{WB}\sigma}{A} + rT \frac{\left(C_{L_f}\right)^2_{WB}}{57.3\left(C_{L_\alpha}\right)_{WB}} - rB + K\left(\frac{t}{c}\right)_{max} \text{(per deg)} \qquad 4.7.1\text{-g}$$

where

σ is Prandtl's interference coefficient from multiplane theory and is obtained from Figure 4.7.1-19 as a function of wing height above the ground.

r accounts for the effect of finite span and is obtained from Figure 4.7.1-16 as a function of wing height above the ground.

T accounts for the reduction of the longitudinal velocity and is obtained from Figure 4.7.1-20 as a function of wing height above the ground.

B accounts for the change in circulation and is obtained from Figure 4.7.1-21 as a function of wing height above the ground.

K accounts for the effective wing thickness and is obtained from Figure 4.7.1-22 as a function of wing height above the ground.

$\left(C_{L_\alpha}\right)_{WB}$ is the wing-body lift-curve slope, per degree, out of ground effect, obtained from test data or Section 4.3.1.2.

$\left(\frac{t}{c}\right)_{max}$ is the ratio of maximum wing thickness to wing chord.

$\left(C_{L_f}\right)_{WB}$ is the wing-body lift coefficient including flap effects, out of ground effect, obtained from test data or Section 4.3.1 and Section 6.1.4.1.

The change in lift on the horizontal tail due to ground effect is accounted for in the same manner as in Method 1 above.

Sample Problems

1. Method 1

Given: a jet-transport configuration

Wing Characteristics:

$A = 6.8$ $\quad \frac{c_r}{b} = 0.291$ $\quad \frac{h_{c_r/4}}{c_r} = 0.29$ $\quad \Lambda_{c/4} = 35^\circ$

$\lambda = 0.30$ $\quad b = 1864.4$ in. $\quad \frac{b_f}{b} = 0.54$ $\quad \delta_f = 50^\circ$

$H = 158$ in. $\quad \left(C_{L_\alpha}\right)_{WB} = 0.078$ per deg (test data) $\quad \frac{h}{b/2} = 0.168$

$\frac{\Delta x}{b/2} = 0.04$ Slotted flaps

From wind-tunnel-test data (out of ground effect):

α (deg)	0	2	4	6	8	10
$(C_{L_f})_{WB}$ (with flaps)	1.19	1.35	1.50	1.66	1.82	1.96
$C_{L_{WB}}$ (without flaps)	0.18	0.34	0.49	0.65	0.81	0.97
ΔC_{L_f}	1.01	1.01	1.01	1.01	1.01	0.99

Tail Characteristics:

$A = 3.79$ $\frac{c_t}{b} = 0.386$ $\Lambda_{c/4} = 35°$ $\frac{S_H}{S_W} = 0.377$

$i_H = -6°$ $H_H = 233.7 \cos\alpha - 664.1 \sin\alpha$

From wind-tunnel-test data (out of ground effect):

α (deg)	0	2	4	6	8	10
C_{L_H}	−0.606	−0.535	−0.475	−0.415	−0.360	−0.300
ϵ (deg)	5.1	6.0	6.9	7.8	8.8	9.7

Compute: The change in wing-body lift due to ground effect

$x = 0.56$ (Figure 4.7.1-14)

$$\frac{57.3\, C_L}{2\pi \cos^2 \Lambda_{c/4}} = \frac{57.3\, C_L}{(6.28)(0.671)} = 13.6\, C_L$$

α (deg)	$\left(C_{L_f}\right)_{WB}$ (test)	13.6 C_L	$\frac{L}{L_o} - 1$ (Fig. 4.7.1-16)
0	1.19	16.2	–0.04
2	1.35	18.4	–0.09
4	1.50	20.4	–0.13
6	1.66	22.6	–0.175
8	1.82	24.8	–0.205
10	1.96	26.7	–0.212

r = 0.845 (Figure 4.7.1-16)

$\Delta\left(\Delta C_L\right)_{flap} = -0.083$ (Figure 4.7.1-17)

Solution:

$$(\Delta\alpha)_G = -\left[\frac{9.12}{A} + 7.16\,\frac{c_f}{b}\right]\left(C_{L_f}\right)_{WB} x - \frac{A}{2\left(C_{L_\alpha}\right)_{WB}}\left(\frac{c_f}{b}\right)\left(\frac{L}{L_o} - 1\right)\left(C_{L_f}\right)_{WB} r$$

$$- \frac{\left(\delta_f/50\right)^2}{\left(C_{L_\alpha}\right)_{WB}}\,\Delta\left(\Delta C_L\right)_{flap} \quad \text{(Equation 4.7.1-a)}$$

$$= -\left[\frac{9.12}{6.8} + 7.16(0.291)\right](0.56)\left(C_{L_f}\right)_{WB} - \frac{(6.8)(0.291)(0.845)}{2(0.078)}\left(\frac{L}{L_o} - 1\right)\left(C_{L_f}\right)_{WB}$$

$$- \frac{(50/50)^2}{0.078}\,(-0.083)$$

$$= -1.92\left(C_{L_f}\right)_{WB} - 10.7\left(\frac{L}{L_o} - 1\right)\left(C_{L_f}\right)_{WB} + 1.064$$

α (deg)	$\left(C_{L_f}\right)_{WB}$ (test)	$\frac{L}{L_o} - 1$	$(\Delta\alpha)_G$ (deg)
0	1.19	–0.04	–0.71
2	1.35	–0.09	–0.23
4	1.50	–0.13	0.27
6	1.66	–0.175	0.99
8	1.82	–0.205	1.57
10	1.96	–0.212	1.76

The in-ground-effect lift curve can be constructed and is shown in Sketch (f). A comparison of the predicted lift curve to wind-tunnel-test data is shown in Sketch (g).

4.7.3 GROUND EFFECTS ON PITCHING-MOMENT VARIATION WITH ANGLE OF ATTACK

A method is presented in this section for estimating the ground effects on pitching moment in the linear-lift region. The reader is referred to Section 4.7 for a basic discussion of various aspects of ground effects.

The change in pitching moment due to ground effects is due primarily to the change in lift on the horizontal tail, which in most cases can be attributed to the change in downwash. An additional pitching-moment increment is produced by the increased lift on the wing and any possible shift in the aerodynamic center due to ground effect.

DATCOM METHOD

The method presented herein is based upon the lift estimates of Section 4.7.1. The method assumes no change in the location of the wing aerodynamic center due to ground effects. The total change in pitching-moment coefficient due to ground effects is the sum of the changes of the horizontal-tail-body and wing-body pitching-moment components, based on the product of wing area and wing MAC, and is expressed as

$$\left(\Delta C_m\right)_G = \left(\Delta C_{m_H}\right)_G + \left(\Delta C_{m_{WB}}\right)_G \qquad 4.7.3\text{-a}$$

The change in pitching-moment coefficient of the horizontal-tail-body due to ground effects may be expressed as

$$\left(\Delta C_{m_H}\right)_G = -\left(\Delta C_{L_H}\right)_G \frac{\ell_H}{\bar{c}} \frac{S_H}{S_W} \frac{q_H}{q_\infty} \qquad 4.7.3\text{-b}$$

where

$\left(\Delta C_{L_H}\right)_G$ is the change in lift on the horizontal-tail-body at a given angle of attack due to ground effect, based on the horizontal-tail area, and is found from the tail-body lift curves constructed by using Section 4.7.1.

ℓ_H is the distance from the quarter-chord point of the horizontal-tail MAC to the moment reference center, measured parallel to the body center line.

$\bar{c}$ is the wing mean aerodynamic chord.

$\frac{S_H}{S_W}$ is the ratio of horizontal-tail area to wing area.

$\frac{q_H}{q_\infty}$ is the effective dynamic-pressure ratio at the horizontal tail, obtained from Section 4.4.1.

The change in pitching-moment coefficient of the wing-body due to ground effects may be expressed as

$$\left(\Delta C_{m_{WB}}\right)_G = \left(n - \frac{x_{a.c.}}{\bar{c}}\right)\left(\Delta C_{L_{WB}}\right)_G \qquad 4.7.3\text{-c}$$

where

n is the distance from the wing apex to the desired moment reference center measured in wing mean aerodynamic chords, positive aft.

$x_{a.c.}$ is the wing-body aerodynamic-center location measured from the wing apex, positive for a.c. aft of wing apex, obtained from Section 4.3.2.2.

$\bar{c}$ is the wing mean aerodynamic chord.

$\left(\Delta C_{L_{WB}}\right)_G$ is the change in lift due to ground effect on the wing-body and is found from the wing-body lift curves constructed by using Section 4.7.1.

Sample Problem

Given: Same jet-transport configuration as Sample Problem 1 of Section 4.7.1.

Wing-Body Characteristics:

$$\frac{x_{a.c.}}{\bar{c}} = 1.182 \qquad n = 1.242$$

From Sample Problem 1 of Section 4.7.1:

α (deg)	0	2	4	6	8	10
$\left(\Delta C_{L_{WB}}\right)_G$	0.04	0.01	−0.025	−0.06	−0.09	−0.11

Tail Characteristics:

$$\frac{\ell_H}{\bar{c}} = 2.43 \qquad \frac{S_H}{S_W} = 0.377 \qquad \frac{q_H}{q_\infty} = 0.95$$

From Sample Problem 1 of Section 4.7.1:

α (deg)	0	2	4	6	8	10
$\left(\Delta C_{L_H}\right)_G$	0.255	0.305	0.355	0.415	0.470	0.530

Compute:

$$\left(\Delta C_{m_H}\right)_G = -\left(\Delta C_{L_H}\right)_G \frac{\ell_H}{\bar{c}} \frac{S_H}{S_W} \frac{q_H}{q_\infty} \qquad \text{(Equation 4.7.3-b)}$$

$$= -\left(\Delta C_{L_H}\right)_G (2.43)(0.377)(0.95)$$

$$= -0.870 \left(\Delta C_{L_H}\right)_G$$

α (deg)	0	2	4	6	8	10
$\left(\Delta C_{m_H}\right)_G$	−0.222	−0.265	−0.309	−0.361	−0.409	−0.461

$$\left(\Delta C_{m_{WB}}\right)_G = \left(n - \frac{X_{a.c.}}{\bar{c}}\right)\left(\Delta C_{L_{WB}}\right)_G \qquad \text{(Equation 4.7.3-c)}$$

$$= (1.242 - 1.182)\left(\Delta C_{L_{WB}}\right)_G$$

$$= (0.06)\left(\Delta C_{L_{WB}}\right)_G$$

α (deg)	0	2	4	6	8	10
$\left(\Delta C_{m_{WB}}\right)_G$	0.0024	0.0006	−0.0016	−0.0036	−0.0054	−0.0066

Solution:

$$\left(\Delta C_m\right)_G = \left(\Delta C_{m_H}\right)_G + \left(\Delta C_{m_{WB}}\right)_G \qquad \text{(Equation 4.7.3-a)}$$

α (deg)	0	2	4	6	8	10
$\left(\Delta C_m\right)_G$	−0.220	−0.264	−0.311	−0.365	−0.414	−0.468

4.7.4 GROUND EFFECTS ON DRAG AT ANGLE OF ATTACK

In this section, methods are presented for estimating the ground effects on drag in the linear-lift region. The reader is referred to Section 4.7 for a basic discussion of various aspects of ground effects.

The drag of a vehicle in the presence of a ground plane is affected in three ways.

1. The drag due to lift is decreased.

2. A change in the drag at zero lift is also experienced, but is small relative to the change in drag due to lift.

3. The presence of a ground plane introduces a pitching-moment increment (Section 4.7.3), which changes the drag due to lift of the trimmed vehicle.

The second effect is ignored in most calculations and is not presented in the Datcom.

Two methods are presented to determine the reduction in drag due to lift in the presence of the ground. Both methods are based on an image-vortex representation of the ground plane (see Sketches (a), (b), (c), and (d) in Section 4.7). The method of Wieselsberger from Reference 1 considers only the effects of the bound image vortex. However, the method of Tani (References 2 and 3) considers the effects of both the bound and trailing image vortices.

The change in drag due to lift resulting from trimming the pitching-moment increment due to ground effect consists of a synthesis of material presented in other sections.

DATCOM METHODS

Change in Trim Drag Due to Ground Plane

Procedures for calculating the drag increment due to longitudinally trimming a vehicle are presented in Section 4.5.3.2. To determine trim drag in ground effect, the pitching-moment increment due to ground effect $(\Delta C_m)_G$ of Equation 4.7.3-a is added to the vehicle pitching moment out of ground effect. The combined pitching moment is then used in the standard procedure for determining trim drag out of ground effect (Section 4.5.3.2).

Change, Due to Ground Effect, of Drag Due to Lift of the Wing

According to Reference 3, the two methods presented herein for predicting ground effects on drag due to lift give nearly identical results at moderate to large ground heights. Therefore, Method 1 is preferred for its simplicity. At ground heights within the approximate range $0.3 \geq h/b > 0$ however, Method 2 should be used, since its accuracy is significantly better than that of Method 1 in this range. Both methods have been modified slightly to include the effects of wing dihedral.

Neither Method 1 nor Method 2 is very successful in estimating ground effects on drag with flaps down. At low heights above the ground, Method 2 gives results closer to experimental data than does Method 1. although both methods underestimate the reduction of drag in ground effect. At intermediate heights above the ground, the two methods yield nearly equivalent results.

Method 1

The change in wing drag due to lift caused by ground effect as determined by Wieselsberger (Reference 1) is given by

$$\left(\Delta C_{D_L}\right)_G = -\frac{\sigma C_L^2}{\pi A} \qquad 4.7.4\text{-a}$$

where

- σ is Prandtl's interference coefficient from multiplane theory and is obtained from Figure 4.7.1-19 as a function of wing height above the ground.
- C_L is the lift coefficient of the wing out of ground effect, obtained from test data or estimated by using the method of Section 4.1.3.3.
- A is the wing aspect ratio.

The total drag of a wing-body configuration in ground effect is then given by

$$\left(C_{D_{WB}}\right)_G = C_{D_{WB}} + \left(\Delta C_{D_L}\right)_G \qquad 4.7.4\text{-b}$$

where $C_{D_{WB}}$ is the total drag coefficient of the wing-body configuration out of ground effect obtained from test data or Section 4.3.3.2, and $\left(\Delta C_{D_L}\right)_G$ is obtained by using either Method 1 or 2.

Method 2

The reduction in drag due to lift as determined by the method of Tani (References 2 and 3) is given by

$$\left(\Delta C_{D_L}\right)_G = -\frac{\sigma C_L^2}{\pi A} - \left(C_D - \frac{\sigma C_L^2}{\pi A}\right)\frac{\tau T C_L}{57.3} \qquad 4.7.4\text{-c}$$

where

- C_D is the wing-alone drag coefficient corresponding to C_L out of ground effect, obtained from test data or estimated by the method of Section 4.1.5.2, i.e., $\left(C_{D_0} + C_{D_L}\right)$.
- τ accounts for the condition of finite span and is obtained from Figure 4.7.1-16 as a function of wing height above the ground.

T accounts for the reduction of the longitudinal velocity and is obtained from Figure 4.7.1-20 as a function of wing height above the ground.

All remaining parameters have been defined in Method 1 above.

The total drag of a wing-body configuration in ground effect is calculated by using the procedure in Method 1 above; i.e.,

$$\left(C_{D_{WB}}\right)_G = C_{D_{WB}} + \left(\Delta C_{D_L}\right)_G \qquad 4.7.4\text{-b}$$

The sample problems presented below illustrate the use of both Methods 1 and 2 applied to a wing-alone configuration. It should be noted that, in applying Method 2 to a wing-body configuration, the value of C_D in Equation 4.7.4-c is that of the wing alone. If no test data are available for the particular configuration, the wing drag may be estimated by using the method of Section 4.1.5.2, as noted previously. On the other hand, if only wing-body test data are available, it is suggested that the wing-body result be used instead of attempting to estimate a wing-alone value.

Sample Problems

1. Method 1

Given: The sweptback wing of Reference 4

Wing Characteristics:

$A = 4.01$ $\quad b = 11.375$ ft $\quad \bar{c} = 2.89$ ft $\quad \Lambda_{c/4} = 40^o$

Additional Characteristics:

$h = 1.97$ ft

The following drag variation with lift (out of ground effect) from Reference 4:

C_L	0.10	0.20	0.40	0.60	0.70	0.80
C_D Wing Alone	0.0063	0.0093	0.0220	0.0400	0.0500	0.0660

Compute:

$h/(b/2) = (2)(1.97)/11.375 = 0.346$

$\sigma = 0.33$ (Figure 4.7.1-19)

Solution:

$$\left(\Delta C_{D_L}\right)_G = -\frac{\sigma C_L^2}{\pi A} \quad \text{(Equation 4.7.4-a)}$$

$$= -\frac{0.33\, C_L^2}{(3.14)(4.01)}$$

$$= -0.0262\, C_L^2$$

① C_L	② C_L^2	③ $\left(\Delta C_{D_L}\right)_G$ (Eq. 4.7.4-a) -0.0262 ②
0.10	0.01	−0.0003
0.20	0.04	−0.0010
0.40	0.16	−0.0042
0.60	0.36	−0.0094
0.70	0.49	−0.0128
0.80	0.64	−0.0168

The calculated results are compared with test values from Reference 4 in Sketch (a).

2. Method 2

Given: The same configuration as that of Sample Problem 1

Compute:

$$\frac{\sigma C_L^2}{\pi A} = 0.0262\, C_L^2 \quad \text{(see Sample Problem 1)}$$

$r = 0.712$ (Figure 4.7.1-16)

$T = 3.24$ (Figure 4.7.1-20)

$rT = (0.712)(3.24) = 2.31$

Solution.

$$\left(\Delta C_{D_L}\right)_G = -\frac{\sigma C_L^2}{\pi A} - \left(C_D - \frac{\sigma C_L^2}{\pi A}\right)\frac{rTC_L}{57.3} \quad \text{(Equation 4.7.4-c)}$$

$$= -0.0262\,C_L^2 - \left(C_D - 0.0262\,C_L^2\right)(0.0403)\,C_L$$

① C_L	② C_D Wing Alone	③ C_L^2	④ $\frac{\sigma C_L^2}{\pi A}$ 0.0262 ③	⑤ $\left(C_D - \frac{\sigma C_L^2}{\pi A}\right)$ ② − ④	⑥ $\left(C_D - \frac{\sigma C_L^2}{\pi A}\right)\frac{rTC_L}{57.3}$ 0.0403 ⑤ ①	⑦ $\left(\Delta C_{D_L}\right)_G$ (Eq. 4.7.4-c) − ④ − ⑥
0.10	0.0053	0.01	0.0003	0.0050	0.00002	−0.0003
0.20	0.0093	0.04	0.0010	0.0083	0.0001	−0.0011
0.40	0.0220	0.16	0.0042	0.0178	0.0003	−0.0045
0.60	0.0400	0.36	0.0094	0.0306	0.0007	−0.0101
0.70	0.0500	0.49	0.0128	0.0372	0.0011	−0.0139
0.80	0.0650	0.64	0.0168	0.0482	0.0016	−0.0184

The calculated results are compared with test values from Reference 4 in Sketch (a).

4.8 LOW-ASPECT-RATIO WINGS AND WING-BODY COMBINATIONS AT ANGLE OF ATTACK

During recent years much work has been done on problems associated with the design and operation of advanced flight vehicles. These vehicles include re-entry configurations and those designed for hypersonic cruise. The requirement that these vehicles operate within the atmosphere at hypersonic speeds necessitates the use of configurations that are not well suited for subsonic flight at low altitudes. The configurations proposed for this type of mission feature, for the most part, extremely low aspect ratios of the order of two or less, and thick, generously-rounded lifting surfaces. These configurations also often have large blunt bases.

The subsonic flow about these vehicles is extremely complex, so much so that in most cases the use of available theoretical methods does not result in satisfactory estimates of the aerodynamic characteristics for this type of vehicle. The methods presented in this section for estimating the aerodynamic characteristics of advanced flight vehicles at subsonic speeds are necessarily semiempirical in nature. The methods are based on test data, which have been correlated with the aid of the extension of available theory. A large portion of the material is related to delta and modified-delta configurations, since a major portion of the pertinent theory and test results relate to these planforms.

In the following group of sections (4.8.1, 4.8.2, and 4.8.3) methods are presented for estimating the normal force, axial force, and pitching moment on specific types of advanced flight vehicles at angles of attack up to 20°.

The aerodynamic forces acting on the vehicle are illustrated in figure 4.8-12. In the lift axis system, the force is resolved into components perpendicular to and parallel to the free stream, called the lift and drag, respectively. In the normal-force axis system, the force is resolved into components perpendicular to and parallel to the zero-normal-force reference plane, called the normal force and axial force, respectively. For unsymmetrical configurations the zero-normal-force reference plane is inclined at some angle α_{N_0} to the body horizontal plane. The body horizontal plane passes through the most forward point on the vehicle nose and its inclination to the free stream defines the angle of attack α in the familiar lift axis system (see figure 4.8-12). The normal-force and axial-force coefficients and the angle of attack of unsymmetrical configurations are designated as $C_{N'}$, $C_{X'}$, and α', respectively. For symmetrical configurations $\alpha_{N_0} = 0$ and $\alpha' = \alpha$, and the zero-normal-force reference plane coincides with the body horizontal plane of symmetry. For symmetrical configurations the normal-force and axial-force ceofficients are designated as C_N and C_X, respectively.

The equations relating lift, drag, normal force, and axial force are as follows:

For unsymmetrical configurations

$$C_{N'} = C_L \cos \alpha' + C_D \sin \alpha'$$

$$C_{X'} = -C_D \cos \alpha' + C_L \sin \alpha'$$

$$C_L = C_{N'} \cos \alpha' + C_{X'} \sin \alpha'$$

$$C_D = -C_{X'} \cos \alpha' + C_{N'} \sin \alpha'$$

For symmetrical configurations (symmetry about the Z = 0 plane)

$$C_N = C_L \cos\alpha + C_D \sin\alpha$$

$$C_X = -C_D \cos\alpha + C_L \sin\alpha$$

$$C_L = C_N \cos\alpha + C_X \sin\alpha$$

$$C_D = -C_X \cos\alpha + C_N \sin\alpha$$

The pitching-moment coefficient at a specified angle is independent of the axis system.

The normal-force axis system is used throughout the following group of sections, since it was found to be more convenient in the correlation of the available test data.

Many of the available test results do not separate the base pressure from other aerodynamic forces. Therefore, the total axial force is analyzed in Section 4.8.2 by separating it into a component produced by base pressure plus a component related to the viscous forces acting on areas other than the base.

A general notation list is included in this section for all sections included under Section 4.8.

Sketches showing planform geometry for nearly all the configurations analyzed in Sections 4.8.1.1 through 4.8.3.2 are presented in table 4.8-A.

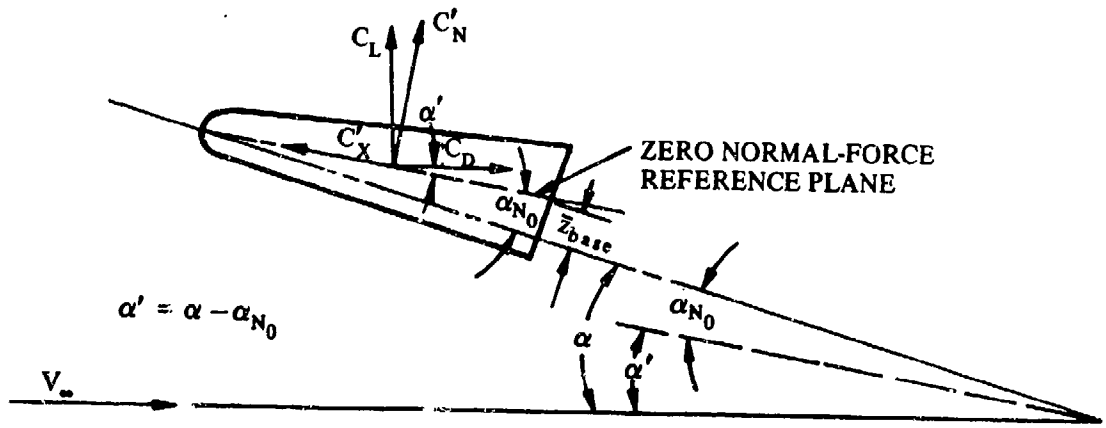

FIGURE 4.8-12 DEFINITION OF REFERENCE-AXIS SYSTEM

4.8.1 WING, WING-BODY NORMAL FORCE

4.8.1.1 WING, WING-BODY ZERO-NORMAL-FORCE ANGLE OF ATTACK

The longitudinal data for the low-aspect-ratio configurations are presented in terms of the normal-force and axial-force coefficients of a normal-force axis system rather than the more common lift and drag coefficients of the lift axis system. The problem arising with the normal-force axis system is that of defining a reference plane for the nonsymmetrical configurations which specifies the direction of the normal force and axial force. This is accomplished by defining a reference axis system which is oriented with respect to the particular configuration so that the normal force is zero at zero angle of attack.

The defined normal-force axis system is illustrated in figure 4.8-12. The normal-force coefficient $C_{N'}$ is perpendicular to and the axial-force coefficient $C_{X'}$ is parallel to a reference plane which passes through the centroid of the base area and the most forward point on the vehicle nose. For symmetrical configurations this is the plane of symmetry.

The zero-normal-force angle of attack α_{N_0} is defined as the angle of attack at which the normal force acting on the body is zero. For a symmetrical configuration, the normal force is zero when the plane of symmetry is parallel to the free stream. Therefore, for symmetrical configurations $\alpha_{N_0} = 0$. For unsymmetrical configurations, α_{N_0} may be related to an arbitrary plane as shown in figure 4.8-12. This arbitrary reference plane is chosen so that its inclination to the free stream defines the angle of attack in the familiar lift axis system. It is referred to as the body horizontal plane.

From the geometry of figure 4.8-12, the angle of attack α' in the defined normal-force axis system is

$$\alpha' = \alpha - \alpha_{N_0} \qquad 4.8.1.1\text{-a}$$

where

α is the angle of attack, positive nose-up, measured from the free stream to the body horizontal axis.

α_{N_0} is the zero-normal-force angle of attack, measured between the reference plane and the body horizontal plane, positive as shown in figure 4.8-12.

DATCOM METHOD

The zero-normal-force angle of attack is determined from the configuration geometry as follows:

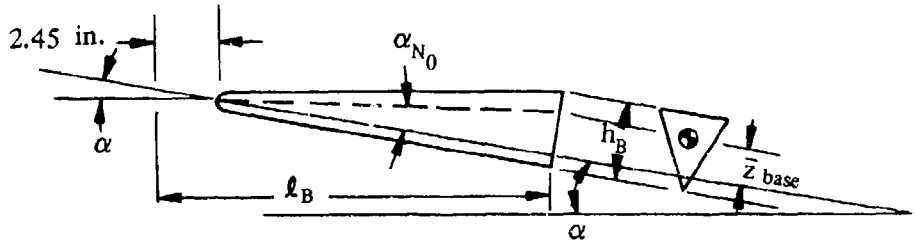
Step 1. Determine the location of the centroid of the base area and the location of the most forward point on the vehicle nose.

Step 2. Determine α_{N_0} as the angle between the line connecting the centroid of the base and the most forward point on the nose, and the horizontal plane of the body.

Values of the zero-normal-force angle of attack calculated by using this method are compared with test results in table 4.8.1.1-A. Many of the configurations tested were complex re-entry shapes, and the reader should refer to table 4.8-A for a more complete description of the model. Unfortunately, there are not enough data available to illustrate a consistent effect of planform geometry on the zero-normal-force angle of attack.

Sample Problems

1. Given: The right-triangular pyramidal body designated as configuration 1 of reference 6.



ℓ_B = 31.55 in. Nose radius = 0.1875 in. h_b = 6.44 in.

Compute:

Centroid of base

$$\bar{z}_{base} = \frac{2}{3} h_b - \text{nose radius} = \frac{2}{3}(5.44) - 0.1875 = 4.106 \text{ in.}$$

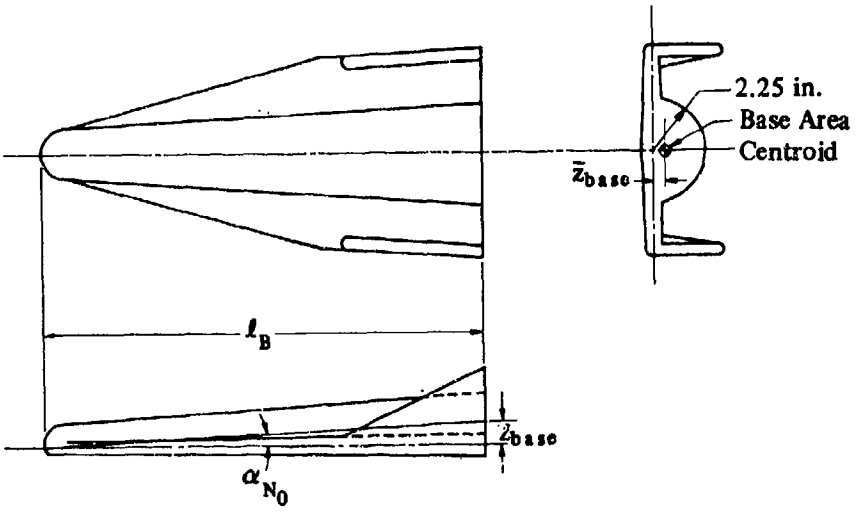
Solution:

$$\alpha_{N_0} = \tan^{-1} \frac{\bar{z}_{base}}{\ell_B - 2.45} = \tan^{-1} \frac{4.106}{31.55 - 2.45} = \tan^{-1} 0.1412$$

$$= 8.04^{\circ}$$

This compares with a test value of $\alpha_{N_0} = 8.6^{\circ}$ from reference 6.

2. Given: A re-entry configuration of the wing-body group of reference 1 designated WB-10(0). This is a round-nosed, wing-body model of 75° sweep back with a semicircular-body cross section at the point of maximum thickness and with twin vertical tails.



ℓ_B = 20.0 in. $\quad\quad$ $\bar{z}_{base}$ = 0.68 in.

Solution:

$$\alpha_{N_0} = \tan^{-1} \frac{\bar{z}_{base}}{\ell_B} = \tan^{-1} \frac{0.68}{20.0} = \tan^{-1} 0.0340$$

$$= 1.95^{o}$$

This compares with a test value of $\alpha_{N_0} = 0.30^{o}$ from reference 1.

4.8.1.2 WING, WING-BODY NORMAL-FORCE VARIATION WITH ANGLE OF ATTACK

A. SUBSONIC

This section presents a method for estimating the normal-force variation with angle of attack for a delta- or modified-delta-planform re-entry configuration at subsonic speeds.

The subsonic normal-force characteristics of thin delta wings at small angles of attack can be satisfactorily predicted through the use of linearized theory, which assumes that the flow is unseparated and that the cross-flow components are negligible. At higher angles ($\alpha \geq 5^{o}$, approximately) both cross-flow and separation phenomena become important and these assumptions are no longer valid. The normal force tends to increase more rapidly with angle of attack as the angle is increased.

A major factor influencing the normal-force characteristics of delta wings is leading-edge geometry. Sharp leading edges influence relatively large amounts of air and the corresponding variation of the normal force with angle of attack tends to be high. Rounded leading edges affect a smaller amount of air and the normal-force-curve slope is consequently less.

The method presented herein is taken from reference 1, and is based on a study of test data on low-aspect-ratio delta wings with thick and thin surfaces, with sharp and rounded leading edges, and with varying degrees of nose bluntness. Thin, sharp-leading-edged delta wings were selected as "reference wings," and theoretical relationships were written for the normal-force characteristics of these planforms. The normal-force characteristics of all the test configurations were then calculated by using these "reference wing" relationships, and any deviation between the calculated and the test values was related to the geometry of the wing leading edge. It was found that satisfactory correlation could be obtained by relating the deviation in normal-force characteristics to the leading-edge geometry in a plane normal to the wing leading edge and located one-third the length of the root chord aft of the nose.

Design charts are presented for estimating the normal-force-curve slope at $C_N' = 0$, the value of C_N' at $\alpha' = 20^{o}$, and the characteristics of the normal-force variation with angle of attack. The correlation parameters used to develop these charts are leading-edge radius and leading-edge angle for round and sharp leading edges, respectively. It should be noted that as the leading-edge radius approaches zero, the normal-force-curve slope at $C_N' = 0$, the normal force at $\alpha' = 20^{o}$, and the normal-force-variation parameter all approach the respective values for a sharp leading edge. Therefore, a configuration with a small leading-edge radius can be analyzed as one having a sharp leading edge.

For configurations with round leading edges, an empirical correction factor is presented to account for the reduction in normal force at higher angles of attack as the wing thickness is increased. This separate correlation is required, since the limited number of test data for very thick delta wings does not correlate well with the thin wing results.

DATCOM METHOD

The normal-force variation with angle of attack for a delta or modified-delta configuration at low speeds, based on the reference area (usually the planform area), is obtained from the procedure outlined in the following steps:

Step 1. Determine the effective leading edge angle. δ_{e_1} for sharp leading edges or the effective

leading-edge radius $R_{\frac{1}{3}LE}$ and lower surface angle δ_L for round leading edges. These parameters are functions of the configuration geometry in a plane normal to the leading edge at $\frac{1}{3} c_r$ from the nose. The applicable configuration geometry is illustrated on figures 4.8.1.2-11a and 4.8.1.2-11b.

Step 2. Determine the normal-force-curve slope at zero normal force ($C_{N'} = 0$) by

$$\left(C_{N_\alpha}\right)'_{N_0} = \left(\frac{C_{N_\alpha}}{C_{N_{\alpha_{calc}}}}\right)'_{N_0} \left(C_{N_{\alpha_{calc}}}\right)'_{N_0} \quad \text{(per radian)} \qquad 4.8.1.2\text{-a}$$

where

$\left(C_{N_\alpha}\right)'_{N_0}$ is the normal-force-curve slope at zero normal force $\left(\frac{\partial C_{N'}}{\partial \alpha'}\right)_{N_0}$

$\left[\frac{C_{N_\alpha}}{C_{N_{\alpha_{calc}}}}\right]'_{N_0}$ is the empirical correlation factor of normal-force-curve slope for delta or modified-delta configurations. It is presented as a function of the effective leading-edge angle for configurations with sharp leading edges in figure 4.8.1.2-12a, and as a function of the effective leading-edge radius for configurations with round leading edges in figure 4.8.1.2-12b.

$\left(C_{N_{\alpha_{calc}}}\right)'_{N_0}$ is the calculated normal-force-curve slope at zero normal force, given by

$$\left(C_{N_{\alpha_{calc}}}\right)'_{N_0} = \left(\frac{\pi A}{2} + 2\frac{S_F}{S_{ref}}\right)\frac{4}{4+A} \quad \text{(per radian)} \qquad 4.8.1.2\text{-b}$$

where

S_{ref} is the reference area.

S_F is the projected frontal area perpendicular to the zero-normal-force reference plane (projected frontal area at $C_{N'} = 0$).

A is the aspect ratio of the surface.

Step 3. Determine the normal-force coefficient at $\alpha' = 20^{o}$ by

$$\left(C_{N'}\right)_{20} = \left[\frac{C_{N'}}{C_{N'_{calc}}}\right]_{20} \left(C_{N'_{calc}}\right)_{20} \qquad 4.8.1.2\text{-c}$$

where

$\left(C_{N'}\right)_{20}$ is the normal-force coefficient at $\alpha' = 20^{o}$.

$\left[\frac{C_{N'}}{C_{N'_{calc}}}\right]_{20}$ is the empirical correlation factor of the normal force for delta and modified-delta configurations. It is presented as a function of the effective leading-edge angle for configurations with sharp leading edges in figure 4.8.1.2-13a, and as a function of the effective leading-edge radius for configurations with round leading edges in figure 4.8.1.2-13b.

$\left(C_{N'_{calc}}\right)_{20}$ is the calculated normal force at $\alpha' = 20^{o}$, given by

$$\left(C_{N'_{calc}}\right)_{20} = 2.195\left(\frac{A + 0.61}{A + 4.0}\right) \qquad 4.8.1.2\text{-d}$$

Step 4.* Determine the thickness correction to the normal force at $\alpha' = 20^{o}$ for configurations with round leading edges by

$$\left[\left(C_{N'}\right)_{20}\right]_{t} = \left(\frac{1 + \cos\delta_{L}}{2}\right)\left(C_{N'}\right)_{20} \qquad 4.8.1.2\text{-e}$$

where δ_{L} is the lower surface angle from step 1 and $\left(C_{N'}\right)_{20}$ is obtained from step 3.

Step 5. Determine Z, the empirical, nonlinear-normal-force correction factor. This parameter is obtained as a function of the effective leading-edge angle or the effective leading-edge radius for configurations with sharp leading edges or round leading edges, respectively, from figure 4.8.1.2-14.

Step 6. The variation of the normal force with angle of attack is given by:

For round-leading-edged configurations

$$C_{N'} = \left(C_{N_{\alpha}}\right)'_{N_0}\alpha' + 8.21\left\{\left[\left(C_{N'}\right)_{20}\right]_{t} - 0.349\left(C_{N_{\alpha}}\right)'_{N_0}\right\}\left[Z + 2.81(1 - Z)\alpha'\right]\alpha'^{2} \qquad 4.8.1.2\text{-f}$$

*Step 4 is required only for configurations with round leading edges. For sharp-leading-edged configurations, go to step 5.

For sharp-leading-edged configurations the normal-force coefficient at $\alpha' = 20^{\circ}$ from step 3 $\left(C_{N'}\right)_{20}$ is used instead of the term $\left[\left(C_{N'}\right)_{20}\right]_t$ in the above equation.

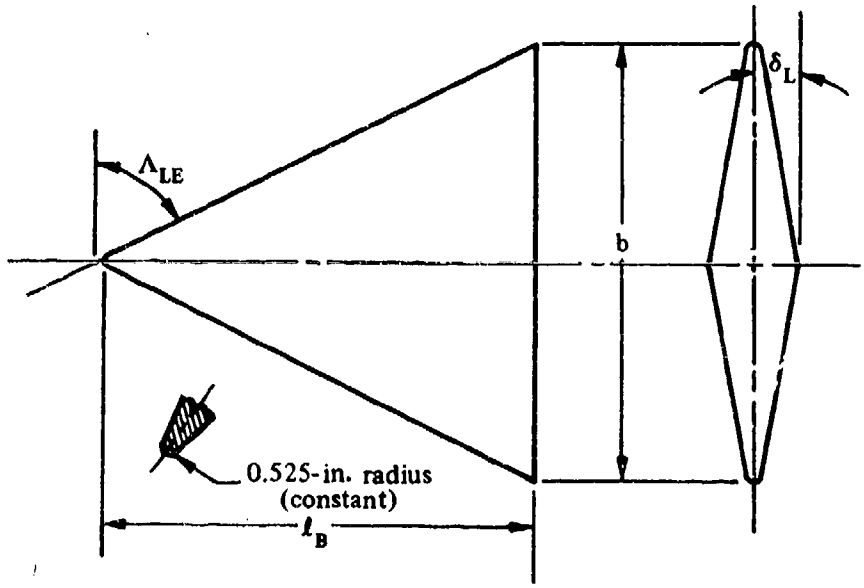
α' in the above relation is in radians.

A comparison of the normal-force variation with angle of attack calculated by this method with test results is presented as table 4.8.1.2-A. The Reynolds-number range of the test data is not sufficient to allow analysis of the effect of Reynolds number on the normal force. However, over the angle-of-attack range of this method ($\alpha' \leq 20^{\circ}$), Reynolds-number effects should be negligible even for the thicker configurations.

Sample Problems

1. Round Leading Edge

Given: A delta model with a symmetrical diamond cross section and a blunt trailing edge. This is model D-6 of reference 6.



$A = 1.868$ $b = 22.116$ in. $S_{ref} = S = 261.95$ sq in. $\Lambda_{LE} = 65^{\circ}$

$S_F = 57.42$ sq in. (base area) $\delta_L = 9^{\circ}$ $R_{\frac{1}{3}\,LE} = 0.525$ in.

Compute:

Determine the normal-force-curve slope at $C_{N'} = 0$

$$R_{\frac{1}{3}\,LE}/b = 0.525/22.116 = 0.0237$$

$$\left[\frac{C_{N_\alpha}}{C_{N_{\alpha_{calc}}}}\right]'_{N_0} = 0.982 \quad \text{(figure 4.8.1.2-12b)}$$

$$\left(C_{N_{\alpha_{calc}}}\right)'_{N_0} = \left(\frac{\pi A}{2} + 2\frac{S_F}{S_{ref}}\right)\frac{4}{4+A} \qquad \text{(equation 4.8.1.2-b)}$$

$$= \left[\frac{\pi(1.868)}{2} + 2\,\frac{57.42}{261.95}\right]\frac{4}{4+1.868}$$

$$= 2.30 \text{ per rad}$$

$$(C_N)'_{N_0} = \left[\frac{C_{N_\alpha}}{C_{N_{\alpha_{calc}}}}\right]_{N_0} \left(C_{N_{\alpha_{calc}}}\right)'_{N_0} \qquad \text{(equation 4.8.1.2-a)}$$

$$= (0.982)\,(2.30)$$

$$= 2.26 \text{ per rad}$$

Determine the normal-force coefficient at $\alpha' = 20^o$

$$\left[\frac{C_{N'}}{C_{N'_{calc}}}\right]_{20} = 0.935 \quad \text{(figure 4.8.1.2-13b)}$$

$$\left(C_{N'_{calc}}\right)_{20} = 2.195\left(\frac{A + 0.61}{A + 4.0}\right) \qquad \text{(equation 4.8.1.2-d)}$$

$$= 2.195\left(\frac{1.868 + 0.61}{1.868 + 4.0}\right)$$

$$= 0.927$$

$$(C_{N'})_{20} = \left[\frac{C_{N'}}{C_{N'_{calc}}}\right]_{20} \left(C_{N'_{calc}}\right)_{20} \qquad \text{(equation 4.8.1.2-c)}$$

$$= (0.935)\,(0.927)$$

$$= 0.867$$

Determine the thickness correction factor to the normal force at $\alpha' = 20^{o}$ (round leading edge)

$$\left[(C_{N'})_{20}\right]_t = \left(\frac{1 + \cos \delta_L}{2}\right) (C_{N'})_{20} \quad \text{(equation 4.8.1.2-e)}$$

$$= \left(\frac{1 + \cos 9^{o}}{2}\right) (0.867)$$

$$= 0.862$$

Determine the empirical, nonlinear-normal-force correction factor

$Z = 0.945$ (figure 4.8.1.2-14)

Solution:

$$C_{N'} = \left(C_{N_\alpha}\right)'_{N_0} \alpha' + 8.21 \left\{\left[(C_{N'})_{20}\right]_t - 0.349 \left(C_{N_\alpha}\right)'_{N_0}\right\} \left[Z + 2.81(1 - Z)\alpha'\right] \alpha'^2$$

(equation 4.8.1.2-f)

$$= 2.26\ \alpha' + 8.21 \left\{0.862 - 0.349(2.26)\right\} \left[0.945 + 2.81(1 - 0.945)\alpha'\right] \alpha'^2$$

$$= 2.26\ \alpha' + 0.568\ \alpha'^2 + 0.0930\ \alpha'^3$$

①	②	③	④	⑤	⑥	⑦	⑧

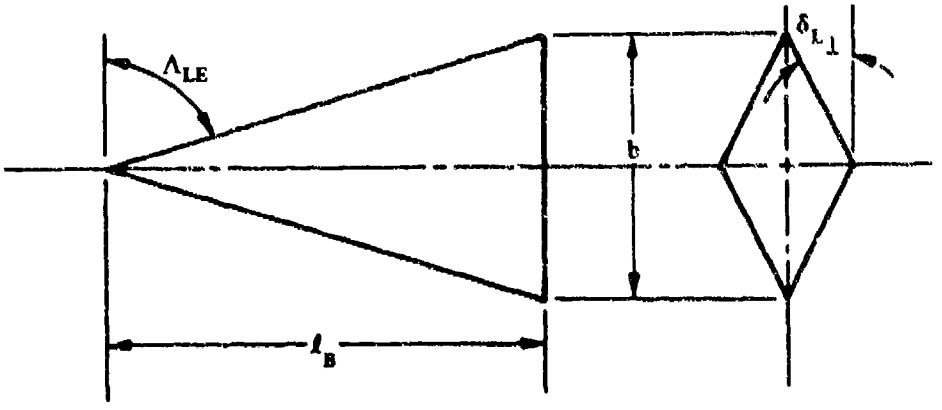
20	0.3490	0.12180	0.04261	0.7887	0.06918	0.003953	0.8618

The calculated results are compared with test values from reference 6 in sketch (a) and in table 4.8.1.2-A.

2. Sharp Leading Edge

Given: A delta model with a symmetrical diamond cross section and a blunt trailing edge. This is model D-3 of reference 6.*



$A = 1.076$ $\quad b = 12.374$ in. $\quad S_{ref} = S = 142.30$ sq in. $\quad \Lambda_{LE} = 75^o$

$S_F = 44.20$ sq in. (base area) $\quad \delta_{L\perp} = 30^o \quad \delta_{\perp} = 60^o \quad \delta_{e\perp} = 90^o$

Compute:

Determine the normal-force-curve slope at $C_N' = 0$

$$\left[\frac{C_{N_\alpha}}{C_{N_{\alpha_{calc}}}}\right]_{N_0} = 0.775 \quad \text{(figure 4.8.1.2-12a)}$$

$$\left(C_{N_{\alpha_{calc}}}\right)'_{N_0} = \left(\frac{\pi A}{2} + 2\frac{S_F}{S_{ref}}\right)\frac{4}{4+A} \quad \text{(equation 4.8.1.2-b)}$$

$$= \left[\frac{\pi(1.076)}{2} + 2\frac{44.20}{142.30}\right]\frac{4}{4+1.076}$$

$$= 1.821 \text{ per rad}$$

$$\left(C_{N_\alpha}\right)'_{N_0} = \left[\frac{C_{N_\alpha}}{C_{N_{\alpha_{calc}}}}\right]_{N_0}\left(C_{N_{\alpha_{calc}}}\right)'_{N_0} \quad \text{(equation 4.8.1.2-a)}$$

$$= (0.775)(1.821)$$

$$= 1.411 \text{ per rad}$$

*Although this model has a very small nose radius (0.032 in.), it is analyzed as having a sharp leading edge.

Determine the normal-force coefficient at $\alpha' = 20^{o}$

$$\left[\frac{C_{N'}}{C_{N'_{calc}}}\right]_{20} = 0.960 \quad \text{(figure 4.8.1.2-13a)}$$

$$\left(C_{N'_{calc}}\right)_{20} = 2.195\left(\frac{A + 0.61}{A + 4.0}\right) \quad \text{(equation 4.8.1.2-d)}$$

$$= 2.195\left(\frac{1.076 + 0.61}{1.076 + 4.0}\right)$$

$$= 0.7291$$

$$(C_{N'})_{20} = \left[\frac{C_{N'}}{C_{N'_{calc}}}\right]_{20}\left(C_{N'_{calc}}\right)_{20} \quad \text{(equation 4.8.1.2-c)}$$

$$= (0.960)(0.7291) = 0.700$$

Determine the empirical, nonlinear-normal-force correction factor

$Z = 0.972$ (figure 4.8.1.2-14)

Solution:

$$C_{N'} = \left(C_{N_\alpha}\right)'_{N_0}\alpha' + 8.21\left\{(C_{N'})_{20} - 0.349\left(C_{N_\alpha}\right)'_{N_0}\right\}[Z + 2.81(1 - Z)\alpha']\alpha'^{2}$$

(equation 4.8.1.2-f, sharp leading edge)

$$= 1.411\alpha' + 8.21\left\{(0.700) - 0.349(1.411)\right\}[0.972 + 2.81(1 - 0.972)\alpha']\alpha'^{2}$$

$$= 1.411\alpha' + 1.656\alpha'^{2} + 0.134\alpha'^{3}$$

①	②	③	④	⑤	⑥	⑦	⑧
α' (deg)	α' (rad)	α'^2 (rad^2)	α'^3 (rad^3)	$1.411\alpha'$ 1.411 ②	$1.656\alpha'^2$ 1.656 ③	$0.134\alpha'^3$ 0.134 ④	$C_{N'}$ (based on S) (eq. 4.8.1.2-f) ⑤ + ⑥ + ⑦

4.8.2 WING, WING-BODY AXIAL FORCE

4.8.2.1 WING, WING-BODY ZERO-NORMAL-FORCE AXIAL FORCE

A. SUBSONIC

This section presents a method, taken from reference 1, for estimating the zero-normal-force axial force of advanced flight vehicles at subsonic speeds.

The drag at zero normal force is assumed to be composed of skin-friction drag, base drag, and the pressure drag acting on portions of the configuration other than the base. For most advanced flight vehicles at subsonic speeds, the component of pressure drag acting on portions of the vehicle other than the base is relatively small compared to the sum of the base drag and the skin-friction drag, and it is difficult to isolate. Consequently, in this section it is included as part of an "effective" friction drag.

The "effective" friction drag is determined by multiplying the total wetted area, excluding the base area, by some friction coefficient. For configurations having an average aerodynamic cleanliness, and for thickness ratios not exceeding approximately fifteen to twenty percent, the equivalent friction drag coefficient, based on wetted area, can be assumed to be $C_f = 0.0040$. Of course, this quantity will depend upon such items as surface condition and Reynolds number. Heat and drag loads during re-entry could be such as to roughen the surface and increase surface drag significantly. However, for most configurations of this class, surface drag is a relatively small part of the total drag at most speeds and angles of attack, and it is not considered necessary to go into these effects in greater detail.

Advanced flight vehicles are frequently characterized by large surface areas approximately normal to the direction of flight and facing aft. The "base pressures" acting upon these areas can significantly increase the drag and reduce the maximum lift-drag ratio of these aircraft. For the purpose of definition, "bases" are considered to be those external surface areas which face aft and are approximately perpendicular to the direction of flight; they are formed by the "cutting-off" of some component. The flow ahead of the base should be unseparated and approximately parallel to the free stream, at least near zero lift. In keeping with this definition, bases include the aft facing areas produced by blunting wing trailing edges and by the jet exits of inoperative rocket engines.

The manner in which base drag arises can be visualized by considering the viscous pumping action of the air flowing around the periphery of the base. The viscous forces produced by the external flow tend to drag the air away from the base and consequently reduce the base pressure. In addition, the base pressure would be other than ambient even for a nonviscous flow, since the base would be influenced by the static pressures in the external flow, which are, in general, other than ambient. Consequently, the base pressure would depend both on the magnitude of the pumping, which is related to the ratio of the viscous mixing area to the total base area, and on the shape of the body ahead of the base, which determines the static pressures in the external flow at the boundary of the base.

Because of the complexity of base pressure phenomena at subsonic speeds, it has not been possible theoretically to predict base pressures for even the most simple configurations without entailing complex computational techniques, which nevertheless produce results of doubtful accuracy. Hence, the approach presented in this section is based on semiempirical techniques aimed at isolating the parameters known to be of primary importance.

Factors that might be expected to influence base pressure but which were not isolated in the analysis reported in reference 1 include scale effect and Reynolds number. Available test data show that the variation in Reynolds number produces little effect in base pressure when the flow is turbulent at the base.

DATCOM METHOD

The subsonic axial-force coefficient at zero normal force, based on the reference area (usually the planform area), is obtained from the procedure outlined in the following steps:

Step 1. Determine the increment in axial-force coefficient due to skin friction at zero normal force by

$$\Delta C_{X'_{f_{N_0}}} = -C_f \frac{S_{wet}}{S_{ref}} \qquad 4.8.2.1\text{-a}$$

where

C_f is the turbulent flat-plate skin-friction coefficient based on the wetted area. It is recommended that a value of $C_f = 0.0040$ be used unless detailed data on surface condition are available. In that case the method of paragraph A of of Section 4.1.5.1 should be used to obtain C_f.

S_{wet} is the wetted area or surface area of the configuration excluding the base area.

S_{ref} is the reference area (usually the configuration planform area).

Step 2. Determine the base-pressure coefficient at zero normal force, based on the base area, by

$$C_{p_{b_{N_0}}} = \frac{C_{p_{b_{N_0}}}}{\frac{P}{2\sqrt{\pi S_b}}} \frac{P}{2\sqrt{\pi S_b}} \qquad 4.8.2.1\text{-b}$$

where

P is the perimeter of the base of the configuration (see figure 4.8.2.1-7a).

S_b is the base area of the configuration.

$\frac{C_{p_{b_{N_0}}}}{\frac{P}{2\sqrt{\pi S_b}}}$ is obtained from figure 4.8.2.1-7b as a function of the shape parameter $\frac{2 S_b}{\pi \ell_B (h_b + b_b)}$.

where

ℓ_B is the total length of the body.

h_b is the maximum height of the base of the configuration (see figure 4.8.2.1-7a).

b_b is the maximum span of the base of the configuration.

Step 3. Determine the increment in axial-force coefficient at zero normal force due to base pressure by

$$\Delta C_{X'_{b_{N_0}}} = C_{p_{b_{N_0}}} \frac{S_b}{S_{ref}} \qquad 4.8.2.1\text{-c}$$

where $C_{p_{b_{N_0}}}$ is obtained from step 2.

Step 4. Determine the axial-force coefficient at zero normal force, based on the reference area, by

$$C_{X'_{N_0}} = \Delta C_{X'_{f_{N_0}}} + \Delta C_{X'_{b_{N_0}}} \qquad 4.8.2.1\text{-d}$$

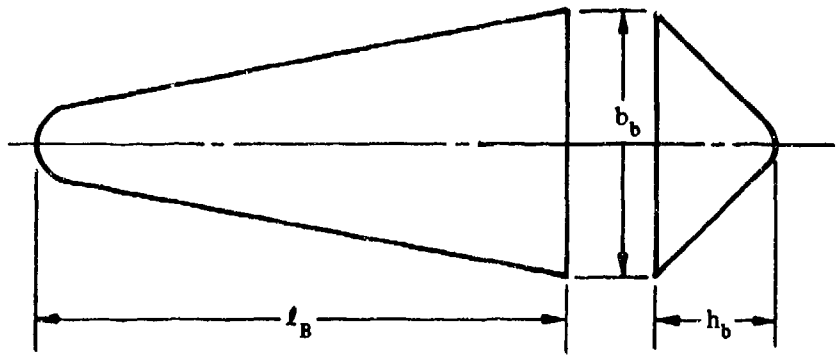
where $\Delta C_{X'_{f_{N_0}}}$ and $\Delta C_{X'_{b_{N_0}}}$ are obtained from steps 1 and 3, respectively.

Figure 4.8.2.1-7b presents a semiempirical correlation of the base-pressure coefficient at zero normal force. This correlation comprises both a measure of the ratio of the viscous pumping area to the base area, and the effect of the shape of the configuration ahead of the base on the pressures in the external flow.

A comparison of the zero-normal-force axial force calculated by this method with test values is presented as table 4.8.2.1-A.

Sample Problem

Given: The blunted, right-triangular pyramidal lifting body of reference 2.



ℓ_B = 19.125 in. S_{ref} = S = 104.98 sq in. S_b = 21.96 sq in.

S_{wet} = 248.83 sq in. P = 22.16 in. h_b = 4.12 in. b_b = 9.08 in.

Compute:

Determine the increment in axial-force coefficient due to skin friction at zero normal force.

C_f = 0.0040

$$\Delta C_{X'_{f_{N_0}}} = -C_f \frac{S_{wet}}{S_{ref}} \quad \text{(equation 4.8.2.1-a)}$$

$$= -(0.0040)\left(\frac{248.83}{104.98}\right)$$

$$= -0.00948$$

Determine the base-pressure coefficient at zero normal force

$$\frac{P}{2\sqrt{\pi S_b}} = \frac{22.16}{2\sqrt{\pi (21.96)}} = 1.333$$

$$\frac{2 S_b}{\pi \ell_B (h_b + b_b)} = \frac{2 (21.96)}{\pi (19.125) (4.12 + 9.08)} = 0.0554$$

$$\frac{C_{p_{b_{N_0}}}}{\frac{P}{2\sqrt{\pi S_b}}} = -0.181 \quad \text{(figure 4.8.2.1-7b)}$$

$$C_{p_{b_{N_0}}} = \frac{C_{p_{b_{N_0}}}}{\frac{P}{2\sqrt{\pi S_b}}} \frac{P}{2\sqrt{\pi S_b}} \quad \text{(equation 4.8.2.1-b)}$$

$$= (-0.181)(1.333)$$

$$= -0.241 \text{ (based on } S_b)$$

Determine the increment in axial-force coefficient at zero normal force.

$$\Delta C_{X'_{b_{N_0}}} = C_{p_{b_{N_0}}} \frac{S_b}{S_{ref}} \quad \text{(equation 4.8.2.1-c)}$$

$$= (-0.241)\left(\frac{21.96}{104.98}\right)$$

$$= -0.0504 \text{ (based on } S_{ref})$$

Solution:

$$C_{X'_{N_0}} = \Delta C_{X'_{f_{N_0}}} + \Delta C_{X'_{b_{N_0}}} \quad \text{(equation 4.8.2.1-d)}$$

$$= -0.00948 - 0.0504$$

$$= -0.0599 \text{ (based on S)}$$

This compares with a test value of −0.0582 from reference 2.

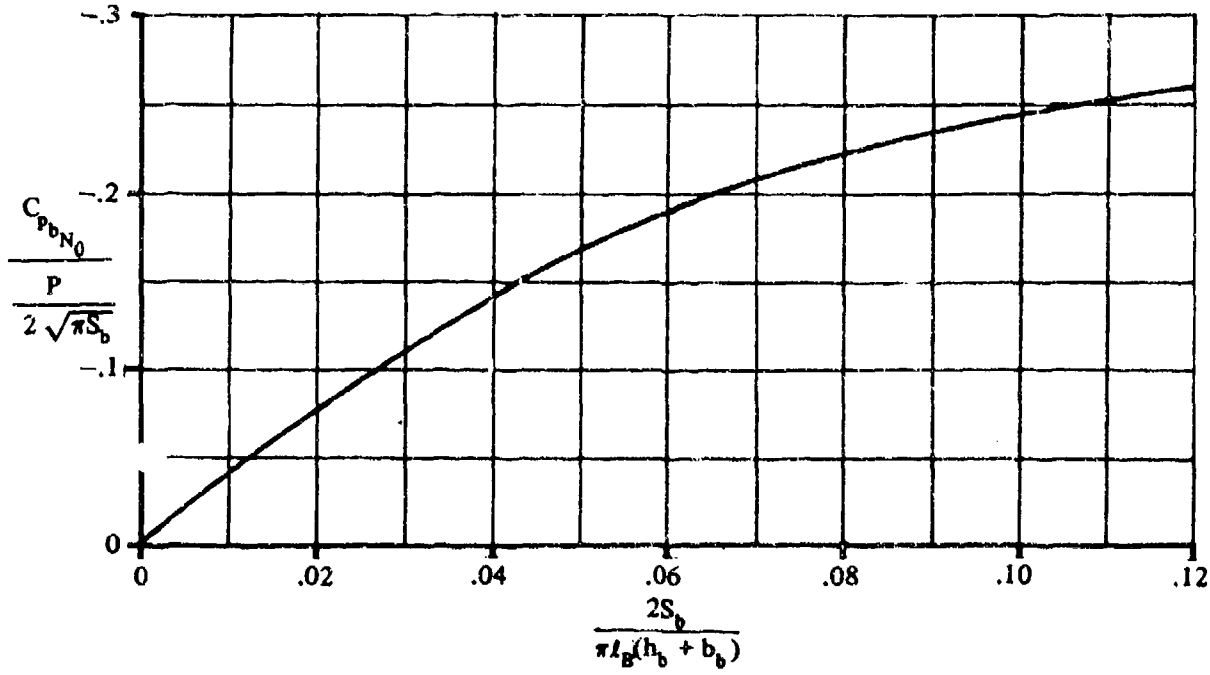

FIGURE 4.8.2.1-7b ZERO-NORMAL-FORCE BASE-PRESSURE COEFFICIENT

4.8.2.2 WING, WING-BODY AXIAL-FORCE VARIATION WITH ANGLE OF ATTACK

A. SUBSONIC

This section presents a method for estimating the axial-force variation with angle of attack for a delta or modified-delta planform re-entry configuration at subsonic speeds.

The method presented herein is taken from reference 1. The total axial force at angle of attack is taken as the sum of that at zero normal force, the increment due to angle of attack, and an increment due to the base pressure at angle of attack.

The axial force at zero normal force is given by the method of Section 4.8.2.1.

The increment of axial force due to angle of attack is obtained by a procedure that closely parallels the one used to obtain the normal-force variation with angle of attack as discussed in Section 4.8.1.2. The method is based on a study of test data on low-aspect-ratio delta wings with thick and thin surfaces, with sharp and rounded leading edges, and with varying degrees of nose bluntness. Thin, sharp-leading-edge delta wings were selected as "reference wings," and theoretical relationships were written for the axial-force characteristics of these planforms. The axial-force characteristics of all the test configurations were then calculated at $\alpha' = 20^{\circ}$ by using these "reference wing" relationships, and any deviation between the calculated and test values was related to aspect ratio, frontal area, and leading-edge characteristics. The variation of this component of axial force between that at zero normal force and that at $\alpha' = 20^{\circ}$ is then approximated as a function of the normal-force variation with angle of attack.

In general, the base pressures acting on advanced flight vehicles become less as the angle of attack increases and, consequently, the component of axial force due to base pressure increases negatively as the angle of attack increases. In reference 1 the change in base pressures of the test configurations are correlated with changes in angle of attack by using the base pressures at $\alpha' = 20^{\circ}$ and at zero normal force as the basis for the correlation.

DATCOM METHOD

The axial-force variation with angle of attack for a delta or modified-delta configuration at low speeds, based on the reference area (usually the planform area), is obtained from the procedure outlined in the following steps:

Step 1. Determine the increment of axial-force coefficient due to angle of attack by

$$\Delta C_{X'} = \left[\left(\frac{X'}{N'}\right)_{calc}\right]_{20} \left[\frac{\Delta C_{X'}}{\Delta C_{X'_{calc}}}\right]_{20} \sqrt{\frac{\alpha'}{20}} \quad C_{N'} \qquad 4.8.2.2\text{-a}$$

where

$\left[\left(\frac{X'}{N'}\right)_{calc}\right]_{20}$ is the calculated ratio of the axial force to the normal force at $\alpha' = 20^{o}$, given by

$$\left[\left(\frac{X'}{N'}\right)_{calc}\right]_{20} = -0.349\left(\frac{A+2}{A+4}\right) \qquad 4.8.2.2\text{-b}$$

$\left[\frac{\Delta C_{X'}}{\Delta C_{X'_{calc}}}\right]_{20}$ is the empirical correlation factor of the axial-force coefficient at $\alpha' = 20^{o}$ for delta or modified-delta configurations. This parameter is presented as a function of configuration geometry in figure 4.8.2.2-10. Figure 4.8.2.2-10 is entered with the following geometric parameters:

A	the aspect ratio of the surface
S_F	the projected frontal area perpendicular to the zero-normal-force reference plane (projected frontal area at $C_{N'} = 0$)
S_{ref}	the reference area (usually the configuration planform area)
b	the surface span
$R_{\frac{1}{3}\ LE}$	the leading-edge radius in a plane normal to the leading edge at $\frac{1}{3}$ c_r from the nose

α' is the angle of attack in degrees.

$$\alpha' = \alpha - \alpha_{N_0}$$

$C_{N'}$ is the normal-force variation with angle of attack obtained by using the method of Section 4.8.1.2.

Step 2. Determine the variation of base pressure with angle of attack by

$$\left(C_{p_b}\right)_{\alpha'} = \left(\frac{C_{p_{b_{20}}}}{C_{p_{b_{N_0}}}} - 1\right)\left(\frac{\alpha}{20}\right)^2 C_{p_{b_{N_0}}} \qquad 4.8.2.2\text{-c}$$

where α' is defined above, and

$\frac{C_{p_{b_{20}}}}{C_{p_{b_{N_0}}}}$ is the empirical correlation of the ratio of the pressure coefficient at $\alpha' = 20^o$ to that at zero normal force. This parameter is obtained from figure 4.8.2.2-11 as a function of the shape parameter

$$\frac{b_b^2}{h_b\sqrt{S_b}}$$

where

b_b is the maximum span of the base of the configuration.

h_b is the maximum height of the base of the configuration (see figure 4.8.2.1-7a).

S_b is the base area of the configuration.

The two curves on figure 4.8.2.2-11 refer to two types of re-entry configurations. The upper curve is to be applied to configurations for which the entire base is influenced directly by the primary lifting surface. The lower curve is to be applied to configurations for which portions of the base are aft of nonlifting components, e.g., bodies and vertical surfaces.

$C_{p_{b_{N_0}}}$ is the base pressure coefficient at zero normal force obtained as outlined in step 2 of the Datcom method of Section 4.8.2.1.

Step 3. Determine the variation of the increment of axial-force coefficient due to the base pressure with angle of attack by

$$\left(\Delta C_{X_{b_\alpha}}\right) = \left(C_{p_b}\right)_{\alpha'} \frac{S_b}{S_{ref}} \qquad 4.8.2.2\text{-d}$$

where

$\left(C_{p_b}\right)_{\alpha'}$ is the variation of base pressure with angle of attack from step 2.

S_{ref} is the reference area (usually the configuration planform area).

Step 4. Determine the zero-normal-force axial force $C_{X'_{N_0}}$ by using the method of Section 4.8.2.1.

Step 5. The variation of axial force with angle of attack, based on the reference area, is given by

$$C_{X'} = -\Delta C_{X'} + \left(\Delta C_{X_{b_\alpha}}\right)' + C_{X'_{N_0}} \qquad 4.8.2.2\text{-e}$$

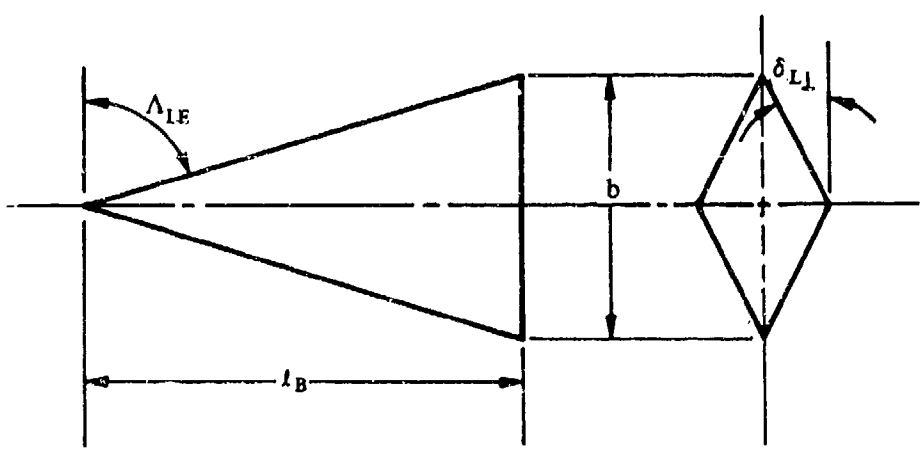
where $\Delta C_{X'}$, $\left(\Delta C_{X_{b_\alpha}}\right)'$, and $C_{X'_{N_0}}$ are from steps 1, 3, and 4, respectively.

A comparison of the axial-force variation with angle of attack calculated by this method with test results is presented as table 4.8.2.2-A.

While it is considered that the results presented are satisfactory for use in preliminary design, it should be noted that scale effect and Reynolds number, which might be expected to influence the base pressure, were not isolated in the data correlation reported in reference 1. (Available test data showed, however, that the variation in Reynolds number produced little effect in base pressure when the flow was turbulent at the base.) Furthermore, in many cases the data were not sufficient to accurately define the variation of base pressure over the surface of the base. Consequently, much of the data included in the empirical correlation for axial-force coefficient at $\alpha' = 20^{\circ}$ (figure 4.8.2.2-10) and in the empirical correlation for the ratio of the pressure coefficient at $\alpha' = 20^{\circ}$ to that at zero normal force (figure 4.8.2.2-11), are known to be in error.

Sample Problem

Given: A delta model with a symmetrical diamond cross section and a blunt trailing edge. This is model D-3 of reference 3 and is the same configuration as sample problem 2 of Section 4.8.1.2.



$A = 1.076$ $b = b_b = 12.374$ in. $S_{ref} = S = 142.30$ sq in.

$S_F = S_b = 44.20$ sq in. $S_{wet} = 329.0$ sq in. $h_b = 7.14$ in.

$\ell_B = 23.0$ in. $P = 28.58$ in.

The following variation of C_N' with α' from sample problem 2 of Section 4.8.1.2:

α'	0	5	10	15	20
C_N'	0	0.1359	0.2573	0.4853	0.6998

Compute:

Determine the increment in axial-force coefficient due to angle of attack.

$$\left[\left(\frac{X'}{N'}\right)_{calc}\right]_{20} = -0.349\left(\frac{A+2}{A+4}\right) \quad \text{(equation 4.8.2.2-b)}$$

$$= -0.349\left(\frac{1.076+2}{1.076+4}\right) = -0.2115$$

$$S_F/S_{ref} = 44.20/142.30 = 0.311$$

$$\left[\frac{\Delta C_{X'}}{\Delta C_{X'_{calc}}}\right]_{20} = 0.389 \quad \text{(figure 4.8.2.2-10, sharp leading edge)}$$

$$\Delta C_{X'} = \left[\frac{X'}{N'_{calc}}\right]_{20}\left(\frac{\Delta C_{X'}}{\Delta C_{X'_{calc}}}\right)_{20}\sqrt{\frac{\alpha'}{20}}\ C_{N'} \quad \text{(equation 4.8.2.2-a)}$$

$$= (-0.2115)(0.389)\sqrt{\frac{\alpha'}{20}}\ C_{N'}$$

$$= -0.0823\sqrt{\frac{\alpha'}{20}}\ C_{N'} \quad \text{(see calculation table below)}$$

Determine the variation of base pressure with angle of attack.

$$\frac{b_b^{\,2}}{h_b\sqrt{S_b}} = \frac{(12.374)^2}{7.14\sqrt{44.20}} = 3.226$$

$$\frac{C_{P_{b_{20}}}}{C_{P_{b_{N_0}}}} = 1.42 \quad \text{(figure 4.8.2.2-11, upper curve)}$$

$$\frac{P}{2\sqrt{\pi S_b}} = \frac{28.58}{2\sqrt{\pi(44.2)}} = 1.213$$

$$\frac{2S_b}{\pi \ell_B (h_b + b_b)} = \frac{2(44.2)}{\pi(23.0)(7.14+12.37)} = 0.0627$$

$$\frac{C_{p_{b_{N_0}}}}{\frac{P}{2\sqrt{\pi S_b}}} = -0.196 \quad \text{(figure 4.8.2.1-7b)}$$

$$C_{p_{b_{N_0}}} = \frac{C_{p_{b_{N_0}}}}{\frac{P}{2\sqrt{\pi S_b}}} \cdot \frac{P}{2\sqrt{\pi S_b}} \quad \text{(equation 4.8.2.1-b)}$$

$$= (-0.196)\,(1.213)$$

$$= -0.238 \left(\text{This result is also used below in calculating } C_{X'_{N_0}}\right)$$

$$\left(C_{p_b}\right)_{\alpha'} = \left(\frac{C_{p_{b_{20}}}}{C_{p_{b_{N_0}}}} - 1\right)\left(\frac{\alpha'}{20}\right)^2 C_{p_{b_{N_0}}} \quad \text{(equation 4.8.2.2-c)}$$

$$= (1.42 - 1)\left(\frac{\alpha'}{20}\right)^2 (-0.238)$$

$$= -0.100\left(\frac{\alpha'}{20}\right)^2$$

Determine the variation of the increment of axial-force coefficient due to the base pressure with angle of attack.

$$\left(\Delta C_{X_{b_\alpha}}\right)' = \left(C_{p_b}\right)_{\alpha'} \frac{S_b}{S_{ref}} \quad \text{(equation 4.8.2.2-d)}$$

$$= \left[-0.100\left(\frac{\alpha'}{20}\right)^2\right]\left(\frac{44.20}{142.3}\right)$$

$$= -0.0311\left(\frac{\alpha'}{20}\right)^2 \quad \text{(see calculation table below)}$$

Determine the zero-normal-force axial force by the method of Section 4.8.2.1.

$$C_f = 0.0040$$

$$\Delta C_{X'_{f_{N_0}}} = -C_f \frac{S_{wet}}{S_{ref}} \quad \text{(equation 4.8.2.1-a)}$$

$$= (-0.0040)\left(\frac{329.0}{142.3}\right)$$

$$= -0.00925$$

$$C_{p_{b_{N_0}}} = -0.238 \text{ (calculated in determining } \left(C_{p_b}\right)_{\alpha'} \text{ above)}$$

$$\Delta C_{X'_{b_{N_0}}} = C_{p_{b_{N_0}}} \frac{S_b}{S_{ref}} \quad \text{(equation 4.8.2.1-c)}$$

$$= (-0.238)\left(\frac{44.2}{142.3}\right)$$

$$= -0.0739$$

$$C_{X'_{N_0}} = \Delta C_{X'_{f_{N_0}}} + \Delta C_{X'_{b_{N_0}}} \quad \text{(equation 4.8.2.1-d)}$$

$$= -0.00925 + (-0.0739)$$

$$= -0.0832$$

Solution:

$$C_{X'} = -\Delta C_{X'} + \left(\Delta C_{X_{b_\alpha}}\right) + C_{X'_{N_0}} \quad \text{(equation 4.8.2.2-e)}$$

$$= -(-0.0823)\sqrt{\frac{\alpha'}{20}}\, C_{N'} + (-0.0311)\left(\frac{\alpha'}{20}\right)^2 + (-0.0832)$$

4.8.3 WING, WING-BODY PITCHING MOMENT

4.8.3.1 WING, WING-BODY ZERO-NORMAL-FORCE PITCHING MOMENT

A. SUBSONIC

This section presents a design chart, taken from reference 1, to be used in approximating the zero-normal-force pitching-moment coefficient of nonsymmetrical delta-planform configurations with rounded leading edges at low speeds.

The design chart is based on a limited amount of experimental data and, furthermore, does not represent an extensive analysis of the zero-normal-force pitching moment. It is considered to provide only a first-order approximation of $C_{m_{N_0}}$.

DATCOM METHOD

The low-speed zero-normal-force pitching-moment coefficient of a nonsymmetrical delta-planform configuration with rounded leading edges, based on the product of the planform area and root chord Sc_r, is approximated from the procedure outlined in the following steps:

Step 1. Determine the zero-normal-force angle of attack α_{N_0} by using the method of Section 4.8.1.1.

Step 2. Obtain the zero-normal-force pitching-moment coefficient $C_{m_{N_0}}$ from figure 4.8.3.1-4 as a function of α_{N_0} determined in step 1.

Figure 4.8.3.1-4 is not applicable to configurations with sharp leading edges.

A comparison of the zero-normal-force pitching-moment coefficient of unsymmetrical delta-planform configurations calculated by this method with test results is presented as table 4.8.3.1-A. The values of α_{N_0} used in this data summary were calculated by using the method of Section 4.8.1.1.

Sample Problem

Given: The right-triangular pyramidal body designated configuration 1 in reference 7. This is the configuration of sample problem 1 of Section 4.8.1.1.

ℓ_B = 31.55 in. Nose radius = 0.1875 in. h_b = 6.44 in.

$\bar{z}_{base}$ = 4.105 in.

Compute:

Determine α_{N_0}

α_{N_0} = 8.04° (sample problem 1, Section 4.8.1.1)

Solution:

$$C_{m_{N_0}} = 0.00\,?7 \quad \text{(based on } Sc_r\text{)} \quad \text{(figure 4.8.3.1-4, extrapolated)}$$

The calculated result compares with a test value of 0.0028 from reference 7.

FICURE 4.8.3.1-4 VARIATION OF ZERO-NORMAL-FORCE PITCHING-MOMENT COEFFICIENT WITH CAMBER – DELTA AND MODIFIED DELTA CONFIGURATIONS

4.8.3.2 WING, WING-BODY PITCHING-MOMENT VARIATION WITH ANGLE OF ATTACK

A. SUBSONIC

This section presents a method for estimating the variation of pitching-moment coefficient with angle of attack for delta or modified-delta planform re-entry configurations at subsonic speeds.

The design charts are given in terms of the center-of-pressure location. The following equation is used to find the pitching-moment coefficient, based on the product of the planform area and root chord Sc_r:

$$C_m = C_{m_{N_0}} + \left(\frac{x_m}{c_r} - \frac{x_{c.p.}}{c_r}\right) C_{N'} \qquad 4.8.3.2\text{-a}$$

where

$\left(\frac{x_m}{c_r}\right)$ is the distance from the nose of the configuration to the desired moment reference center measured in root chords, positive aft.

$\left(\frac{x_{c.p.}}{c_r}\right)$ is the distance from the nose of the configuration to the center of pressure measured in root chords, positive aft.

$C_{N'}$ is the normal-force variation with angle of attack obtained by using the method of Section 4.8.1.2.

$C_{m_{N_0}}$ is the zero-normal-force pitching-moment coefficient obtained by using the method of Section 4.8.3.1. For symmetrical configurations $C_{m_{N_0}} = 0$.

The method for estimating the center-of-pressure location is taken from reference 1. A theoretical variation of center-of-pressure location with aspect ratio (or semiapex angle) from reference 2 was corrected to provide center-of-pressure estimates for thin, pointed-nose, symmetrical delta configurations. This result was then corrected to account for the effects of nose blunting and finite thickness.

The effect of nose blunting on delta wings was evaluated by assuming that the normal force acting on a pure delta wing can be divided into two components. One of these components is distributed uniformly over the planform and the other is concentrated at the leading edge. The strength of the concentrated component has a magnitude at any spanwise station proportional to the local chord. In accordance with this concept, the resultant of the uniform load acts 1/3 of the root chord forward of the trailing edge and the resultant of the leading-edge component acts 2/3 of the root chord forward of the trailing edge for a pure delta wing. The nose-blunting effects were then determined by assuming that the pitching moment depends only on normal force and by analyzing a simplified situation where a part of the nose of a pure delta wing is removed by a straight cut normal to the root chord. The center-of-pressure movement predicted in this manner is different from experimental results, since actual nose blunting usually consists of a rounding of the forward part of the wing rather than a sharp cut-off. Therefore, an empirical factor was applied, based on the results of reference 3, to compensate for this difference.

Finite thickness modifies the center-of-pressure location because of the contribution of axial force to pitching moment. The axial force produces a nose-down pitching moment at positive lifts as a result of the negative pressures on the upper surface of the wing and the positive pressures on the lower surface. An empirical correction for this effect, taken from reference 1, is presented in the Datcom method.

The Datcom method is applicable for angles of attack up to 20°.

DATCOM METHOD

The center-of-pressure location of delta or modified-delta configurations is given by

$$\frac{X_{c.p.}}{c_r} = \left(\frac{X_{c.p.}}{c_r}\right)_{\Delta} + \Delta\left(\frac{X_{c.p.}}{c_r}\right)_{B} + \Delta\left(\frac{X_{c.p.}}{c_r}\right)_{t} \qquad 4.8.3.2\text{-}b$$

where

$\left(\frac{X_{c.p.}}{c_r}\right)_{\Delta}$ is the distance from the wing apex to the center-of-pressure location, measured in root chords, of thin, pointed-nose, symmetrical delta configurations. This parameter is obtained from figure 4.8.3.2-6b as a function of the wing semiapex angle θ. The semiapex angle is measured as illustrated on figure 4.8.3.2-6a.

$\Delta\left(\frac{X_{c.p.}}{c_r}\right)_{B}$ is the increment in the center-of-pressure location, measured in root chords, due to nose blunting. This parameter is obtained from figure 4.8.3.2-7a as a function of the configuration semiapex angle θ and aspect ratio. The aspect ratio is that of the blunt-nose configuration.

$\Delta\left(\frac{X_{c.p.}}{c_r}\right)_{t}$ is the increment in the center-of-pressure location, measured in root chords, due to finite thickness. This parameter is obtained from figure 4.8.3.2-7b as a function of the ratio of the projected frontal area to the planform area S_F/S.

Figure 4.8.3.2-6a illustrates the configuration geometry used in this method.

A comparison of the center-of-pressure location calculated by this method with test results is presented as table 4.8.3.2-A. It should be noted that Reynolds-number effects might be expected to influence the pitching-moment characteristics of these configurations as the angle of attack and normal-force coefficients increase. However, the limited Reynolds-number range of the test data precluded isolation of Reynolds-number effects during the data correlation reported in reference 1.

Sample Problem

Given: A blunt-nose delta-wing model with a symmetrical diamond cross section and a blunt trailing edge. This is model D-4 of reference 5.

$A = 1.087$ $b = 13.934$ in. $S = 178.56$ sq in. $S_F = 41.44$ in.

$\theta = 15^{\circ}$ $c_r = 23.0$ in.

Compute:

$$\left(\frac{X_{c.p.}}{c_r}\right)_{\Delta} = 0.60 \quad \text{(figure 4.8.3.2-6b)}$$

$$1 - \frac{4 \tan \theta}{A} = 1 - \frac{4 \tan 15^{o}}{1.087} = 0.0140$$

$$\Delta\left(\frac{X_{c.p.}}{c_r}\right)_{B} = -0.049 \quad \text{(figure 4.8.3.2-7a)}$$

$$S_F/S = 41.44/178.56 = 0.232$$

$$\Delta\left(\frac{X_{c.p.}}{c_r}\right)_{t} = 0.0238 \quad \text{(figure 4.8.3.2-7b)}$$

Solution:

$$\frac{X_{c.p.}}{c_r} = \left(\frac{X_{c.p.}}{c_r}\right)_{\Delta} + \Delta\left(\frac{X_{c.p.}}{c_r}\right)_{B} + \Delta\left(\frac{X_{c.p.}}{c_r}\right)_{t} \quad \text{(equation 4.8.3.2-b)}$$

$$= 0.600 - 0.049 + 0.0238$$

$$= 0.5748$$

This compares with a test value of 0.582 from reference 5.

5.1 WINGS IN SIDESLIP

5.1.1 WING SIDESLIP DERIVATIVE C_{Y_β}

5.1.1.1 WING SIDESLIP DERIVATIVE C_{Y_β} IN THE LINEAR ANGLE-OF-ATTACK RANGE

The wing contribution to the derivative C_{Y_β} is small, of the order α^2, and its accurate estimation is not vital.

Methods are presented in this section for estimation of wing side force due to sideslip in the subsonic and supersonic speed regimes. Methods for the estimation of this derivative in the transonic speed regime are not available.

A. SUBSONIC

InReference 1 a simplified theory consisting of an application of strip theory and lifting-line theory is applied to constant-chord swept wings in sideslip to determine approximate relations for the low-speed sideslip derivatives. The method presented in this section for estimating the wing side force due to sideslip at low subsonic speeds is taken from Reference 1. It is valid in the linear-lift region.

DATCOM METHOD

The wing sideslip derivative C_{Y_β} at low speeds neglecting the effect of dihedral is given inReference 1 as

$$C_{Y_\beta} = C_L^2 \left[\frac{6 \tan \Lambda_{c/4} \sin \Lambda_{c/4}}{\pi A (A + 4 \cos \Lambda_{c/4})} \right] \frac{1}{57.3} \text{ (per deg)} \qquad 5.1.1.1\text{-a}$$

The increment in side force due to dihedral at low subsonic speeds can be approximated by

$$\frac{\Delta C_{Y_\beta}}{|\Gamma|} = -0.0001 \ (\beta \text{ and } \Gamma \text{ in degrees}) \qquad 5.1.1.1\text{-b}$$

For subcritical speeds, the low-speed derivative can be modified by the Prandtl-Glauert rule to yield approximate corrections for the first-order three-dimensional effects of compressibility. The resulting expression fromReference 2 is

$$\left(\frac{C_{Y_\beta}}{C_L} \right)_M = \frac{A + 4 \cos \Lambda_{c/4}}{AB + 4 \cos \Lambda_{c/4}} \left(\frac{C_{Y_\beta}}{C_L} \right)_{\substack{\text{low} \\ \text{speed}}} \qquad 5.1.1.1\text{-c}$$

where

$$B = \sqrt{1 - M^2 \cos^2 \Lambda_{c/4}}$$

Calculated values for the wing side force due to sideslip obtained by the Datcom method for the wing configurations of References 3, 4, and 5 are compared with experimental data in Figure 5.1.1.1-5. The comparison indicates that the calculated values are fairly reliable over a range of lift coefficient (starting from zero) that decreases as wing sweep increases. Large discrepancies are noted for highly swept wings at lift coefficients for which the flow is believed to be partially separated.

Sample Problem

Given: The wing of Reference 5

$A = 4.0 \qquad \Lambda_{c/4} = 60^{\circ} \qquad \lambda = 0.6 \qquad \Gamma = 0.6 \qquad M = 0.13$

Compute:

$\sin \Lambda_{c/4} = 0.866$
$\cos \Lambda_{c/4} = 0.500$
$\tan \Lambda_{c/4} = 1.732$

Solution:

$$\frac{C_{Y_\beta}}{C_L^2} = \left[\frac{6 \tan \Lambda_{c/4} \sin \Lambda_{c/4}}{\pi A (A + 4 \cos \Lambda_{c/4})}\right] \frac{1}{57.3} \text{ (per deg)} \qquad \text{(Equation 5.1.1.1-a)}$$

$$= \frac{(6)(1.732)(0.866)}{\pi(4)\,[4 + 4(0.500)]} \frac{1}{57.3}$$

$$= \frac{9}{24\pi} \frac{1}{57.3}$$

$$= 0.00208 \text{ per deg}$$

C_L	C_L^2	$C_{Y_\beta} \times 10^3$ (per deg)
0.05	0.0025	0.0052
0.10	0.010	0.0208
0.20	0.040	0.0832
0.30	0.090	0.1872
0.40	0.160	0.3328
0.50	0.250	0.5200
0.60	0.360	0.7488

These results are compared with experimental values in Figure 5.1.1.1-5.

B. TRANSONIC

No method is available in the literature for estimation of the wing contribution to the derivative C_{Y_β} in the transonic speed regime and none is presented in the Datcom. Furthermore, no experimental data are available in this speed regime.

C. SUPERSONIC

No general method has been developed for estimating the wing side force due to sideslip at supersonic speeds. However, theoretical methc is are available for discrete planforms over certain speed ranges. A comprehensive summary of the available theoretical methods for calculating the wing side force due to sideslip is presented in Reference 6. The expressions for the derivatives for each planform have been obtained from application of the linearized theory for compressible flow as applied to thin airfoils. The linearized theory is directly applicable for the lateral motion of sideslip and the results are limited only by the complexity of the calculations required to determine the load distributions for certain planforms under certain conditions. Calculation complexities arise as a result of the existence of regions of interacting or mutually subsonic edges (a subsonic edge lying within the region of influence of another). Consequently, the theoretical calculations available are limited primarily to combinations of planforms and Mach lines that do not have interacting or mutually subsonic edges.

No experimental data are available in the supersonic speed regime; consequently, the quantitative accuracy of the estimation methods cannot readily be assessed. However, a review of the application of linearized theory for the prediction of wing lift-curve slope at supersonic speeds can at least lead to a qualitative conclusion of the theory's accuracy when applied to lateral derivatives. Comparison has shown that the agreement between experiment and linear compressible-flow theory with regard to wing lift-curve slope is satisfactory for most practical purposes. To conclude that linearized theory is therefore adequate for lateral derivative prediction seems somewhat questionable in that the lift-curve slope is dependent on the integrated pressure; whereas the lateral derivatives are dependent on pressure distribution. However, when coupled with the fact that the lateral derivatives are relatively insensitive to small shifts in spanwise center of pressure, the indication is that application of the linearized compressible-flow theory should give fairly good results at least insofar as general trends and orders of magnitude are concerned.

DATCOM METHODS

The Datcom methods are taken from References 7, 8, and 9 and present the wing side force due to sideslip over limited Mach number ranges for rectangular planforms, triangular planforms, and fully tapered sweptback planforms with swept forward or sweptback trailing edges. The results are mainly functions of planform geometry and Mach number.

Rectangular Planform: $A\beta \geq 1.0$

The wing side force due to sideslip for rectangular planforms (neglecting the effect of dihedral) is derived in Reference 7 as

$$\frac{C_{Y_\beta}}{\alpha^2} = -\frac{8M^2}{\pi A\beta^2}\,\frac{1}{57.3} \text{ (per deg)} \qquad 5.1.1.1\text{-d}$$

where α is in radians and $\beta = \sqrt{M^2 - 1}$.

Equation 5.1.1.1-d is valid for Mach number and aspect ratio greater than that for which the Mach line from the leading edge of the tip section intersects the trailing edge of the opposite tip section ($A\beta \geq 1.0$).

Sweptback Planform ($\lambda = 0$): $\beta \cot \Lambda_{LE} \leq 1.0$

The wing side force due to sideslip for fully tapered sweptback planforms (neglecting the effect of dihedral) is derived in Reference 8 for triangular planforms and in Reference 9 for planforms with sweptforward or sweptback trailing edges as

$$\frac{C_{Y_\beta}}{\alpha^2} = -\frac{\pi}{4} AM^2 Q(\beta C) \frac{1}{57.3} \text{ (per deg)} \qquad 5.1.1.1\text{-e}$$

where α is in radians and $Q(\beta C)$ is obtained from figure 5.1.1.1-6.

Equation 5.1.1.1-e is valid for Mach number and aspect ratio for which the wing is contained within the Mach cones springing from the apex and the trailing edge at the center of the wing.

The increment in side force due to dihedral given by Equation 5.1.1.1-b is also applicable at supersonic speeds.

5.1.2 WING SIDESLIP DERIVATIVE C_{l_β}

5.1.2.1 WING SIDESLIP DERIVATIVE C_{l_β} IN THE LINEAR ANGLE-OF-ATTACK RANGE

A. SUBSONIC

For wings at low angles of attack and subsonic speeds, the rolling moment due to sideslip is principally a function of wing aspect ratio, taper ratio, dihedral angle, and sweep.

The effect of aspect ratio on the rolling moment of unswept wings is treated theoretically in reference 1. In this reference, a wing in sideslip is represented by a suitably restricted system of vortices. The span loading is calculated and then integrated to obtain the rolling moment. The results show that C_{l_β} for three-dimensional unswept wings increases approximately linearly with $1/A$ and decreases slightly with taper ratio.

The vortex representation used in reference 1 for unswept wings is applied to swept straight-tapered planforms in reference 2. Here, the rolling moment is found to be a strong function of sweep, but the increment provided by sweep is relatively insensitive to variations of aspect ratio and taper ratio.

A rather different approach to the straight-tapered-wing rolling-moment problem is taken in reference 3. Here, the effects of sweep on C_{l_β} are calculated as the difference between the effective lift-curve slopes for the upwind and downwind wing panels. Panel lift-curve slope is assumed to be a function of effective sweep angle $(\Lambda \pm \beta)$ and effective geometric aspect ratio. Aspect-ratio effects are then taken to be the difference between the experimental and the calculated values for swept wings.

In spite of their widely differing approaches, references 2 and 3 give similar results. For very low aspect ratios, slender-body theory, as applied in reference 4, shows that $C_{l_\beta} = -2/3\ A$ (per radian). This value compares well with experimental data for low-aspect-ratio delta wings.

Neither reference 2 nor reference 3 defines a lower aspect-ratio limit, below which the respective theories are invalid. However, since neither theory converges to the slender-body value at low aspect ratios, there must be a transition region between the high-aspect-ratio values of references 2 and 3 and the slender-body value of reference 4.

At subsonic speeds methods are presented for determining the rolling moment due to sideslip for the following classes of wing planforms:

Straight-Tapered Wings (conventional, trapezoidal wings)

Non-Straight-Tapered Wings

- Double-delta wings
- Cranked wings

These two general categories of non-straight-tapered wings are illustrated in sketch (a) of Section 4.1.3.2. Their wing-geometry parameters are presented in Section 2.2.2.

The Datcom method for straight-tapered wings is a combination of the methods of references 1, 2, 3, and 4. Reference 4 is used for low-aspect-ratio wings. References 1, 2, and 3 are used for high aspect ratios, with experimental data serving as a guide as to which theory is most applicable. For intermediate aspect ratios the experimental data of references 8 through 13 are used as a guide in constructing a faired curve between the slender-body values of reference 4 and the high-aspect-ratio values of references 1, 2, and 3. Mach number effects are calculated by the method of reference 3. The effect of uniform geometric dihedral is accounted for by the method of references 5 and 6, that of nonuniform geometric dihedral by the method of reference 6, and that of wing twist by the method of reference 7.

The Datcom method for double-delta and cranked wings is taken from reference 14. In addition to wing aspect ratio, taper ratio, dihedral angle, and sweep, the location of the leading-edge or trailing-edge sweep break is an important factor in determining the rolling moment due to sideslip of these non-straight-tapered wings. The method is based on the results presented for straight-tapered wings. The composite wing is divided into two individual panels and a "weighted-lift" relationship is applied to the rolling moment due to sideslip of each panel calculated using the straight-tapered wing method.

The subsonic methods presented in this section are valid for sideslip angles between -5^{o} and $+5^{o}$ at speeds up to $M = 0.60$ and low angles of attack.

No provision is made for the effective-dihedral contribution of the wing tip shape. This contribution is important only for thick wings and taper ratios near 1.0.

DATCOM METHODS

Straight-Tapered Wings

The subsonic rolling moment due to sideslip of a straight-tapered wing with uniform geometric dihedral at low angles of attack is given by the following equations:

For $A \geq 1.0$:

$$C_{l_\beta} = C_L \left[\left(\frac{C_{l_\beta}}{C_L} \right)_{\Lambda_{c/2}} K_{M_\Lambda} + \left(\frac{C_{l_\beta}}{C_L} \right)_{A} \right] + \Gamma \left(\frac{C_{l_\beta}}{\Gamma} K_{M_\Gamma} \right) + \theta \tan \Lambda_{c/4} \frac{\Delta C_{l_\beta}}{\theta \tan \Lambda_{c/4}} \text{ (per degree)} \qquad 5.1.2.1\text{-a}$$

For $A < 1.0$:

$$C_{l_\beta} = C_L \left[-\frac{1}{57.3} \frac{2}{3} \frac{1}{A} \right] - \Gamma \left(\frac{A}{6} \right) \text{ (per degree)} \qquad 5.1.2.1\text{-a}'$$

where

$\left(\frac{C_{l_\beta}}{C_L} \right)_{\Lambda_{c/2}}$ is the wing-sweep contribution obtained from figure 5.1.2.1-27.

K_{M_Λ} is the compressibility correction to the sweep contribution, obtained from figure 5.1.2.1-28a.

$\left(\frac{C_{l_\beta}}{C_L}\right)_A$ is the aspect-ratio contribution, including taper-ratio effects, obtained from figure 5.1.2.1-28b.

$\frac{C_{l_\beta}}{\Gamma}$ is the dihedral effect for uniform geometric dihedral, obtained from figure 5.1.2.1-29.

Γ is the dihedral angle in degrees.

$K_{M\Gamma}$ is the compressibility correction factor to the uniform-geometric-dihedral effect, obtained from figure 5.1.2.1-30a.

$\frac{\Delta C_{l_\beta}}{\theta \tan \Lambda_{c/4}}$ is the wing-twist correction factor, obtained from figure 5.1.2.1-30b.

θ is the wing-twist between the root and tip stations, negative for washout (see figure 5.1.2.1-30b).

For wings with nonuniform dihedral, the dihedral term of equation 5.1.2.1-a; i.e., $\Gamma\left(\frac{C_{l_\beta}}{\Gamma} K_{M\Gamma}\right)$, is replaced by $\left(\frac{\beta C_{l_\beta}}{\kappa\Gamma}\right)\left(\frac{\kappa\Gamma}{\beta}\right)$ (per degree).

where

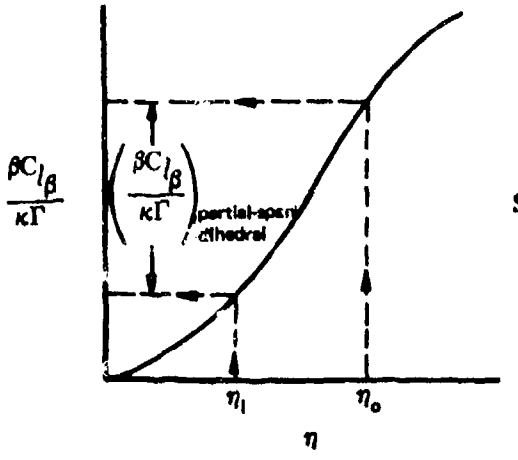
$\frac{\beta C_{l_\beta}}{\kappa\Gamma}$ is the rolling-moment-due-to-sideslip parameter for any symmetric, spanwise distribution of dihedral angle, obtained from figure 5.1.2.1-31 as a function of Λ_β and $\beta A/\kappa$.

The parameter κ is the ratio of the two-dimensional lift-curve slope at the appropriate Mach number to 2π; i.e., $\left(c_{\ell_\alpha}\right)_M / 2\pi$. The two-dimensional lift-curve slope is obtained from Section 4.1.1.2. For wings with airfoil sections varying in a reasonably linear manner with span, the average value of the lift-curve slopes of the root and tip sections is adequate.

The parameter Λ_β is the compressible sweep parameter given as $\Lambda_\beta = \tan^{-1}(\tan \Lambda_{c/4}/\beta)$.

Γ is the geometric dihedral in degrees.

Figure 5.1.2.1-31 applies directly to a gull-wing arrangement with the dihedral starting at the wing root and extending outboard to some spanwise station. For partial-span dihedral starting at some spanwise station η_i and extending outboard to some spanwise station η_o, the value of $\frac{\beta C_{l_\beta}}{\kappa\Gamma}$ is obtained as illustrated in sketch (a).



SKETCH (a)

Lifting-surface theory has been used in reference 6 to obtain the rolling moment due to sideslip for any symmetric, spanwise distribution of dihedral. The theory is applicable only to wings for which $\beta A \geq 2$ and $\Lambda_\beta \leq 60^\circ$.

It should be noted that at $\eta = 1.0$ figure 5.1.2.1-31 gives the dihedral effect due to uniform dihedral. However, the uniform-dihedral term of equation 5.1.2.1-a has been retained because of the ease with which figure 5.1.2.1-29 can be applied.

Sample problem 1 at the conclusion of this paragraph (page 5.1.2.1-5) illustrates the use of this method applied to a straight-tapered, untwisted wing with no dihedral. A sample problem including the effect of uniform dihedral is presented in paragraph A of Section 5.2.2.1.

A comparison of low-speed test values with results calculated by using this method for straight-tapered wings is presented as table 5.1.2.1-A. The ranges of geometric parameters of the test data are:

$$0.25 \leq A \leq 6.93$$

$$\leq \Lambda_{c/2} \leq 75.3^\circ$$

$$0 \leq \lambda \leq 1.0$$

$$\Gamma = 0$$

$$\theta = 0$$

Test data are not available to permit substantiation of the effects of either wing-twist or dihedral on the wing rolling moment due to sideslip.

Non-Straight-Tapered Wings

The method for determining the rolling moment due to sideslip of double-delta and cranked wings is taken from reference 14. The non-straight-tapered wing is divided into two panels, with each panel having conventional straight-tapered geometry. Then for each of the constructed panels, the individual rolling moment due to sideslip is estimated by the method presented above for straight-tapered wings. The individual rolling-moment coefficients derived for each constructed panel are then weighted according to the proportion of the total lift that those panels produce. In order to maintain the proper span reference, the rolling-moment coefficient of the constructed inboard set of panels is further modified by multiplying its contribution by the ratio of the inboard span to the reference span (total wing span).

The method is applicable only to untwisted wings with zero degrees dihedral at low angles of attack.

The rolling moment due to sideslip of double-delta and cranked wings is obtained from the procedure outlined in the following steps:

Step 1. Divide the composite wing into constructed inboard and outboard panels as discussed in paragraph A of Section 4.1.4.2 (see pages 4.1.4.2-5, -6), and determine their pertinent geometric parameters.

Step 2. Determine the lift-curve slopes of the constructed inboard and outboard panels from figure 4.1.3.2-49, based on their respective areas S_i and S_o'.

Step 3. Determine the rolling moment due to sideslip, based on the total wing area and span, by

$$\frac{C_{l_\beta}}{C_L} = \frac{1}{(C_{L_\alpha})_{total}} \left\{ (C_{L_\alpha})_i \frac{S_i}{S_W} \left[\left(\frac{C_{l_\beta}}{C_L} \right)_{\Lambda_{c/2_i}} K_{M_{\Lambda_i}} + \left(\frac{C_{l_\beta}}{C_L} \right)_{A_i} \right] \frac{b_i}{b_W} \right.$$
$$\left. + (C_{L_\alpha})_o' \frac{S_o'}{S_W} \left[\left(\frac{C_{l_\beta}}{C_L} \right)_{\Lambda_{c/2_o}'} K_{M_{\Lambda_o'}} + \left(\frac{C_{l_\beta}}{C_L} \right)_{A_o'} \right] \right\} \text{(per degree)} \qquad 5.1.2.1\text{-b}$$

where the subscript i and the prime and subscript o denote the constructed inboard and outboard panels, respectively.

The parameters $(C_{l_\beta}/C_L)_{\Lambda_{c/2}}$, K_{M_Λ}, and $(C_{l_\beta}/C_L)_A$ are obtained from figures 5.1.2.1-27, 5.1.2.1-28a, and 5.1.2.1-28b, respectively, by using the geometry of the constructed inboard and outboard panels.

$$(C_{L_\alpha})_{total} = (C_{L_\alpha})_i \frac{S_i}{S_W} + (C_{L_\alpha})_o' \frac{S_o'}{S_W}$$

If the aspect ratio of an individual set of constructed wing panels is less than one, C_{l_β}/C_L for that set of panels is calculated by equation 5.1.2.1-a'. For example, if the aspect ratio of the constructed inboard panel is less than one, then equation 5.1.2.1-b would be expressed as

$$\frac{C_{l_\beta}}{C_L} = \left(\frac{1}{C_{L_\alpha}} \right)_{total} \left\{ (C_{L_\alpha})_i \frac{S_i}{S_W} \left[\frac{1}{57.3} \frac{2}{3} \frac{1}{A_i} \right] \frac{b_i}{b_W} + (C_{L_\alpha})_o' \frac{S_o'}{S_W} \left[\left(\frac{C_{l_\beta}}{C_L} \right)_{\Lambda_{c/2_o}'} K_{M_{\Lambda_o'}} + \left(\frac{C_{l_\beta}}{C_L} \right)_{A_o'} \right] \right\}$$

Sample problem 2 on page 5.1.2.1-6 illustrates the use of this method.

A comparison of low-speed test values with results calculated by this method is presented as table 5.1.2.1-B (taken from reference 14). The limited availability of experimental data precludes substantiation of this method.

Sample Problems

1. Straight-Tapered Wing

Given: A sweptback wing of reference 29.

$A = 4.0$ $\lambda = 0.60$ $\Lambda_{c/2} = 59.2^{o}$ $\Gamma = 0$ $\theta = 0$ $M = 0.13$

Compute:

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2}} = \text{-0.0072 per deg (figure 5.1.2.1-27, interpolated)}$$

$$\frac{A}{\cos \Lambda_{c/2}} = \frac{4.0}{\cos 59.2^{o}} = 7.81$$

$$M \cos \Lambda_{c/2} = 0.13 \cos \Lambda_{c/2} = 0.067$$

$K_{M_\Lambda} = 1.00$ (figure 5.1.2.1-28a)

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{A} = \text{-0.0016 per deg (figure 5.1.2.1-28b)}$$

Solution:

$$\frac{C_{l_\beta}}{C_L} = \left[\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2}} K_{M_\Lambda} + \left(\frac{C_{l_\beta}}{C_L}\right)_{A}\right] \text{(equation 5.1.2.1-a with } \Gamma = 0,\ \theta = 0)$$

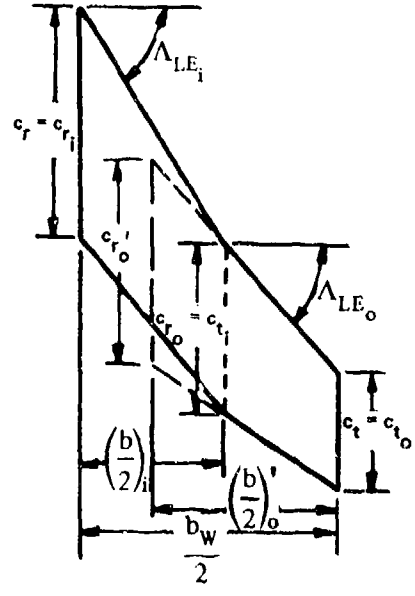
$$= \left[-(0.0072)\,(1.0) + (-0.0016)\right]$$

$$= \text{-0.0088 per deg (based on } S_W\, b_W)$$

This result compares with a test value of -0.0094 from reference 29.

2. Non-Straight-Tapered Wing

Given: A cranked wing of reference 30.



Total-Wing Characteristics:

$S_W = 12.10$ sq ft $\quad \frac{b_W}{2} = 3.0$ ft $\quad \lambda_W = 0.470$

$\eta_B = 0.583$ $\quad c_{r_W} = 2.75$ ft $\quad A_W = 2.975$

$\Lambda_{LE_i} = 59.0^{o}$ $\quad \Lambda_{LE_o} = 48.5^{o}$ $\quad \Lambda_{c/2_i} = 55.0^{o}$

$\Lambda_{c/2_o} = 41.0^{o}$ $\quad \Gamma = 0$ $\quad \theta = 0$

Constructed-Inboard-Panel Characteristics:

$S_i = 8.18$ sq ft $\quad A_i = 1.50$ $\quad \lambda_i = 0.70$

$\left(\frac{b}{2}\right)_i = 1.75$ ft $\quad \Lambda_{c/2_i} = 55.0^{o}$ $\quad \Lambda_{LE_i} = 59.0^{o}$

$$\frac{S_i}{S_W} = 0.676$$

Constructed-Outboard-Panel Characteristics:

$S'_o = 7.72$ sq ft $\quad A'_o = 2.34 \quad \lambda'_o = 0.55 \quad \left(\frac{b}{2}\right)'_o = 2.125$ ft

$\left(\Lambda_{LE}\right)'_o = \Lambda_{LE_o} = 48.5^o \quad \left(\Lambda_{c/2}\right)'_o = \Lambda_{c/2_o} = 41.0^o \quad \frac{S'_o}{S_W} = 0.638$

Additional Characteristics:

$M = 0.18; \quad \beta = 0.984 \qquad \kappa = 1.0$ (assumed)

Compute

$\left(C_{L_\alpha}\right)_i$ and $\left(C_{L_\alpha}\right)'_o$ (Section 4.1.3.2)

$$\frac{A_i}{\kappa}\left[\beta^2 + \tan^2 \Lambda_{c/2_i}\right]^{1/2} = \frac{1.50}{1.0}\left[0.9676 + (1.4281)^2\right]^{1/2} = 2.60$$

$$\left(\frac{C_{L_\alpha}}{A}\right)_i = 1.19 \text{ per rad (figure 4.1.3.2-49)}$$

$$\left(C_{L_\alpha}\right)_i = \left(\frac{C_{L_\alpha}}{A}\right)_i A_i = (1.19)(1.5) = 1.785 \text{ per rad}$$

$$\frac{A'_o}{\kappa}\left[\beta^2 + \tan^2 \Lambda_{c/2'_o}\right]^{1/2} = \frac{2.34}{1.0}\left[0.9676 + (0.8693)^2\right]^{1/2} = 3.07$$

$$\left(\frac{C_{L_\alpha}}{A}\right)'_o = 1.11 \text{ per rad (figure 4.1.3.2-49)}$$

$$\left(C_{L_\alpha}\right)'_o = \left(\frac{C_{L_\alpha}}{A}\right)'_o A'_o = (1.11)(2.34) = 2.60 \text{ per rad}$$

$$\left(C_{L_\alpha}\right)_{total} = \left(C_{L_\alpha}\right)_i \frac{S_i}{S_W} + \left(C_{L_\alpha}\right)'_o \frac{S'_o}{S_W}$$

$$= 1.785\,(0.676) + 2.60\,(0.638) = 2.865$$

$\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2_i}}$ and $\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2_o}'}$

$\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2_i}}$ = -0.0045 per deg (figure 5.1.2.1-27, interpolated for A_i, λ_i, and $\Lambda_{c/2_i}$)

$\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2_o}'}$ = -0.0032 per deg (figure 5.1.2.1-27, interpolated for A_o', λ_o', and $\Lambda_{c/2_o}'$)

$K_{M\Lambda_i}$ and $K_{M\Lambda_o'}$

$$\frac{A_i}{\cos \Lambda_{c/2_i}} = \frac{1.50}{0.5736} = 2.615$$

$$M \cos \Lambda_{c/2_i} = (0.18)(0.5736) = 0.103$$

$K_{M\Lambda_i}$ = 1.0 (figure 5.1.2.1-28a)

$$\frac{A_o'}{\cos \Lambda_{c/2_o}'} = \frac{2.34}{0.7547} = 3.10$$

$$M \cos \Lambda_{c/2_o}' = (0.18)(0.7547) = 0.136$$

$K_{M\Lambda_o'}$ = 1.0 (figure 5.1.2.1-28a)

$\left(\frac{C_{l_\beta}}{C_L}\right)_{A_i}$ and $\left(\frac{C_{l_\beta}}{C_L}\right)_{A_o'}$

$\left(\frac{C_{L_\beta}}{C_L}\right)_{A_i}$ = -0.0065 per deg (figure 5.1.2.1-28b at A_i and λ_i)

$\left(\frac{C_{L_\beta}}{C_L}\right)_{A_o'}$ = -0.0034 per deg (figure 5.1.2.1-28b at A_o' and λ_o')

Solution:

$$\frac{C_{l_\beta}}{C_L} = \frac{1}{\left(C_{L_\alpha}\right)_{total}}\left\{\left(C_{L_\alpha}\right)_i \frac{S_i}{S_W}\left[\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2_i}} K_M \Lambda_i + \left(\frac{C_{l_\beta}}{C_L}\right)_{A_i}\right]\frac{b_i}{b_W}\right.$$

$$\left. + \left(C_{L_\alpha}\right)_o' \frac{S_o'}{S_W}\left[\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2_o}'} K_M \Lambda_o' + \left(\frac{C_{l_\beta}}{C_L}\right)_{A_o'}\right]\right\} \quad \text{(equation 5.1.2.1-b)}$$

$$= \frac{1}{2.865}\left\{1.785\,(0.676)\left[-0.0045\,(1.0) + (-0.0065)\right]\frac{3.5}{6.0} + 2.60\,(0.638)\left[-0.0032\,(1.0) + (-0.0034)\right]\right\}$$

$$= \frac{1}{2.865}\left\{-0.00774 - 0.01095\right\} = -0.00652 \text{ per deg (based on } S_W b_W)$$

This result compares with a test value of -0.00628 from reference 30.

B. TRANSONIC

As the Mach number increases above M = 0.6, the rolling-moment derivative C_{l_β} of straight-tapered wings also increases, up to the force-break Mach number. The increase is nonlinear, with the largest gradient occurring just below the force-break Mach number. Beyond the force-break Mach number the value of the rolling-moment derivative falls off abruptly.

This variation with Mach number is quite similar to that of the wing lift-curve slope, as discussed in paragraph B of Section 4.1.3.2. This correspondence should perhaps be expected, since C_{l_β} has been successfully treated by using the effective lift-curve slopes of the upwind and downwind panels (reference 3).

The similarity in Mach number characteristics between rolling moment and lift-curve slope suggests a transonic interpolation method based on lift-curve slope, for calculating rolling moment. An interpolation equation is presented that is based on the square of the lift-curve slope values at M = 0.6 and at M = 1.4.

Although this interpolation method gives good results in most cases, it must be recognized that it is an interpolation technique and should be replaced by more accurate methods or data if they are available.

The Datcom method is limited to straight-tapered wings and is valid for sideslip angles between -5° and +5° and low angles of attack.

DATCOM METHOD

The wing rolling moment due to sideslip of straight-tapered wings may be approximated through the transonic region by means of the interpolation formula

$$\frac{C_{l_\beta}}{C_L} = \left\{\left[\frac{\left(\frac{C_{l_\beta}}{C_N}\right)_{M=1.4}}{\left(C_{N_\alpha}^2\right)_{M=1.4}} - \frac{\left(\frac{C_{l_\beta}}{C_L}\right)_{M=0.6}}{\left(C_{L_\alpha}^2\right)_{M=0.6}}\right]\left(\frac{M-0.6}{0.8}\right) + \frac{\left(\frac{C_{l_\beta}}{C_L}\right)_{M=0.6}}{\left(C_{L_\alpha}^2\right)_{M=0.6}}\right\}\left(C_{L_\alpha}^2\right) \quad \text{(per degree)} \qquad 5.1.2.1\text{-c}$$

where

$\left(\frac{C_{l_\beta}}{C_L}\right)_{M=0.6}$ is the sideslip derivative at M = 0.6 from the straight-tapered wing method of paragraph A.

$\left(\frac{C_{l_\beta}}{C_N}\right)_{M=1.4}$ is the sideslip derivative at M = 1.4 from the straight-tapered-wing method of paragraph C.

$\left(C_{L_\alpha}{}^2\right)_{M=0.6}$ is the square of the lift-curve slope at M = 0.6 from the straight-tapered-wing method of paragraph A of Section 4.1.3.2 (figure 4.1.3.2-49).

$\left(C_{N_\alpha}{}^2\right)_{M=1.4}$ is the square of the normal-force-curve slope at M = 1.4 from the straight-tapered-wing method of paragraph C of Section 4.1.3.2.

The transonic interpolation procedure is the same for wing-alone and wing-body configurations. Since the only available experimental data are for wing-body configurations, the sample problem of paragraph B of Section 5.2.2.1 can be taken as an example of the application of this method.

C. SUPERSONIC

The rolling moment due to sideslip for a wing at supersonic speeds is mainly a function of planform, Mach number, and dihedral angle.

A comprehensive summary of theoretical methods for calculating the effect of planform on rolling moment is given in reference 15. The information presented in this reference is not generalized, but is presented for discrete straight-tapered planforms over certain speed ranges. This is done because the theoretical calculations available are limited primarily to combinations of planforms and Mach lines that do not have mutually interacting subsonic edges. Techniques for handling mutually interacting subsonic edges are lengthy and involved. Consequently, numerical results are available for only a relatively few planforms that require such methods. Even when the boundary conditions can be specified and a linear-theory analysis carried out, the rolling moment cannot be generally expressed as a linear function of sideslip angle (see reference 16). To obtain the derivative C_{l_β}, it is necessary to plot C_l against β and measure the slope.

For planforms having streamwise tips there are additional questions concerning whether or not the Kutta condition applies at the trailing tip. In reference 6 it is assumed that it does. In reference 8 it is assumed that it does not, and values of opposite (negative) sign are obtained. In very few cases should any significant contribution be expected from the trailing tip. Nevertheless, most experimental measurements made to date give negative values of C_{l_β}.

Reference 17 indicates that agreement between experiment and theory for straight-tapered swept wings with streamwise tips may be obtained by integrating the span loading at combined angles of attack and sideslip; references 7 and 18 show calculations for such span loadings. However, there is no simple analytic expression for calculating C_{l_β}/α, and general digital computer solutions are not yet available.

For delta wings, the theory of reference 16 predicts a discontinuity and change in sign for C_{l_β} at the Mach number at which the leading edge is sonic. Since discontinuities of this type do not occur physically, there is some question as to what shape the C_{l_β} curve should have in the sonic-leading-edge region.

The above discussions indicate the present uncertain status of supersonic rolling-moment theory.

None of the previously mentioned theoretical methods are used in the Datcom. However, the discussion is included because no method yet developed is entirely satisfactory for all configurations over the entire speed range. It is felt that the Datcom does give best results for the widest range of configurations and speeds, but it must be recognized that there may be regions where one of the references mentioned gives better results.

Methods are presented for determining the rolling moment due to sideslip for the following classes of wing planforms:

Straight-Tapered Wings (conventional, trapezoidal wings)

Non-Straight-Tapered Wings

Double-delta wings
Cranked wings

These two general categories of non-straight-tapered wings are illustrated in sketch (a) of Section 4.1.3.2. Their wing-geometry parameters are presented in Section 2.2.2.

The straight-tapered-wing method is essentially that of reference 19, with the nomograph of page J.2-1.10 represented by an equation. This is done because of the inaccuracy of the nomograph at the higher Mach numbers, where the rolling moments are small. The nomograph of reference 19 was derived by writing the effective lift-curve slope for each wing panel as a function of sweepback and sideslip, multiplying this effective lift-curve slope by the spanwise center-of-pressure location, and taking the derivative of this product with respect to sideslip angle. One characteristic of this method is that it does not give positive rolling moments with positive sideslip angles (negative dihedral effect) for any speed range or planform. This is in direct opposition to certain other theories (reference 16) but is in qualitative agreement with experimental data. (References 20 through 27).

Another characteristic of the straight-tapered-wing method is that it predicts a linear variation of C_{l_β} with C_L. This, however, is not in agreement with the experimental data of references 20 through 27. In these tests, C_{l_β} is nonlinear with both angle of attack and sideslip. Since all these experimental tests are on wing-body combinations, it is not known to what extent the experimental nonlinearities may be caused by the body or by wing-body interference effects.

Geometric-dihedral effects are accounted for by the method of reference 28. This reference bases the dihedral parameter C_{l_β}/Γ on the damping-in-roll parameter C_{l_p}, by means of the following equation:

$$\frac{C_{l_\beta}}{\Gamma} = \frac{2}{(57.3)^2}\left(\frac{1+2\lambda}{1+3\lambda}\right)C_{l_p} \quad \text{(per degree}^2\text{)} \qquad 5.1.2.1\text{-d}$$

Although this equation is strictly an approximation, comparison of experimental data with values calculated from it shows that it gives good results. This success is largely due to the use of C_{l_p} as a base, since this latter derivative is one for which supersonic theory has given best results.

The Datcom method for double-delta and cranked wings is taken from reference 14. The supersonic prediction method has resulted from an analysis based on the same guide lines as the subsonic analysis. The straight-tapered-wing method is used as a base and a wing-lift prediction technique is used to weight the rolling-moment contributions of the various portions of the wing.

The nonlinearities of C_{l_β} with both angle of attack and sideslip, discussed above in connection with straight-tapered wings, also exist for the double-delta and cranked wings investigated during the course of the study conducted in connection with reference 11.

DATCOM METHODS

Straight-Tapered Wings

The rolling moment at Mach numbers above 1.4 for conventional, untwisted wings with uniform geometric dihedral in the linear angle-of-attack and sideslip ranges is given by

$$C_{l_\beta} = -0.061\, C_N \frac{C_{N_\alpha}}{57.3}\left[1 + \lambda\,(1 + \Lambda_{LE})\right]\left(1 + \frac{\Lambda_{LE}}{2}\right)\frac{\tan \Lambda_{LE}}{\beta}\left[\frac{M^2 \cos^2 \Lambda_{LE}}{A} + \left(\frac{\tan \Lambda_{LE}}{4}\right)^{4/3}\right] + \Gamma\left(\frac{C_{l_\beta}}{\Gamma}\right) \quad \text{(per degree)} \qquad 5.1.2.1\text{-e}$$

where

Λ_{LE} is the wing leading-edge sweep in radians.

C_{N_α} is the wing normal-force-curve slope per radian, obtained from the straight-tapered-wing method of paragraph C of Section 4.1.3.2.

$\frac{C_{l_\beta}}{\Gamma}$ is the dihedral parameter calculated by using equation 5.1.2.1-d with C_{l_p} (per radian) obtained from paragraph C of Section 7.1.2.2.

Γ is the dihedral angle in degrees (uniform dihedral).

Sample problem 1 on page 5.1.2.1-16 illustrates the use of this method applied to a straight-tapered wing with zero degrees dihedral.

A sample problem including the effect of uniform dihedral is presented in paragraph C of Section 5.2.2.1.

A comparison of test values of supersonic wing rolling moments due to sideslip with results calculated by using this method is presented as table 5.1.2.1-C. The ranges of Mach number and geometric parameters of the data are:

$$3.0 \le A \le 4.0$$

$$20.9^o \le \Lambda_{LE} \le 62.9^o$$

$$0.140 \le \lambda \le 0.250$$

$$\Gamma = 0$$

$$1.62 \le M \le 4.65$$

A data summary of calculated versus test values of the dihedral parameter $(\Delta C_{l_\beta})_\Gamma$ (including fuselage effects) is presented for wing-body configurations at supersonic speeds in Section 5.2.2.1 (table 5.2.2.1-E).

Non-Straight-Tapered Wings

The method for determining the rolling moment due to sideslip of double-delta and cranked wings is taken from reference 14. The composite wing is divided into two panels with each panel having conventional straight-tapered geometry. Then the lift-curve slopes and geometric characteristics of the two panels are substituted into the straight-tapered-wing method (equation 5.1.2.1-e). In order to maintain the proper span reference the rolling-moment contribution of the innermost panel is further modified by multiplying its contribution by the ratio of its span to the reference span (total wing span).

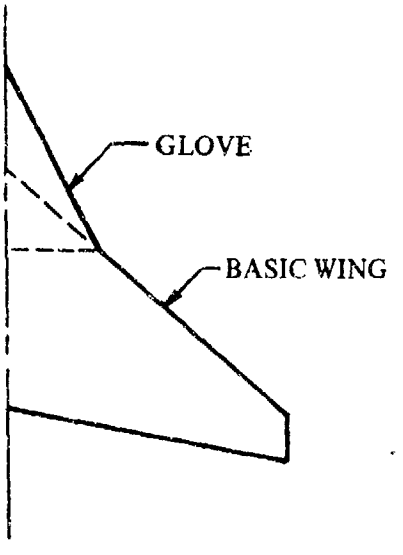
The method is applicable only to untwisted wings with zero degrees dihedral at low angles of attack and sideslip. A further restriction is that the composite-wing trailing edge must be unbroken (straight trailing edge from root to tip).

The rolling-moment derivative C_{l_β} of double-delta and cranked wings is obtained from the procedure outlined in the following steps:

Step 1. Divide the composite wing into two panels as follows (see sketch (b)), and determine their pertinent geometric characteristics.

Basic Wing – the outboard leading and trailing edges extended to the center line. This constructed panel is denoted by the subscript bw.

Glove – a delta wing superimposed over the basic wing. The glove leading edge is that of the inboard panel. This zero-taper wing is denoted by the subscript g.



SKETCH (b)

Step 2. Determine the normal-force-curve slopes of the glove and basic wing (per radian) by using the supersonic design charts of Section 4.1.3.2. $\left(C_{N_\alpha}\right)_{bw}$ is obtained from figure 4.1.3.2-56 and $\left(C_{N_\alpha}\right)_g$ from figure 4.1.3.2-63.

Step 3. Determine the "lift-interference factor" K_L from figure 4.1.3.2-61 as a function of the glove normal-force-curve slope.

Step 4. Determine the rolling moment due to sideslip, based on the total wing area and span, by

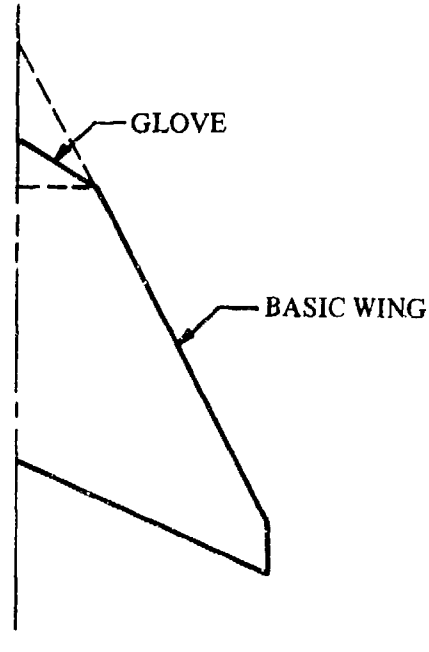
$$\frac{C_{l_\beta}}{C_N} = -0.061 \left[\frac{K_L \left(C_{N_\alpha}\right)_g \frac{S_g}{S_W}}{57.3}\right]\left(1 + \frac{\Lambda_{LE_g}}{2}\right)\left(\frac{\tan \Lambda_{LE_g}}{\beta}\right)\left[\frac{M^2 \cos^2 \Lambda_{LE_g}}{A_g} + \left(\frac{\tan \Lambda_{LE_g}}{4}\right)^{4/3}\right]\frac{b_g}{b_W}$$

$$-0.061 \left[\frac{K_L \left(C_{N_\alpha}\right)_{bw} \frac{S_{bw}}{S_W}}{57.3}\right]\left[1 + \lambda_{bw}\left(1 + \Lambda_{LE_{bw}}\right)\right]\left(1 + \frac{\Lambda_{LE_{bw}}}{2}\right) \cdot$$

$$\left(\frac{\tan \Lambda_{LE_{bw}}}{\beta}\right)\left[\frac{M^2 \cos^2 \Lambda_{LE_{bw}}}{A_{bw}} + \left(\frac{\tan \Lambda_{LE_{bw}}}{4}\right)^{4/3}\right] \text{ (per degree)} \qquad 5.1.2.1\text{-f}$$

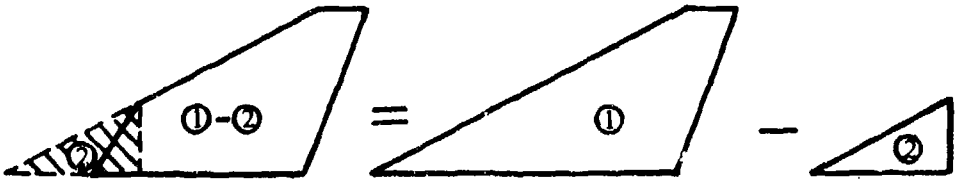
where the subscripts g and bw denote the glove and basic wing, respectively. The leading-edge sweep of the panels, Λ_{LE_g} and $\Lambda_{LE_{bw}}$, are in radians.

Another class of composite wings of practical interest are those with the outboard wing sweep greater than the inboard wing sweep. In treating such wings, if the basic wing breakdown is defined as in sketch (b), some additional wing area is created forward of the wing sweep break as illustrated in sketch (c).



SKETCH (c)

For this class of composite wings the normal-force-curve slope of the basic wing $\left(C_{N_\alpha}\right)_{bw}$ is determined by extending the basic-wing leading edge to the center line, calculating the normal-force-curve slope of the extended basic wing panel, and calculating and subtracting the normal-force-curve slope of the section of the basic-wing panel forward of the wing sweep break. This is shown schematically in sketch (d).



$$\left(C_{N_\alpha}\right)_{bw} \frac{S_{bw}}{S_w} = \left(C_{N_\alpha}\right)_1 \frac{S_1}{S_w} - \left(C_{N_\alpha}\right)_2 \frac{S_2}{S_w}$$

SKETCH (d)

During the course of study conducted in connection with reference 14, the normal-force-curve slopes of the basic wing and glove were correlated with test data for configurations with the outboard wing sweep greater than the inboard wing sweep through the use of an empirical correlation factor K, which corresponds to the "lift-interference factor" K_L. A complete analysis was not accomplished; however, based on a limited amount of rolling-moment data, K appears to be approximately one.

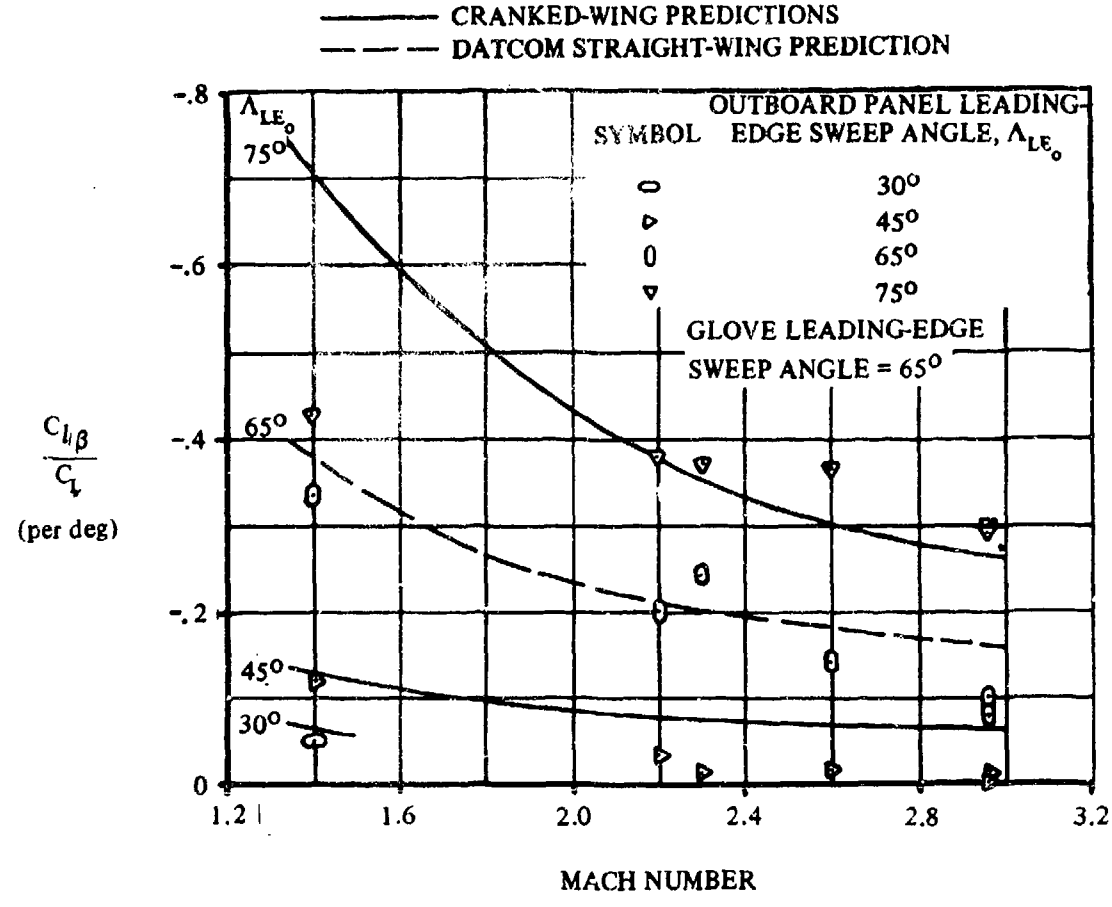
The rolling moment due to sideslip for this class of composite wings is obtained using equation 5.1.2.1-f in the following manner:

1. The term K_L is replaced by the term K, where K = 1.0.
2. The product of the normal-force-curve slope and the ratio of basic-wing area to total-wing area is replaced by the expression shown in sketch (d).
3. The aspect ratio, taper ratio, and sweepback of the basic wing are considered to be those of the extended basic wing, which corresponds to panel (i) in sketch (d).
4. The glove has the same geometry as in cases where the glove sweep is greater than the outboard wing sweep.

Sample problem 2 on page 5.1.2.1-18 illustrates the use of the non-straight-tapered-wing method.

A comparison of test values of supersonic wing rolling moments due to sideslip with results calculated by using this method is presented as table 5.1.2.1-D (taken from reference 14). A specific comparison of test values with calculated results for a cranked wing is shown in sketch (e). Also shown is a comparison of test values and results calculated by using the straight-tapered-wing method for the case where the basic-wing and the glove sweep angles are the same.

It is suggested that this method be restricted to Mach numbers above 1.4 and to glove leading-edge sweep angles less than 80°. At high leading-edge sweep angles the terms $\tan\Lambda_{LE_g}/\beta$ and $\left(\tan\Lambda_{LE_g}/4\right)^{4/3}$ become excessively large and equation 5.1.2.1-f overpredicts C_{l_β}.



COMPARISON OF CRANKED-WING ROLLING-MOMENT-COEFFICIENT PREDICTIONS WITH TEST DATA

SKETCH (e)

Sample Problems

1. Straight-Tapered Wing

Given: A wing-body configuration with a midwing location from reference 25.

$A = 3.0$ $\lambda = 0.250$ $\Lambda_{LE} = 30.97^\circ = 0.540$ rad $\Gamma = 0$

$M = 2.01$; $\beta = 1.744$ Airfoil section: 4-percent circular arc

Compute:

$\Delta y = 0.47$ (figure 2.2.1-8)

$$\Delta y_{\perp} = \frac{\Delta y}{\cos \Lambda_{LE}} = \frac{0.47}{0.8575} = 0.548 \qquad \text{(Section 4.1.3.2)}$$

$$\delta_{\perp} = \tan^{-1} \frac{\Delta y_{\perp}}{5.85} = \tan^{-1} 0.09368 = 5.35^{o}$$

$$\frac{\tan \Lambda_{LE}}{\beta} = \frac{0.6002}{1.744} = 0.3442$$

$$\frac{M^2 \cos^2 \Lambda_{LE}}{A} = \frac{(2.01)^2 \ (0.8575)^2}{3.0} = 0.990$$

$$\left(\frac{\tan \Lambda_{LE}}{4}\right)^{4/3} = \left(\frac{0.6002}{4.0}\right)^{4/3} = 0.0797$$

C_{N_α} (Section 4.1.3.2)

$$A \tan \Lambda_{LE} = (3.0)\ (0.6002) = 1.80$$

$$\beta \left(C_{N_\alpha}\right)_{theory} = 3.83 \text{ per rad (figure 4.1.3.2-56c)}$$

$$\left(C_{N_\alpha}\right)_{theory} = 2.20 \text{ per rad}$$

$$\frac{C_{N_\alpha}}{\left(C_{N_\alpha}\right)_{theory}} = 1.0 \qquad \text{(figure 4.1.3.2-60)}$$

$$C_{N_\alpha} = \frac{C_{N_\alpha}}{\left(C_{N_\alpha}\right)_{theory}} \left(C_{N_\alpha}\right)_{theory} = (1.0)\ (2.20) = 2.20 \text{ per rad}$$

Solution:

$$\frac{C_{l_\beta}}{C_N} = -0.061 \frac{C_{N_\alpha}}{57.3} \left[1 + \lambda\ (1 + \Lambda_{LE})\right] \left(1 + \frac{\Lambda_{LE}}{2}\right) \frac{\tan \Lambda_{LE}}{\beta} \left[\frac{M^2 \cos^2 \Lambda_{LE}}{A} + \left(\frac{\tan \Lambda_{LE}}{4}\right)^{4/3}\right]$$

(equation 5.1.2.1-e with $\Gamma = 0$)

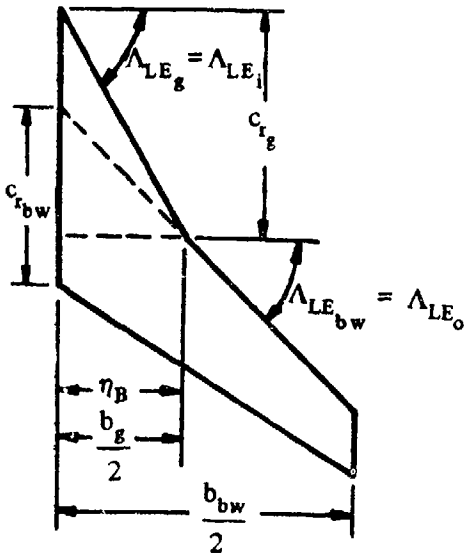
$$= -0.061 \frac{2.20}{57.3} \left[1 + 0.25\ (1 + 0.540)\right] \left(1 + \frac{0.540}{2}\right) (0.3442) \left[0.990 + 0.0797\right]$$

$$= -0.00152 \text{ per deg (based on } S_w b_w)$$

This result compares with a test value of -0.00143 from reference 25.

2. Non-Straight-Tapered Wing

Given: A hypothetical cranked wing



Total Wing Characteristics:

$S_W = 7.05$ sq ft $\quad \frac{b_W}{2} = 2.50$ ft

$c_{t_W} = 0.608$ ft $\quad \eta_B = 0.400 \quad \Lambda_{LE_i} = 60^o$

$\Lambda_{LE_o} = 45^o$

Glove Characteristics:

$A_g = 2.31 \quad \lambda_g = 0 \quad S_g = 1.732$ sq ft

$\frac{S_g}{S_W} = 0.246 \quad \frac{b_g}{2} = 1.0$ ft

$\Lambda_{LE_g} = \Lambda_{LE_i} = 60^o = 1.047$ rad

Basic Wing Characteristics:

$A_{bw} = 3.97 \quad \lambda_{bw} = 0.407 \quad S_{bw} = 6.30$ sq ft $\quad \frac{b_{bw}}{2} = \frac{b_W}{2} = 2.50$ ft

$\Lambda_{LE_{bw}} = \Lambda_{LE_o} = 45^o = 0.785$ rad $\quad \frac{S_{bw}}{S_W} = 0.894$

Additional Characteristics:

$M = 2.96; \ \beta = 2.79$

Compute:

$$1 + \frac{\Lambda_{LE_g}}{2} = 1.524$$

$$\frac{\tan \Lambda_{LE_g}}{\beta} = \frac{1.732}{2.79} = 0.621$$

$$\frac{M^2 \cos^2 \Lambda_{LE_g}}{A_g} = \frac{(2.96)^2 (0.50)^2}{2.31} = 0.948$$

$$\left(\frac{\tan \Lambda_{LE_g}}{4}\right)^{4/3} = \left(\frac{1.732}{4}\right)^{4/3} = 0.3276$$

$\left(C_{N_\alpha}\right)_g$ (Section 4.1.3.2)

$$\frac{\beta}{\tan \Lambda_{LE_g}} = \frac{2.79}{1.732} = 1.611$$

$$\frac{\left(C_{N_\alpha}\right)_g}{A_g} = 0.624 \text{ per rad (figure 4.1.3.2-63)}$$

$$\left(C_{N_\alpha}\right)_g = 1.44 \text{ per rad}$$

K_L (Section 4.1.3.2)

$$\frac{1}{\beta}\left(C_{N_\alpha}\right)_g \frac{S_g}{S_W} = \frac{1}{2.79}(1.44)(0.246) = 0.127 \text{ per rad}$$

$K_L = 0.873$ (figure 4.1.3.2-61)

$$1 + \lambda_{LE_{bw}} = 1.785;\ 1 + \frac{\Lambda_{LE_{bw}}}{2} = 1.393$$

$$\frac{\tan \Lambda_{LE_{bw}}}{\beta} = \frac{1.00}{2.79} = 0.358$$

$$\frac{M^2 \cos^2 \Lambda_{bw}}{A_{bw}} = \frac{(2.96)^2 (0.7071)^2}{3.97} = 1.103$$

$$\left(\frac{\tan \Lambda_{LE_{bw}}}{4}\right)^{4/3} = \left(\frac{1.00}{4.0}\right)^{4/3} = 0.1575$$

$\left(C_{N_\alpha}\right)_{bw}$ (Section 4.1.3.2)

$$\frac{\tan \Lambda_{LE_{bw}}}{\beta} = 0.358;\ A \tan \Lambda_{LE_{bw}} = 3.97$$

$\beta C_{N_\alpha} = 4.07$ per rad (figures 4.1.3.2-56c through -56e, interpolated)

$$\left(C_{N_\alpha}\right)_{bw} = 1.46 \text{ per rad}$$

Solution:

$$\frac{C_{l_\beta}}{C_L} = -0.061 \left[\frac{K_L \left(C_{N_\alpha}\right)_g \frac{S_g}{S_W}}{57.3}\right]\left(1 + \frac{\Lambda_{LE_g}}{2}\right)\left(\frac{\tan \Lambda_{LE_g}}{\beta}\right)\left[\frac{M^2 \cos^2 \Lambda_{LE_g}}{A_g} + \left(\frac{\tan \Lambda_{LE_g}}{4}\right)^{4/3}\right]\frac{b_g}{b_W}$$

$$-0.061 \left[\frac{K_L \left(C_{N_\alpha}\right)_{bw} \frac{S_{bw}}{S_W}}{57.3}\right]\left[1 + \lambda_{bw}\left(1 + \Lambda_{LE_{bw}}\right)\right]\left(1 + \frac{\Lambda_{LE_{bw}}}{2}\right)$$

$$\left(\frac{\tan \Lambda_{LE_{bw}}}{\beta}\right)\left[\frac{M^2 \cos^2 \Lambda_{LE_{bw}}}{A_{bw}} + \left(\frac{\tan \Lambda_{LE_{bw}}}{4}\right)^{4/3}\right] \qquad \text{(equation 5.1.2.1-f)}$$

$$= -0.061 \left[\frac{0.873\ (1.44)\ (0.246)}{57.3}\right](1.524)\ (0.621)\left[0.948 + 0.3276\right]\frac{2.0}{5.0}$$

$$-0.061 \left[\frac{0.873\ (1.46)\ (0.894)}{57.3}\right]\left[1 + 0.407\ (1.785)\right](1.393)\ (0.358)\left[1.103 + 0.1575\right]$$

$$= -0.061 \left[0.00261\right] - 0.061 \left[0.0216\right]$$

$$= -0.00148 \text{ per deg}$$

5.1.2.2 WING ROLLING-MOMENT COEFFICIENT C_l AT ANGLE OF ATTACK

A. SUBSONIC

In Section 5.1.2.1, the wing rolling moments due to sideslip were discussed in terms of the parameters $\frac{C_{l_\beta}}{C_L}$ and $\frac{C_{l_\beta}}{\Gamma}$. These parameters imply that the rolling moment is a linear function of both lift coefficient and dihedral angle. This linearity holds true only if the flow is everywhere attached. Once separation takes place, the rolling-moment derivatives may vary considerably from the linear-range value, even changing sign in certain cases.

Because of the nonlinear nature of the separation effects governing C_{l_β}, no theoretical analysis of this parameter at the higher angles of attack has been successful. An empirical approach along the lines of Section 4.1.3.4 appears to be feasible. However, until a systematic method is developed, the presentation of this Handbook will be limited to a qualitative discussion of the important parameters governing C_{l_β} at high angles of attack, including certain representative examples.

Effect of Planform

As was mentioned in Section 4.1.3.4, planform shape plays an important part in determining the place at which separation first appears on a wing and how it subsequently progresses with increasing angle of attack. The manner in which the various separation patterns influence the rolling-moment characteristics is illustrated in figure 5.1.2.2-4.

For the unswept wing of figure 5.1.2.2-4 , separation occurs first at the wing trailing edge and then progresses forward with increasing angle of attack. When this wing is yawed, the separated area is displaced toward the downwind wing tip (presumably the result of spanwise boundary-layer flow). The size of the separated area on the downwind panel also increases with increasing angle of attack. The resulting lift differential between the upwind and downwind panels then gives rise to a powerful negative rolling moment (positive dihedral effect).

For swept and delta wings, separation occurs first at the wing leading edge. The separated flow rolls into two strong vortices lying along the wing leading edges. Changes in magnitude and distribution of the lift force on the wing are associated with these vortices. When these wings are yawed, the decrease in sweep angle of the upwind wing panel causes the leading-edge vortex on this panel to lose strength and to turn away from the leading edge farther inboard than the corresponding vortex on the downwind panel (see figure 5.1.2.2-4). This asymmetry results in a relative loss in lift on the upwind wing panel, even though there is a partially compensating effective increase in angle of attack due to the geometry of combined sweep and yaw. At angles of attack beyond the stall, flow over the wing is completely separated and all wing planforms have basically similar rolling-moment characteristics.

The trends presented in figure 5.1.2.2-4 are valid only for small sideslip angles ($\pm 5°$). At larger angles of sideslip, the curves of C_l as a function of β for the swept and delta wings reverse, and these wings then show positive-dihedral characteristics, as shown in figure 5.1.2.2-5.

Effect of Leading-Edge Shape

Since leading-edge shape is shown to have an important effect on the strength of the wing leading-edge vortex, and hence on the wing lift (Section 4.1.3.4), it is to be expected that wing rolling moments that also depend on vortex characteristics are influenced by wing leading-edge shape.

The effect of wing airfoil section (leading-edge shape) on C_{l_β} is illustrated in figure 5.1.2.2-6.

Briefly summarised, this figure shows that the sharper the wing leading edge, the lower the lift coefficient at which C_{l_β} deviates from the linear-theory value (figures 5.1.2.2-6a and 5.1.2.2-6b). Reducing the Reynolds number tends to promote leading-edge separation and thus produces the same effects as sharpening the leading edge (figure 5.1.2.2-6c).

Under certain circumstances, introduction of leading-edge roughness also triggers leading-edge separation and therefore causes the rolling-moment characteristics to deviate from linear values.

Very Low Aspect Ratios

For very low-aspect-ratio wings, C_{l_β} at high angles of attack is not only highly nonlinear but may also be non-symmetrical with respect to sideslip. Experimental data showing this effect for low-aspect-ratio triangular wings is given in reference 3. This unusual characteristic may be related to the formation of unsymmetrical leading-edge vortices similar to those observed for bodies of revolution at high angles of attack in references 4 and 5. In these two references it is shown that as the angle of attack is increased for bodies of revolution, the vortex system changes from a steady symmetric pair to a steady asymmetric configuration of two or more vortices and, finally, at large angles of attack, to an unsteady asymmetric arrangement. Experimental tests with free flying low-aspect-ratio-wing models have shown that undesirable lateral characteristics are present for aspect ratios considerably larger than those at which static asymmetric rolling moments cease to be apparent (reference 6). However, in this test the static rolling-moment characteristics may be obscured by the dynamic coupling effects of free flight.

Geometric Dihedral

The effects of geometric dihedral on wings at high angles of attack are directly related to the lift-curve slope at the same angle of attack. This relationship is

$$\left(\frac{C_{l_\beta}}{\Gamma}\right)_{C_L} = \left(\frac{C_{l_\beta}}{\Gamma}\right)_{C_L=0} \frac{(C_{L_\alpha})_{C_L}}{(C_{L_\alpha})_{C_L=0}} \qquad 5.1.2.2\text{-a}$$

It is evident that near maximum lift, where the lift-curve slope is small, a variation in geometric dihedral is not an effective way to change the wing rolling-moment characteristics.

B. TRANSONIC

The transonic rolling-moment characteristics of wings at high angles of attack generally show considerable variation with Mach number. (reference 2).

The changes in rolling-moment characteristics are roughly related to changes in panel lift characteristics. At transonic Mach numbers ($M > .9$) the wing lift-curve slope and maximum-lift characteristics undergo marked changes (see Sections 4.1.3.2 and 4.1.3.4), which are reflected in changes in the wing rolling moments.

For swept wings, the negative-dihedral effects at high angles of attack are reduced or eliminated with increasing Mach number. This is due to changes in the leading-edge vortex characteristics with Mach number that permit the leading wing panel to carry more lift.

For unswept wings, the increased compressibility effects on the force-break characteristics of the more highly loaded leading wing tend to reduce or even reverse the positive-dihedral characteristics in evidence at lower speeds. Mach number effects on the rolling moment due to geometric dihedral of any wing at high angles of attack are small.

C. SUPERSONIC

Experimental data on wing rolling moments due to sideslip at supersonic speeds and high angles of attack are relatively scarce, but the following general trends are observed.

Effect of Planform

For swept wings, the positive-dihedral effects that are in evidence at low angles of attack increase in magnitude with increasing angle of attack. This characteristic is relatively insensitive to Mach number variations (reference 7).

For unswept wings at Mach numbers below 2 the value of C_{l_β} tends toward zero with increasing angle of attack. This is true for the high-wing, midwing, and low-wing configurations tested in reference 8. At Mach numbers above 2 the same configurations show a trend toward increasingly positive dihedral effects with increasing angle of attack. At the higher Mach numbers the unswept-wing characteristics are similar to the swept-wing characteristics.

Geometric Dihedral

The experimental data of reference 7 show that up to 12° angle of attack the rolling-moment increment due to dihedral is essentially the same as at zero angle of attack. This result is somewhat unexpected, since a calculation of the local angles of attack of the left and right wing panels individually would predict a variation in dihedral effect (see reference 7). Possibly the discrepancy is due to sweep and/or wing-body interference effects.

If the geometric dihedral effects are assumed to be independent of angle of attack for all configurations at supersonic speeds, then the methods of Section 5.1.2.1 intended for low angles of attack are also applicable at the higher angles of attack.

5.1.3 WING SIDESLIP DERIVATIVE C_{n_β}

5.1.3.1 WING SIDESLIP DERIVATIVE C_{n_β} IN THE LINEAR ANGLE-OF-ATTACK RANGE

The yawing moment of a wing in sideslip is primarily caused by the asymmetrical induced-drag distribution associated with the asymmetrical lift distribution. The wing contribution to the derivative C_{n_β} is important only at large incidences.

Methods are presented in this section for estimating the wing yawing moment due to sideslip in the subsonic and supersonic speed regimes. Methods for estimating this derivative in the transonic speed regime are not available.

A. SUBSONIC

The Datcom method presented herein is based on the same theory as that used to determine wing side force due to sideslip, and the general discussion of Paragraph A of Section 5.1.1.1 is directly applicable here. The method is valid in the linear angle-of-attack region.

DATCOM METHOD

The yawing moment derivative at low speeds is given in Reference 1 as

$$\frac{C_{n_\beta}}{C_L^2} = \frac{1}{57.3}\left[\frac{1}{4\pi A} - \frac{\tan \Lambda_{c/4}}{\pi A(A + 4\cos \Lambda_{c/4})}\left(\cos \Lambda_{c/4} - \frac{A}{2} - \frac{A^2}{8\cos \Lambda_{c/4}} + 6\frac{\bar{x}}{\bar{c}}\frac{\sin \Lambda_{c/4}}{A}\right)\right]$$

(per deg) 5.1.3.1-a

where $\bar{x}$ is the longitudinal distance (positive rearward) from the coordinate origin (usually the center of gravity) to the wing aerodynamic center.

The wing contribution to the yawing moment due to sideslip at low speeds is shown to be independent of both taper ratio and dihedral in References 2 and 3, respectively.

For subcritical speeds, the low-speed derivative can be modified by the Prandtl-Glauert rule to yield approximate corrections for the first-order three-dimensional effects of compressibility. The resulting expression from Reference 4 is

$$\left(\frac{C_{n_\beta}}{C_L^2}\right)_M = \left(\frac{A + 4\cos \Lambda_{c/4}}{AB + 4\cos \Lambda_{c/4}}\right)\left(\frac{A^2B^2 + 4AB\cos \Lambda_{c/4} - 8\cos^2 \Lambda_{c/4}}{A^2 + 4A\cos \Lambda_{c/4} - 8\cos^2 \Lambda_{c/4}}\right)\left(\frac{C_{n_\beta}}{C_L^2}\right)_{\substack{\text{low}\\\text{speed}}}$$

5.1.3.1-b

where

$$B = \sqrt{1 - M^2\cos^2 \Lambda_{c/4}}.$$

5.1.3.1-1

Calculated values for the wing yawing moment due to sideslip at low subsonic speeds obtained by the Datcom method for the wing configurations of References 5, 6, and 7 are compared with experimental data in Figure 5.1.3.1-5. The comparison indicates that the calculated values are fairly reliable over a range of lift coefficient (starting from zero) that decreases as wing sweep increases. Large discrepancies are noted for highly swept wings at lift coefficients for which the flow is believed to be partially separated.

Sample Problem

Given: The wing of Reference 5

$$A = 4.0 \qquad \Lambda_{c/4} = 60^\circ \qquad \frac{\bar{x}}{\bar{c}} = 0.037 \qquad M = 0.13$$

Compute:

$$\sin \Lambda_{c/4} = 0.866$$
$$\cos \Lambda_{c/4} = 0.500$$
$$\tan \Lambda_{c/4} = 1.732$$

Solution:

$$\frac{C_{n_\beta}}{C_L^2} = \frac{1}{57.3}\left[\frac{1}{4\pi A} - \frac{\tan \Lambda_{c/4}}{\pi A(A + 4 \cos \Lambda_{c/4})}\left(\cos \Lambda_{c/4} - \frac{A}{2} - \frac{A^2}{8 \cos \Lambda_{c/4}} + 6\,\frac{\bar{x}}{\bar{c}}\,\frac{\sin \Lambda_{c/4}}{A}\right)\right]$$

(per deg) (equation 5.1.3.1-a)

$$= \frac{1}{57.3}\left[\frac{1}{16\pi} - \frac{1.732}{4\pi\,[4 + (4)\,(0.50)]}\left(0.50 - \frac{4}{2} - \frac{(4)^2}{(8)\,(0.50)} + (6)\,(0.037)\,\frac{0.866}{4}\right)\right]$$

$$= \frac{1}{57.3}\,[(0.01989) - (0.02297)\,(-5.452)]$$

$$= \frac{1}{57.3}\,[(0.01989) + (0.1252)]$$

$$= 0.00253 \text{ per deg}$$

C_L	C_L^2	$C_{n_\beta} \times 10^3$ (per deg)
0.05	0.0025	0.00633
0.10	0.010	0.0253
0.20	0.040	0.1012
0.30	0.090	0.2277
0.40	0.160	0.4048
0.50	0.250	0.6325
0.60	0.360	0.9108

These results are compared with experimental values in Figure 5.1.3.1-5.

B. TRANSONIC

There are no methods available for estimating the wing yawing moment due to sideslip in the transonic regime and none are presented in the Datcom. Furthermore, there are no experimental data available in the transonic speed regime.

C. SUPERSONIC

No general method has been developed for estimating the wing yawing moment due to sideslip at supersonic speeds. However, theoretical methods are available for discrete planforms over certain speed ranges. A comprehensive summary of the available theoretical methods for calculating the wing yawing moment due to sideslip is presented in Reference 9. Datcom methods are based on the same theory as that used to determine wing side force due to sideslip, and the general discussion of Paragraph C of Section 5.1.1.1 is directly applicable here.

DATCOM METHODS

The Datcom methods are taken from References 10, 11, and 12 and present the wing yawing moment due to sideslip for rectangular planforms, triangular planforms, and fully tapered sweptback planforms with sweptforward or sweptback trailing edges. The results are mainly functions of planform geometry and Mach number. The general trend of the variation of C_{n_β} with Mach number and aspect ratio is a reduction in the magnitude of the derivative with an increase in these parameters.

Rectangular Planform: $A\beta \geq 1.0$

The wing yawing moment due to sideslip for rectangular planforms referred to an arbitrary moment center is given in Reference10 as

$$\frac{C_{n_\beta}}{\alpha^2} = \frac{1}{\pi A^2 \beta^2}\left[\frac{4M^2}{3} + 8M^2\frac{x}{\bar{c}} - \pi\left\{\frac{A(1-\beta^2)}{\beta}\frac{3+\beta^2}{3\beta^2}\right\}\right]\frac{1}{57.3} \text{ (per deg)} \qquad 5.1.3.1\text{-c}$$

where α is in radians, $\beta = \sqrt{M^2 - 1}$ and x is the distance of the origin of moments from the midchord point, measured along the longitudinal axis, positive ahead of midchord point.

Equation 5.1.3.1-c is valid for Mach number and aspect ratio greater than that for which the Mach line from the leading edge of the tip section intersects the trailing edge of the opposite tip section ($A\beta \geq 1.0$).

Sweptback Planform ($\lambda = 0$): $\beta \cot \Lambda_{LE} \leq 1.0$

The wing yawing moment due to sideslip for fully tapered sweptback planforms is derived in Reference 11 for triangular planforms and in Reference 12 for planforms with sweptforward or sweptback trailing edges as

$$\frac{C_{n_\beta}}{\alpha^2} = \frac{\pi}{3}\left[E''(\beta C)F_9(N) + \left(\frac{A^2}{16}F_{11}(N) + \frac{x}{\bar{c}}\right)M^2 Q(\beta C)\right]\frac{1}{57.3} \text{ (per deg)} \qquad 5.1.3.1\text{-d}$$

where α is in radians and

$Q(\beta C)$ is obtained from Figure 5.1.1.1-6
$E''(\beta C)$ is obtained from Figure 7.1.1.1-8
$F_{11}(N)$ is obtained from Figure 7.1.1.2-8
$F_9(N)$ is obtained from Figure 5.1.3.1-6

x is the distance of the origin of moments from the 2/3 c_{r_B} point of the basic triangular wing, measured along the longitudinal axis, positive ahead of the 2/3 c_{r_B} point. (See Sketch (a) of Section 7.1.1.1 for definition of basic triangular wing.)

For a triangular planform the factors $F_9(N)$ and $F_{11}(N)$ are equal to 1.0.

Equation 5.1.3.1-d is valid for Mach number and aspect ratio for which the wing is contained within the Mach cones springing from the apex and the trailing edge at the center of the wing.

5.2 WING-BODY COMBINATIONS IN SIDESLIP
5.2.1 WING-BODY SIDESLIP DERIVATIVE C_{Y_β}

5.2.1.1 WING-BODY SIDESLIP DERIVATIVE C_{Y_β} IN THE LINEAR ANGLE-OF-ATTACK RANGE

The wing-body side force due to sideslip can be considered as the sum of the side forces of the body, the wing, the wing-body interference, and the wing dihedral effect. The wing side force due to sideslip at low lift coefficient is small in comparison to that due to the body and is neglected in the Datcom methods of this Section.

Wing-body interference, which is primarily a function of wing vertical position on the body, is presented as a fraction of the body contribution. Experimental investigations show that the contribution of wing-body interference to the sideslip derivative C_{Y_β} is essentially independent of sweep, wing planform, taper ratio, and Mach number.

The body is the chief contributor to the side force of a wing-body combination. Experimental results for the body alone show a negative lateral force which increases as the body fineness ratio is decreased.

The range of applicability of the method is limited to the linear angle-of-attack range.

A. SUBSONIC

The wing-body side force due to sideslip is estimated by the following method.

DATCOM METHOD

The wing-body side force due to sideslip, based on wing area, is given by

$$(C_{Y_\beta})_{WB} = K_i\,(C_{Y_\beta})_B \left(\frac{\text{Body Reference Area}}{S_W}\right) + (\Delta C_{Y_\beta})_\Gamma \qquad \text{5.2.1.1-a}$$

where

K_i is the wing-body interference factor obtained from figure 5.2.1.1-7

$(C_{Y_\beta})_B$ is the body side force due to sideslip obtained from paragraph A of Section 4.2.1.1 as

$$(C_{Y_\beta})_B = -\,(C_{L_\alpha})_B$$

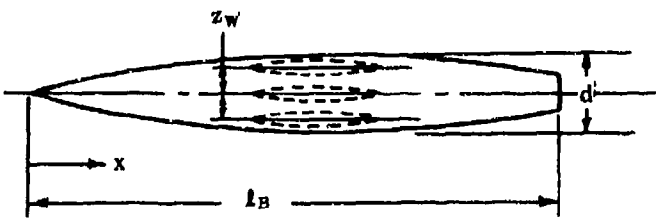
$(\Delta C_{Y_\beta})_\Gamma$ is the increment in side force due to wing dihedral and is approximated by $(\Delta C_{Y_\beta})_\Gamma = -0.0001\,|\Gamma|$ (Γ and β in degrees) (equation 5.1.1.1-b)

For a rapid but approximate estimation of the body side force due to sideslip, slender-body theory can be used, which gives $(C_{Y_\beta})_B = -2$ (per rad), where $(C_{Y_\beta})_B$ is based on the body cross-sectional area at x_0 (see page 4.2.1.1-1 for definition of x_0).

A comparison of experimental data and values of wing-body side force due to sideslip at subsonic speeds calculated by equation 5.2.1.1-a is presented as table 5.2.1.1-A.

Sample Problem

Given: The wing body configuration of reference 3.



ℓ_B = 3.45 ft d = 0.5 ft f = 6.90 z_W = 0, ±0.1667 ft S_W = 2.25 sq ft

$\frac{x_1}{\ell_B}$ = 0.50 $V_B^{2/3}$ = 0.542 sq ft Γ = 0

S_0 = 0.175 sq ft (area distribution curve at $\frac{x_0}{\ell_B}$)

Compute:

$z_W/\frac{d}{2}$ = 0, ±0.667

$K_{l\ High}$ = 1.57
$K_{l\ Mid}$ = 1.0
$K_{l\ Low}$ = 1.33
} (figure 5.2.1.1-7)

$(k_2 - k_1)$ = 0.890 (figure 4.2.1.1-20a)

$\frac{x_0}{\ell_B}$ = 0.640 (figure 4.2.1.1-20b)

$$(C_{Y_\beta})_B = -\left[\frac{2(k_2 - k_1)\,S_0}{V_B^{2/3}}\right] \text{ (per rad)} \quad \text{(equation 4.2.1.1-a)}$$

$$= -\frac{(2)(0.89)(0.175)}{0.542} = -0.575 \text{ per rad (based on } V_B^{2/3})$$

Solution:

$$(C_{Y_\beta})_{WB} = K_l\,(C_{Y_\beta})_B\left(\frac{\text{Body Reference Area}}{S_W}\right) + (\Delta\, C_{Y_\beta})_\Gamma \quad \text{(equation 5.2.1.1-a)}$$

$$= K_l(-0.575)\left(\frac{0.542}{2.25}\right) + 0$$

$$= -0.1385\, K_l \text{ per rad}$$

$$= -0.00242\, K_l \text{ per deg}$$

Wing Position	K_l	$(C_{Y_\beta})_{WB}$ (per deg)
High	1.57	-0.00380
Mid	1.0	-0.00242
Low	1.33	-0.00322

These results compare with experimental values of -0.004 per deg, -0.0024 per deg, and -0.0034 per deg for the high-, mid-, and low-wing configurations, respectively, obtained from reference 3.

B. TRANSONIC

The contribution of wing-body interference to the side force derivative is essentially independent of Mach number. Furthermore, slender-body theory states that body force characteristics are not functions of Mach number.

DATCOM METHOD

The method presented in paragraph A is applicable throughout the transonic speed regime.

C. SUPERSONIC

The contribution of wing-body interference to the side force derivative is essentially independent of Mach number. Several of the theoretical methods that have been developed for estimating body force characteristics at supersonic speeds are discussed in paragraph C of Section 4.2.1.1.

The experimental results of reference 6 indicate a negative lateral force increment due to wing camber at supersonic speeds; however, no method is available to predict this effect.

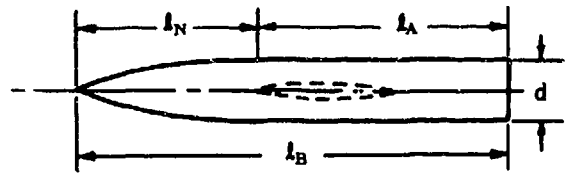
DATCOM METHOD

The method presented in paragraph A is applicable throughout the supersonic speed range. The body side force due to sideslip is obtained by conversion of the body lift-curve slope of paragraph C of Section 4.2.1.1.

A comparison of experimental data and values of wing-body side force due to sideslip at supersonic speeds calculated by the Datcom method is presented as table 5.2.1.1-B.

Sample Problem

Given: The midwing-ogive-cylinder body configuration of reference 12.



$d = 0.0625$ ft $\quad l_N = 0.2188$ ft $\quad l_A = 0.4062$ ft $\quad S_W = 0.0506$ sq ft $\quad S_b = 0.00307$ sq ft

$\Gamma = 10°$ $\quad M = 1.62, 2.62$

Compute:

$$f_N = \frac{l_N}{d} = 3.5$$

$$f_A = \frac{l_A}{d} = 6.5$$

$$\frac{f_A}{f_N} = \frac{6.5}{3.5} = 1.857$$

$$\beta_{M = 1.62} = \sqrt{M^2 - 1} = 1.275$$

$$\beta_{M = 2.62} = \sqrt{M^2 - 1} = 2.42$$

$$(\beta/f_N)_{M = 1.62} = \frac{1.275}{3.5} = 0.364$$

$$(\beta/f_N)_{M = 2.62} = \frac{2.42}{3.5} = 0.691$$

$[(C_{Y_\beta})_B]_{M = 1.62} = -2.78$ per rad (based on S_b)

$[(C_{Y_\beta})_B]_{M = 2.62} = -3.06$ per rad (based on S_b)

(figure 4.2.1.1-21a; $(C_{Y_\beta})_B = -(C_{N_\alpha})_B$)

$K_1 = 1.0$ (figure 5.2.1.1-7; mid-wing configuration)

$(\Delta C_{Y_\beta})_\Gamma = (-0.0001)(10) = -0.0010$ per deg (equation 5.1.1.1-b)

Solution:

$$(C_{Y\beta})_{WB} = K_I (C_{Y\beta})_B \left(\frac{\text{Body Reference Area}}{S_W} \right) + (\Delta C_{Y\beta})_\Gamma \qquad \text{(equation 5.2.1.1-a)}$$

$$= 1.0 (C_{Y\beta})_B \left(\frac{0.00307}{0.0506} \right) + (-0.0010)$$

$$= 0.0607 (C_{Y\beta})_B - 0.0010$$

M	$(C_{Y\beta})_B$ (per rad)	$(C_{Y\beta})_B$ (per deg)	$0.0607 (C_{Y\beta})_B$ (per deg)	$(C_{Y\beta})_{WB}$ (per deg)
1.62	-2.78	-0.0485	-0.00294	-0.00394
2.62	-3.06	-0.0534	-0.00324	-0.00424

These results compare with experimental values of -0.0038 per degree and -0.0042 per degree at Mach numbers 1.62 and 2.62, respectively, obtained from reference 12.

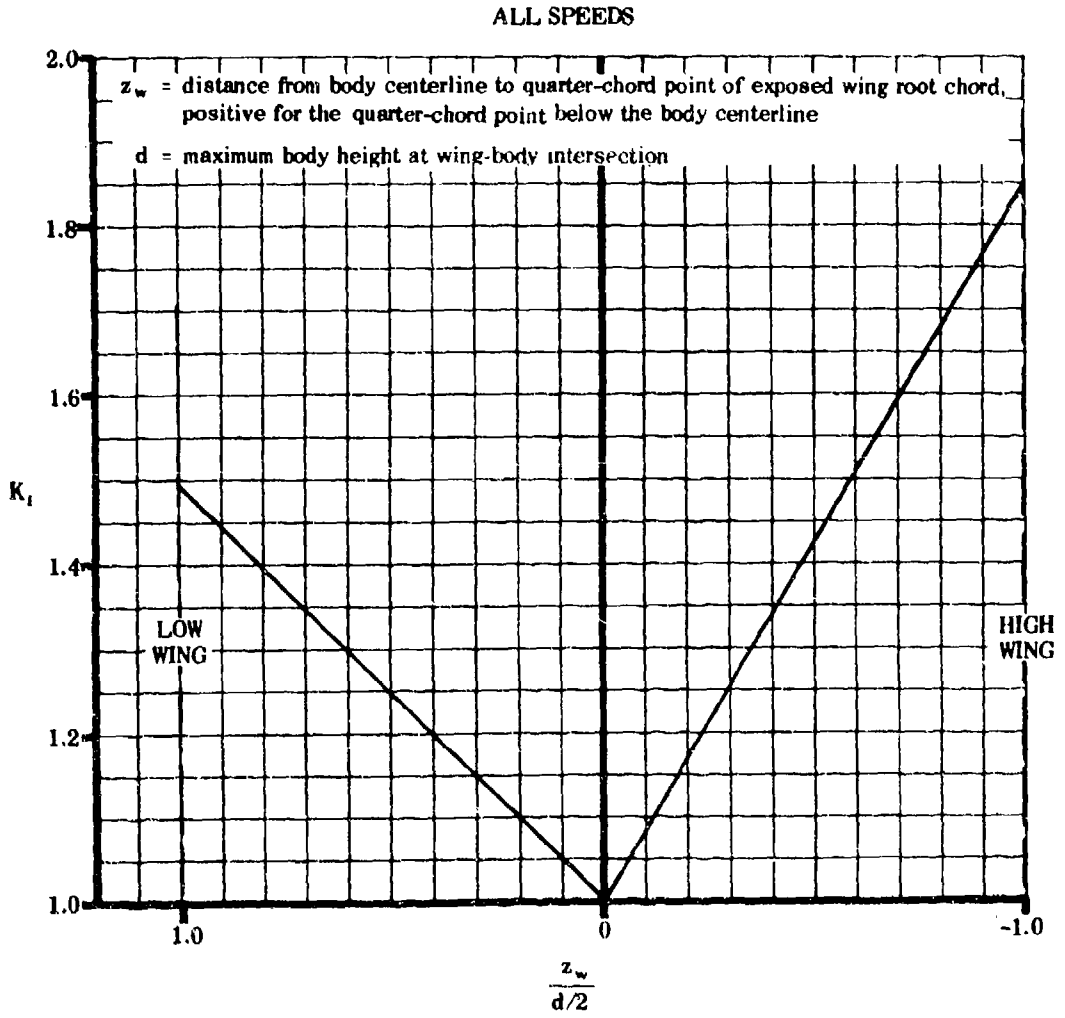

FIGURE 5.2.1.1-7 WING-BODY INTERFERENCE FACTOR FOR WING-BODY SIDESLIP DERIVATIVE C_{Y_β}

5.2.1.2 WING-BODY SIDE-FORCE COEFFICIENT C_Y AT ANGLE OF ATTACK

The wing-body side force developed at combined angles is nonlinear with respect to both sideslip and angle of attack due to viscous cross-flow effects and cross-coupling of upwash and sidewash velocities. To obtain the sideslip derivative $C_{Y_{\beta_{WB}}}$ it is recommended that $C_{Y_{WB}}$ be calculated at several angles of attack for a small sideslip angle ($\beta \leq 4^\circ$). Then at each angle of attack the side force is assumed linear with sideslip for small values of β so that

$$C_{Y_{\beta_{WB}}} \approx \frac{C_{Y_{WB}}}{\beta} .$$

A. SUBSONIC

No method is presently available for determining the viscous cross-flow effects and cross-coupling of upwash and sidewash velocities at angles of attack and subsonic speeds.

The method presented herein is restricted to first-order approximations at relatively low angles of attack.

DATCOM METHOD

It is recommended that the method of paragraph A of Section 5.2.1.1 be used in the linear-lift angle-of-attack region.

B. TRANSONIC

The comments of paragraph A for the subsonic case also apply to wing-body combinations at combined angles and transonic speeds.

DATCOM METHOD

It is recommended that the method of paragraph B of Section 5.2.1.1 be used in the linear-lift angle-of-attack region.

C. SUPERSONIC

Although higher order slender-body solutions which account for cross-coupling of upwash and sidewash velocities at supersonic speeds are presently unavailable, an approximate method is developed in reference 1 which accounts for the effects of angle of attack on wing-body interference.

Two types of interference forces are considered significant at combined sideslip and angle of attack. One effect is due to the influence of the forebody on cross flow. The resulting asymmetric wing loading causes interference pressures on the sides of the body that increase the body side force. The other effect is produced by the wing inhibiting the viscous cross flow occuring along the body at large angles of attack. This phenomenon is termed "viscous cross-flow suppression" in that it reduces the body side force. No attempt is made to estimate the magnitude of wing sweepback effects on wing-body interference and the effect of body vortices on wing-body interference is considered negligible.

DATCOM METHOD

The method presented in this Section for estimating the wing-body side-force coefficient is that of reference 1. The determination of the body-alone contribution is adapted from the method of reference 2 which is discussed in Section 4.2.1.2. For combined angles the method is valid only for circular bodies. In addition reference 1 specifies that the wing leading edge be supersonic. But fair accuracy is obtained for configurations with subsonic leading edges when the aspect ratio is not too low. The wing-alone contribution to side force is usually very small and is therefore neglected.

Reference 1 gives two expressions for wing-body interference effects, one for midwing and one for tangent-wing configurations. The forebody cross-flow effect is zero for the midwing case since the wing plane then coincides with a body-alone cross-flow streamline and no change in cross flow takes place. Therefore, the midwing case is based on the premise that the sole effect of the wing is to inhibit the nonlinear effects of the viscous body cross flow.

The wing-body contribution to the side-force coefficient at combined sideslip and angle of attack is given by

$$C_{Y_{WB}} = C_{Y_B} + C_{Y_{W(B)}} \qquad 5.2.1.2\text{-a}$$

where C_{Y_B} is the body-alone side-force contribution given by

$$C_{Y_B} = -\frac{S_B}{S_W} 2\beta - c_{d_c} \frac{S_{B_S}}{S_W} \beta\alpha' \qquad 5.2.1.2\text{-b}$$

where

$\frac{S_B}{S_W}$ is the ratio of the body frontal area to the total wing area

β is the sideslip angle in radians

c_{d_c} is the cross-flow drag coefficient, obtained from figure 4.2.1.2-23b, with $M_c = M_\infty \sin \alpha'$

$\frac{S_{B_S}}{S_W}$ is the ratio of the body side area to the total wing area

α' is the angle of inclination, $\alpha' = \sqrt{\alpha^2 + \beta^2}$, in radians

$C_{Y_{W(B)}}$ is the side-force contribution of the wing due to the presence of the body, given by

$$C_{Y_{W(B)}} = -2\eta_B K_{W(B)} k(\alpha) \frac{S_B}{S_W} \beta - \frac{c_{d_c} c_{r_e} d}{S_W} \beta(\beta - \alpha') \qquad 5.2.1.2\text{-c}$$

where the first term on the right-hand side is the forebody cross-flow effect and is taken as zero for the midwing case, and the second term on the right-hand side is an approximate effect of the wing inhibiting the viscous cross flow occuring along the body at large angles of attack.

η_B is the Mach number correction to the wing-body interference coefficient, from figure 5.2.1.2-7

$K_{W(B)}$ is the wing-body interference coefficient, or apparent-mass ratio, from figure 5.3.1.1-25oo. For wing positions other than midwing ($K_{W(B)} = 0$) or tangent, a nonlinear interpolation is described in Method 3, paragraph A, Section 5.3.1.1.

$k(\alpha)$ is the angle-of-attack correction to the wing-body interference coefficient. Values of this parameter for high- and low-tangent wings are presented in figure 5.2.1.2-8. For wing positions other than midwing ($k(\alpha) = 0$) or tangent, a nonlinear interpolation is described in Method 3, paragraph A, Section 5.3.1.1.

d is the average body diameter at the exposed wing root

c_{r_e} is the exposed root chord of the wing

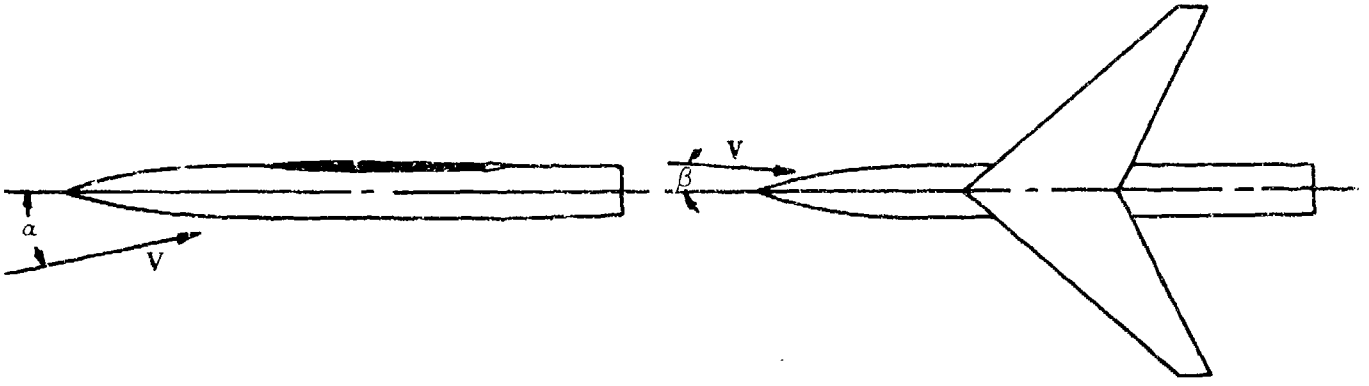
Values for the incremental coefficient resulting from the addition of wings in the mid- and high- and low-tangent positions on circular bodies, calculated using equation 5.2.1.2-c, are compared with experimental results in figure 5.2.1.2-5.

The incremental coefficient resulting from the addition of a wing in the midbody position is presented in figure 5.2.1.2-5a. The Datcom method does not account for additional differential load on the body resulting from unequal panel loading occuring with yawed sweptback wings. This neglected effect, in conjunction with the approximate account of viscous cross-flow suppression may account for the lack of better agreement between experimental and calculated results at higher angles of attack.

The incremental coefficient resulting from the addition of sweptback wings in the high- and low-tangent positions on a body are presented in figure 5.2.1.2-5b through -5d. The agreement between experimental and calculated values is surprisingly good in view of the fact that the angle-of-attack correction to the wing-body interference coefficient, $k(\alpha)$, applies strictly to unswept two-dimensional wings. The additional differential load on the body occuring with yawed sweptback wings tends to compensate for the reduction in $k(\alpha)$ resulting from wing sweepback.

Sample Problem

Given: The wing-body configuration of reference 3. Find the side-force coefficient developed by the wing-body combination at $\alpha = 12^\circ$ and $\beta = 4^\circ$.



Wing Characteristics

High-tangent wing	$S_W = 144.0$ sq in.	$b_W = 24.0$ sq in.	$c_{r_e} = 8.90$ in.

Body Characteristics

Ogive-cylinder body	$d = 3.33$ in.	$S_B = 8.70$ sq in.	$S_{B_S} = 110.0$ sq in.

Additional Characteristics

$M_\infty = 2.01$	$\alpha = 12^\circ = 0.209$ rad	$\beta = 4^\circ = 0.070$ rad

$\alpha' = \sqrt{\alpha^2 + \beta^2} = 12.65$ deg $= 0.221$ rad

Compute:

Body-along contribution

$M_c = M_\infty \sin \alpha' = 2.01 \sin 12.56^\circ = 0.440$

$c_{d_c} = 1.30$ (figure 4.2.1.2-23b)

$$C_{Y_B} = -\frac{S_B}{S_W} 2\beta - c_{d_c} \frac{S_{B_S}}{S_W} \beta\alpha' \qquad \text{(equation 5.2.1.2-b)}$$

$$= -\frac{8.70}{144.0} (2)(0.070) - (1.30) \frac{110.0}{144.0} (0.070)(0.221)$$

$= -0.0238$ (based on S_W)

Wing interference contribution

$$\sqrt{M^2 - 1} \frac{d}{c_{r_e}} = \sqrt{(2.01)^2 - 1} \left(\frac{3.33}{8.90}\right) = 0.651$$

$\eta_B = 0.81$ (figure 5.2.1.2-7)

$$\frac{d}{b_W} = \frac{3.33}{24.0} = 0.139$$

$K_{W(B)}$ = 1.22 (figure 5.3.1.1-25oo)

$$\frac{c_{r_e}}{d} = \frac{8.90}{3.33} = 2.67$$

$k(\alpha)$ = 2.27 (figures 5.2.1.2-8d, 5.2.1.2-8e, and 5.2.1.2-8f by interpolation)

$$C_{Y_{W(B)}} = -2\eta_B K_{W(B)} k(\alpha) \frac{S_B}{S_W}\beta - \frac{c_{d_c} c_{r_e} d}{S_W}\beta(\beta - \alpha') \qquad \text{(equation 5.2.1.2-c)}$$

$$= -2(0.81)(1.22)(2.27)\frac{8.70}{144.0}(0.070) - \frac{(1.30)(8.90)(3.33)(0.70)(0.070 - 0.221)}{144.0}$$

$$= -0.0162 \text{ (based on } S_W)$$

Solution:

$$C_{Y_{WB}} = C_{Y_B} + C_{Y_{W(B)}} \qquad \text{(equation 5.2.1.2-a)}$$

$$= -0.0238 - 0.0162$$

$$= -0.0400 \text{ (based on } S_W)$$

This compares with an experimental value (based on S_W) of $C_{Y_{WB}} = -0.0480$ from reference 3.

A comparison between calculated and experimental results for this configuration at sideslip angles of 2, 4, and 8 degrees and over an angle-of-attack range to 16 degrees is presented in figure 5.2.1.2-6.

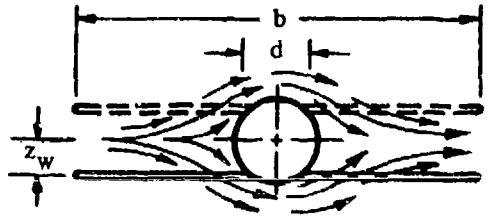
5.2.2 WING-BODY SIDESLIP DERIVATIVE C_{l_β}

5.2.2.1 WING-BODY SIDESLIP DERIVATIVE C_{l_β} IN THE LINEAR ANGLE-OF-ATTACK RANGE

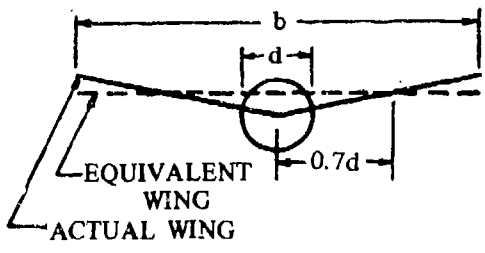
A. SUBSONIC

The addition of a body to a wing in sideslip is shown experimentally to change the wing rolling moment in two ways. First, there is the well known change in effective dihedral as a function of wing height on the body. This occurs because the cross flow around the body induces changes in the local angle of attack of the wing (see sketch (a)). The resulting change in lift distribution has a significant influence on C_{l_β}. The simplified expression presented in the Datcom for determining the body-induced effect on wing height is based on a fuselage of circular cross section, and is presented in such sources as references 1 and 2. The sign of the value of this effect is dependent upon whether the wing is located above or below the center line of the fuselage. A high location of the wing results in more positive effective dihedral and a low location results in less positive effective dihedral than a midwing location.



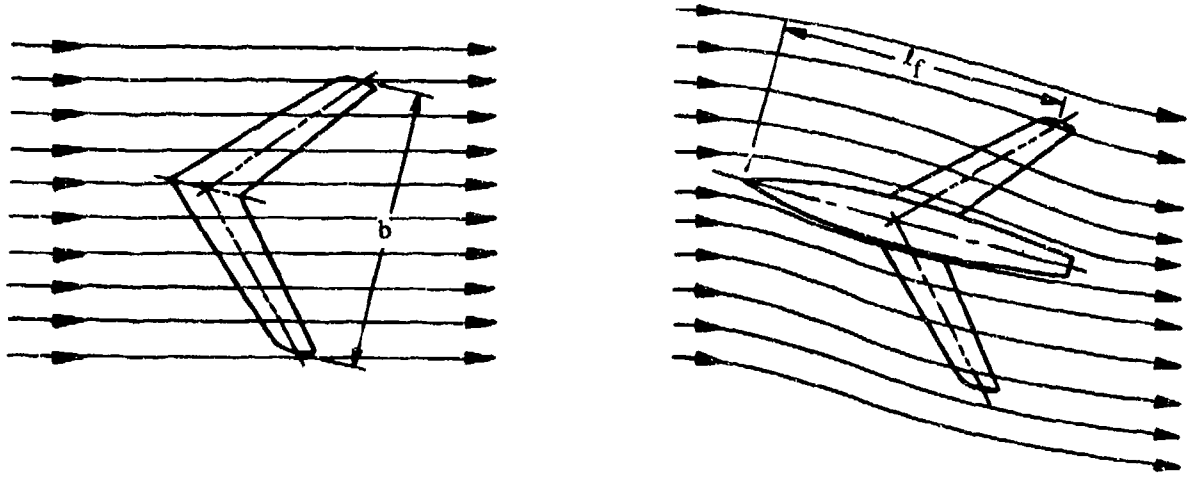
SKETCH (a)

For wings with geometric dihedral, the body-induced effect on wing height must be modified, since the vertical position of the wing relative to the fuselage varies along the span (see sketch (b)). The method presented in the Datcom to account for this modification is taken from reference 3. The method is applicable only for wings with dihedral that intersect the vertical plane of symmetry of a body of circular cross section at or near the midfuselage height. In reference 3 the wing with dihedral is replaced with a wing without dihedral at some effective height relative to the fuselage, and the fuselage flow effect for the equivalent wing is then evaluated. The vertical position of the equivalent wing was taken to coincide with the wing with dihedral at the spanwise position equal to 0.7d.



SKETCH (b)

The second fuselage effect on rolling moment is a decrease in wing-body positive effective dihedral with increasing fuselage length. This effect is discussed in reference 3, where it is suggested that this may be the result of the fuselage reducing the wing effective sideslip angle (see sketch (c)).



SKETCH (c)

In reference 3 an empirical study of limited scope shows that the fuselage effects may be correlated as a function of the ratio of fuselage length ahead of the wing-tip half-chord point and the wing span $\frac{l_f}{b}$

More extensive studies indicate that the parameter $\frac{A}{\cos \Lambda_{c/2}}$ is also important. There may be additional parameters, such as the ratio of the body diameter to wing span and fuselage cross-sectional shape that also exert an influence. The design chart presented herein is limited to the parameters $\frac{l_f}{b}$ and $\frac{A}{\cos \Lambda_{c/2}}$, and is based on experimental data from configurations employing fuselages of circular cross section.

The increments in C_{l_β} due to the body-induced effects on wing height and the effect of fuselage length have been derived for configurations with fuselages of circular cross section. Not enough test data exist to determine any effect the fuselage cross-sectional shape may have on the fuselage-length parameter. On the other hand, both theory and experiment indicate that the body-induced effects on wing height are strongly influenced by the cross-sectional shape of the fuselage.

It is suggested that for non-body-of-revolution configurations the equivalent diameter be used in determining the increments in C_{l_β} due to the body induced effects on wing height.

The subsonic method is valid for configurations with straight-tapered wings for sideslip angles between -5^o and $+5^o$ at speeds up to the force-break Mach number and at low angles of attack. The

fuselage-effect parameters do not include the effect of either nonuniform geometric dihedral or non-straight-tapered planforms.

DATCOM METHOD

The rolling moment due to sideslip, based on the product of the wing area and span Sb, for straight-tapered wing-body combinations at low angles of attack is given by

$$C_{l_\beta} = C_L \left[\left(\frac{C_{l_\beta}}{C_L} \right)_{\Lambda_{c/2}} K_{M_\Lambda} K_f + \left(\frac{C_{l_\beta}}{C_L} \right)_A \right] + \Gamma \left[\frac{C_{l_\beta}}{\Gamma} K_{M_\Gamma} + \frac{\Delta C_{l_\beta}}{\Gamma} \right]$$

$$+ \left(\Delta C_{l_\beta} \right)_{z_W} + \theta \tan \Lambda_{c/4} \left(\frac{\Delta C_{l_\beta}}{\theta \tan \Lambda_{c/4}} \right) \text{ (per degree)} \qquad 5.2.2.1\text{-a}$$

where

C_L is the wing-body lift coefficient.

$\left(\frac{C_{l_\beta}}{C_L} \right)_{\Lambda_{c/2}}$ is the wing-sweep contribution obtained from paragraph A of Section 5.1.2.1 (figure 5.1.2.1-27)

K_{M_Λ} is the compressibility correction to the sweep contribution obtained from paragraph A of Section 5.1.2.1 (figure 5.1.2.1-28a)

K_f is the empirical fuselage-length-effect correction factor obtained from figure 5.2.2.1-26.

$\left(\frac{C_{l_\beta}}{C_L} \right)_A$ is the aspect ratio contribution obtained from paragraph A of Section 5.1.2.1 (figure 5.1.2.1-28b)

Γ is the geometric dihedral angle in degrees, positive for the wing tip above the plane of the root chord.

$\frac{C_{l_\beta}}{\Gamma}$ is the wing dihedral effect for uniform geometric dihedral obtained from paragraph A of Section 5.1.2.1 (figure 5.1.2.1-29).

K_{M_Γ} is the compressibility correction factor to the dihedral effect obtained from paragraph A of Section 5.1.2.1 (figure 5.1.2.1-30a).

$\frac{\Delta C_{l_\beta}}{\Gamma}$ is the body-induced effect on wing height due to uniform geometric dihedral given by*

$$\frac{\Delta C_{l_\beta}}{\Gamma} = -0.0005 \sqrt{A} \left(\frac{d}{b}\right)^2 \quad \text{(per degree}^2\text{)} \qquad 5.2.2.1\text{-b}$$

where d/b is the average fuselage diameter at the wing root divided by the wing span. For non-body-of-revolution configurations, the average equivalent diameter at the wing root should be used, where $(d_{equiv})_{av} = \sqrt{\frac{\text{average cross-sectional area}}{0.7854}}$

$\left(\Delta C_{l_\beta}\right)_{z_W}$ is the increment in C_{l_β} due to the body-induced effect on wing height for configurations with wings located above or below the midfuselage height. This increment is given by

$$\left(\Delta C_{l_\beta}\right)_{z_W} = \frac{1.2\sqrt{A}}{57.3}\left(\frac{z_W}{b}\right)\left(\frac{2d}{b}\right) \quad \text{(per degree)} \qquad 5.2.2.1\text{-c}$$

where

$\frac{z_W}{b}$ is the vertical distance from the center line of the fuselage to the quarter-chord point of the root chord divided by the wing span, positive for the wing located below the center line of the fuselage.

$\frac{d}{b}$ is defined under equation 5.2.2.1-b

$\frac{\Delta C_{l_\beta}}{\theta \tan \Lambda_{c/4}}$ is the wing-twist correction factor obtained from paragraph A of Section 5.1.2.1 (figure 5.1.2.1-30b).

θ is the wing twist between the root and tip sections in degrees, negative for washout (see figure 5.1.2.1-30b).

For the case of a wing with dihedral mounted on a body at a location other than at or near the midfuselage height, both the modification of the body-induced effect on wing height due to dihedral (equation 5.2.2.1-b) and the body-induced effect on wing height (equation 5.2.2.1-c) should be considered.

A comparison of test values with results calculated by using the Datcom method for wing-body configurations without dihedral and with the wings mounted at the midufselage location is presented as table 5.2.2.1-A. Comparisons of test values with results calculated by using the Datcom method for the effects of dihedral and wing height are presented in tables 5.2.2.1-B and 5.2.2.1-C, respectively.

*Equation 5.2.2.1-b is derived by replacing z_W in equation 5.2.2.1-c with the expression for the height above the fuselage center line of an equivalent wing at a height corresponding to the height of the .0.7d spanwise station of a wing with dihedral (see sketch (b)).

Test data are not available to permit substantiation of the effect of wing twist on the wing-body rolling moment due to sideslip.

Sample Problem

1. Midwing, no dihedral, no twist

Given: The wing-body configuration of reference 8 designated 60-4-0.6-006.

$A = 4.0$ $\quad \lambda = 0.6$ $\quad \Lambda_{c/2} = 59.08^{o}$ $\quad b = 36.0$ in. $\quad \ell_f = 49.58$ in.

$z_w = 0$ (midwing) $\quad \Gamma = 0$ $\quad \theta = 0$ $\quad M = 0.60$

Body of revolution

Compute:

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2}} = -0.00723 \text{ per deg} \quad \text{(figure 5.1.2.1-27)}$$

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{A} = -0.00180 \text{ per deg} \quad \text{(figure 5.1.2.1-28b)}$$

$M \cos \Lambda_{c/2} = (0.60) \cos 59.08^{o} = 0.308$

$A/\cos \Lambda_{c/2} = 4.0/\cos 59.08^{o} = 7.785$

$K_{M_\Lambda} = 1.02$ (figure 5.1.2.1-28a)

$\ell_f/b = 49.58/36.0 = 1.377$

$K_f = 0.685$ (figure 5.2.2.1-26)

Solution:

$$C_{l_\beta} = C_L \left[\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2}} K_{M_\Lambda} K_f + \left(\frac{C_{l_\beta}}{C_L}\right)_{A}\right] \text{(equation 5.2.2.1-a)}$$

$$= C_L \left[(-0.00723)(1.02)(0.685) + (-0.00180)\right]$$

$$= C_L \left[-0.00505 - 0.00180\right]$$

$$\frac{C_{l_\beta}}{C_L} = -0.00685 \text{ per deg}$$

This result compares with a test value of −0.0074 per degree from reference 8.

2. High wing, dihedral, no twist

Given: A wing-body configuration of reference 16.

$A = 6.383$ $\lambda = 1.0$ $\Lambda_{c/2} = 0$ $b = 60.0$ in. $\ell_f = 15.7$ in.

$d = 6.70$ in. (average over root chord) $z_W = -2.66$ in. (high wing)

$\Gamma = 5^o$ $\theta = 0$ $M = 0.105$ Body of revolution

Compute:

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2}} = 0 \quad \text{(figure 5.1.2.1-27)}$$

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{M} = -0.0013 \text{ per deg} \quad \text{(figure 5.1.2.1-28b)}$$

$M \cos \Lambda_{c/2} = (0.105)(\cos 0) = 0.105$

$A/\cos \Lambda_{c/2} = 6.383/(\cos 0) = 6.383$

$K_{M_A} = 1.0$ (figure 5.1.2.1-28a)

$\ell_f/b = 15.7/60.0 = 0.262$

$K_f = 1.0$ (figure 5.2.2.1-26)

Determine dihedral-effect parameters

Geometric dihedral

$$\frac{C_{l_\beta}}{\Gamma} = -0.000224 \text{ per deg}^2 \quad \text{(figure 5.1.2.1-29)}$$

$$K_{M_\Gamma} = 1.0 \quad \text{(figure 5.1.2.1-30a)}$$

Body-induced effect on wing height due to dihedral

$$\frac{\Delta C_{l_\beta}}{\Gamma} = -0.0005 \sqrt{A} \left(\frac{d}{b}\right)^2 \qquad \text{(equation 5.2.2.1-b)}$$

$$= -0.0005 \sqrt{6.383} \left(\frac{6.7}{60}\right)^2$$

$$= -0.000016 \quad \text{per deg}^2$$

Determine the effect of wing height

$$z_w/b = -2.66/60.0 = -0.0443$$

$$2d/b = 2(6.70)/60.0 = 0.223$$

$$\Delta C_{l_{\beta_{z_w}}} = \frac{1.2\sqrt{A}}{57.3} \left(\frac{z_w}{b}\right)\left(\frac{2d}{b}\right) \qquad \text{(equation 5.2.2.1-c)}$$

$$= \frac{1.2\sqrt{6.383}}{57.3} (-0.0443)(0.233)$$

$$= -0.000547 \quad \text{per deg}$$

Solution:

$$C_{l_\beta} = C_L \left[\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2}} K_{M_\Lambda} K_f + \left(\frac{C_{l_\beta}}{C_L}\right)_A\right] + \Gamma\left[\frac{C_{l_\beta}}{\Gamma} K_{M_\Gamma} + \frac{\Delta C_{l_\beta}}{\Gamma}\right]$$

$$+ \Delta C_{l_{\beta_{z_w}}} \qquad \text{(equation 5.2.2.1-a)}$$

Midwing, no dihedral

$$\frac{C_{l_\beta}}{C_L} = \left[\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2}} K_{M_\Lambda} K_f + \left(\frac{C_{l_\beta}}{C_L}\right)_A\right]$$

$$= [(0)(1.0)(1.0) + (-0.0013)]$$

$$= -0.0013 \text{ per deg}$$

Dihedral effect

$$\Gamma\left[\frac{C_{l_\beta}}{\Gamma}\ K_{M_\Gamma} + \frac{\Delta C_{l_\beta}}{\Gamma}\right] = (5.0)\,[(-0.000224)\,(1.0) + (-0.000016)] = -0.0012 \text{ per deg}$$

This compares with a test value of −0.00115 per degree from reference 16.

Wing-height effect

$$\left(\Delta C_{l_\beta}\right)_{z_W} = -0.000547 \text{ per deg}$$

This compares with a test value of −0.00053 per degree from reference 16.

B. TRANSONIC

Test data show that the variation of wing-body rolling moment due to sideslip is similar to that of the lift-curve slope. This correspondence should be expected, since C_{l_β} has been treated by using effective lift-curve slopes in reference 3.

The similarity in Mach number characteristics between rolling moment and lift-curve slope suggests a transonic interpolation method, based on lift-curve slope, for calculating rolling moment. An interpolation equation is presented that is based on the square of the lift-curve-slope values at the force-break Mach number M_{fb} and at M = 1.4.

Since no reliable method exists for predicting the variation of the wing-body lift-curve slope with Mach number over the transonic speed range, wing-alone lift-curve slopes are used in the Datcom method. For slender wing-body configurations, the aerodynamic interference effects are relatively insensitive to Mach number, and the use of the wing-alone lift-curve-slope values in the interpolation method should give satisfactory results. However, for nonslender configurations transonic interference effects can become quite large and sensitive to minor changes in local contour. For these configurations the interpolation method cannot be expected to provide satisfactory results unless wing-body test values of the lift-curve slope are used.

The method is limited to configurations with straight-tapered wings and is applicable over the sideslip-angle range of $\beta = \pm 5^o$.

DATCOM METHOD

The wing-body rolling moment due to sideslip of straight-tapered wing-body configurations, based on the product of the wing area and span Sb, may be approximated through the transonic region from M_{fb} to M = 1.4 by means of the interpolation formula

$$\frac{C_{l_\beta}}{C_L} = \left\{ \left[\frac{\left(\frac{C_{l_\beta}}{C_N}\right)_{M=1.4} - \left(\frac{C_{l_\beta}}{C_L}\right)_{M_{fb}}}{\left(C_{N_\alpha}{}^2\right)_{M=1.4} \left(C_{L_\alpha}{}^2\right)_{M_{fb}}} \right] \left(\frac{M - M_{fb}}{1.4 - M_{fb}}\right) + \frac{\left(\frac{C_{l_\beta}}{C_L}\right)_{M_{fb}}}{\left(C_{L_\alpha}{}^2\right)_{M_{fb}}} \right\} \left(C_{L_\alpha}{}^2\right)_M \quad \text{(per degree)} \qquad 5.2.2.1\text{-d}$$

where

$\left(\frac{C_{l_\beta}}{C_L}\right)_{M_{fb}}$ is the wing-body sideslip-derivative slope at the force-break Mach number M_{fb}, obtained by using the method of paragraph A. The force-break Mach number is defined in paragraph B of Section 4.1.3.2.

$\left(\frac{C_{l_\beta}}{C_N}\right)_{M=1.4}$ is the wing-body sideslip-derivative slope $M = 1.4$, obtained by using the method of paragraph C.

$\left(C_{L_\alpha}{}^2\right)_{M_{fb}}$ is the square of the wing-alone lift-curve slope at M_{fb}, obtained by using the method of paragraph B of Section 4.1.3.2.

$\left(C_{N_\alpha}{}^2\right)_{M=1.4}$ is the square of the wing-alone normal-force-curve slope at $M = 1.4$, obtained by using the straight-tapered-wing method of paragraph C of Section 4.1.3.2.

$\left(C_{L_\alpha}{}^2\right)_M$ is the square of the wing-alone lift-curve slope at pre-determined Mach numbers, obtained by using the methods of paragraphs B and C of Section 4.1.3.2. The pre-determined Mach numbers consist of those at the end points of the method ($M = M_{fb}$ and $M = 1.4$) and two intermediate Mach numbers defined in paragraph B of Section 4.1.3.2 as $M_a = M_{fb} + 0.007$ and $M_b = M_{fb} + 0.14$.

The increments in C_{l_β} due to fuselage transverse flow and wing height may be approximated by equations 5.2.2.1-b and 5.2.2.1-c, respectively.

Equation 5.1.2.1-d for determining the effect of geometric dihedral at supersonic speeds is also applicable at transonic speeds. However, no known method exists for determining transonic values of C_{l_p} required for this method. It is suggested that reference be made to table 7-A for transonic C_{l_p} test data.

If test data are not available the supersonic method of paragraph C of Section 7.1.2.2 should be used to approximate C_{l_p}.

Sample Problem

Given: A wing-body configuration of reference 6.

Wing Characteristics:

$A = 2.0$ $\lambda = 0$ $\Lambda_{LE} = 63.4^{o}$ $\Lambda_{TE} = 0$ $\Lambda_{c/2} = 45^{o}$

$b = 34.0$ in. $S_W = 578.0$ sq in. $z_W = 0$ (midwing)

NACA 0005-63 airfoil $\theta = 0$ $\Gamma = 0$ $t/c = 0.05$

Body of revolution

Body Characteristics:

$d = 6.12$ in. $\ell_f = 55.12$ in.

Additional Characteristics:

$\kappa = 1.0$ (assumed) $M_{fb} < M < 1.4$

Compute:

Determine M_{fb}, M_a, M_b, $(C_{L_\alpha})_{M_{fb}}$, $(C_{L_\alpha})_{M_a}$, and $(C_{L_\alpha})_{M_b}$ (paragraph B, Section 4.1.3.2).

$(M_{fb})_{\Lambda=0} = 1.0$ (figure 4.1.3.2-53a)

$(M_{fb})_{\Lambda} = 1.0$ (figure 4.1.3.2-53b)

$(C_{L_\alpha})_{fb}$

$$\beta_{fb} = \sqrt{M_{fb}^{\ 2} - 1} = 0$$

$$\frac{A}{\kappa}\left[(\beta_{fb})^2 + \tan^2 \Lambda_{c/2}\right]^{1/2} = \frac{2.0}{1.0}\left[(0) + (1)\right]^{1/2} = 2.0$$

$$\frac{\left[(C_{L_\alpha})_{M_{fb}}\right]_{theory}}{A} = 1.30 \text{ per rad} \quad \text{(figure 4.1.3.2-49)}$$

$$\left[(C_{L_\alpha})_{M_{fb}}\right]_{theory} = (1.30)(2) = 2.60 \text{ per rad}$$

$$\frac{\left(C_{L_\alpha}\right)_{M_{fb}}}{\left[\left(C_{L_\alpha}\right)_{M_{fb}}\right]_{theory}} = 1.08 \quad \text{(figure 4.1.3.2-54a)}$$

$$\left(C_{L_\alpha}\right)_{M_{fb}} = (2.60)\,(1.08) = 2.81 \text{ per rad} = 0.049 \text{ per deg}$$

$$M_a = M_{fb} + 0.07 = 1.07$$

$$\left(C_{L_\alpha}\right)_{M_a}$$

$$\frac{a}{c} = -0.07 \quad \text{(figure 4.1.3.2-54b)}$$

$$\left(C_{L_\alpha}\right)_{M_a} = \left(1 - \frac{a}{c}\right)\left(C_{L_\alpha}\right)_{M_{fb}}$$

$$= [1 - (-0.07)]\,(2.81) = 3.00 \text{ per rad} = 0.0524 \text{ per deg}$$

$$M_b = M_{fb} + 0.14 = 1.14$$

$$\left(C_{L_\alpha}\right)_{M_b}$$

$$\frac{b}{c} = 0.11 \quad \text{(figure 4.1.3.2-54c)}$$

$$\left(C_{L_\alpha}\right)_{M_b} = \left(1 - \frac{b}{c}\right)\left(C_{L_\alpha}\right)_{M_{fb}}$$

$$= [1 - (0.11)]\,(2.86) = 2.55 \text{ per rad} = 0.0444 \text{ per deg}$$

Determine $\left(C_{N_\alpha}\right)_{M=1.4}$ (paragraph C, Section 4.1.3.2)

$$\beta = \sqrt{M^2 - 1} = 0.98$$

$$\beta/\tan \Lambda_{LE} = 0.98/\tan 63.4^\circ = 0.491$$

$$\tan \Lambda_{TE}/\tan \Lambda_{LE} = 0$$

$$\frac{\left(C_{N_\alpha}\right)_{theory}}{A} = 1.31 \text{ per rad} \quad \text{(figure 4.1.3.2-63)}$$

$$\left(C_{N_\alpha}\right)_{\text{theory}} = (1.31)\,(2) = 2.62 \text{ per rad}$$

$\Delta y_\perp = 1.37$ (figure 2.2.1-8)

$$\frac{C_{N_\alpha}}{\left(C_{N_\alpha}\right)_{\text{theory}}} = 1.0 \quad \text{(figure 4.1.3.2-60)}$$

$$\left(C_{N_\alpha}\right)_{M=1.4} = (1.0)\,(2.62) = 2.62 \text{ per rad} = 0.0457 \text{ per deg}$$

Determine $\left(\frac{C_{l_\beta}}{C_L}\right)_{M_{fb}}$ and $\left(\frac{C_{l_\beta}}{C_L}\right)_{M=1.4}$

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{M_{fb}}$$

$\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2}} = -0.0035$ per deg (figure 5.1.2.1-27)

$\left(\frac{C_{l_\beta}}{C_L}\right)_{A} = -0.0022$ per deg (figure 5.1.2.1-28b)

$M_{fb} \cos \Lambda_{c/2} = (1.0)\,(\cos 45^{O}) = 0.7071$

$$\frac{A}{\cos \Lambda_{c/4}} = \frac{2}{0.7071} = 2.83$$

$K_{M_\Lambda} = 1.015$ (figure 5.1.2.1-28a)

$\ell_f/b = 55.12/34.0 = 1.62$

$K_f = 1.0$ (figure 5.2.2.1-26)

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{M_{fb}} = \left[\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2}} K_{M_\Lambda}\, K_f + \left(\frac{C_{l_\beta}}{C_L}\right)_{A}\right] \quad \text{(equation 5.2.2.1-a)}$$

$$= [(-0.0035)\ (1.015)\ (1.0) + (-0.0022)]$$

$$= -0.00575 \text{ per deg}$$

$$\left(\frac{C_{l_\beta}}{C_N}\right)_{M=1.4}$$

$$\left(\frac{C_{l_\beta}}{C_N}\right)_{M=1.4} = -0.061\ \frac{C_{N_\alpha}}{57.3}\left[1 + \lambda(1 + \Lambda_{LE})\right]\left(1 + \frac{\Lambda_{LE}}{2}\right)\left(\frac{\tan \Lambda_{LE}}{\beta}\right) \cdot$$

$$\left[\frac{M^2 \cos^2 \Lambda_{LE}}{A} + \left(\frac{\tan \Lambda_{LE}}{4}\right)^{4/3}\right] \quad \text{(equation 5.2.2.1-e)}$$

$$= -0.061\ \frac{2.62}{57.3}\ [1 + 0]\left(1 + \frac{63.4/57.3}{2}\right)\left(\frac{\tan 63.4^\circ}{0.98}\right) \cdot$$

$$\left[\frac{(1.4)^2 \cos^2 63.4^\circ}{2.0} + \left(\frac{\tan 63.4^\circ}{4}\right)^{4/3}\right]$$

$$= -0.061\ (0.0457)[1](1 + 0.5532)\ (2.038)[0.1965 + (0.3965)]$$

$$= -0.00523 \text{ per deg}$$

Solution:

$$\frac{C_{l_\beta}}{C_L} = \left\{\left[\frac{\left(\frac{C_{l_\beta}}{C_N}\right)_{M=1.4}}{\left(C_{N_\alpha}{}^2\right)_{M=1.4}} - \frac{\left(\frac{C_{l_\beta}}{C_L}\right)_{M_{fb}}}{\left(C_{L_\alpha}{}^2\right)_{M_{fb}}}\right]\left(\frac{M - M_{fb}}{1.4 - M_{fb}}\right) + \frac{\left(\frac{C_{l_\beta}}{C_L}\right)_{M_{fb}}}{\left(C_{L_\alpha}{}^2\right)_{M_{fb}}}\right\}\left(C_{L_\alpha}{}^2\right)_M$$

(equation 5.2.2.1-d)

$$= \left\{\left[\frac{(-0.00523)}{(0.0457)^2} - \frac{(-0.00575)}{(0.049)^2}\right]\left(\frac{M - 1.0}{1.4 - 1.0}\right) + \frac{(-0.00575)}{(0.049)^2}\right\}\left(C_{L_\alpha}{}^2\right)_M$$

$$= \left\{[-0.10]\left(\frac{M - 1.0}{0.4}\right) - 2.309\right\}\left(C_{L_\alpha}{}^2\right)_M$$

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{M_a=1.07}$$

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{M_a=1.07} = \left\{[-0.100]\left(\frac{1.07-1.0}{0.4}\right) - 2.309\right\}(0.0524)^2$$

$$= \left\{[-0.100]\ (0.175)\ -2.309\right\}(0.002745)$$

$$= -0.00639 \text{ per deg}$$

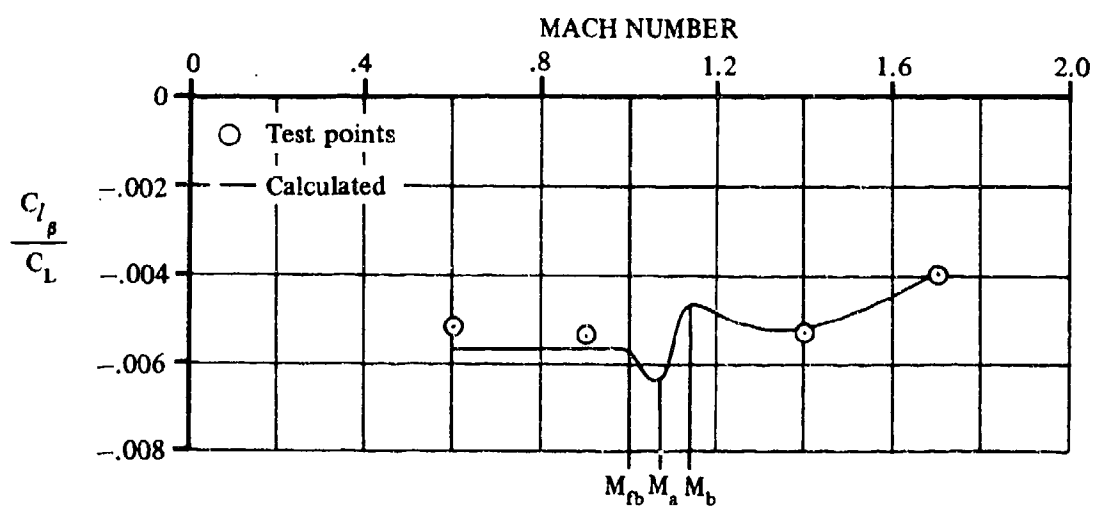
$$\left(\frac{C_{l_\beta}}{C_L}\right)_{M_b=1.14}$$

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{M_b=1.14} = \left\{[-0.100]\left(\frac{1.14-1.0}{0.4}\right) - 2.309\right\}(0.0444)^2$$

$$= \left\{[-0.100]\ (0.350) - 2.309\right\}(0.00197)$$

$$= -0.00462 \text{ per deg}$$

The calculated results are compared with test values in sketch (d). Additional points have been calculated at M = 0.6, 0.9, and 1.7.



SKETCH (d)

C. SUPERSONIC

The present status of supersonic rolling-moment theory is discussed in paragraph C of Section 5.1.2.1. As indicated therein, insufficient experimental data exist at the present time to distinguish between the supersonic rolling moments for wing-alone and for wing-body configurations where the wing is mounted on the fuselage center line. Therefore, for configurations with the wing mounted on the fuselage center line the supersonic wing-alone method of paragraph C is employed.

Experimental data indicate that for wings located at positions other than on the fuselage center line there is a considerable variation in effective dihedral with wing height on the body. Furthermore, the effect of geometric dihedral on the body-induced effect due to wing height, discussed in paragraph A, must also be considered at supersonic speeds. No methods have been developed to account for the body-induced effects on wing height at supersonic speeds. The subsonic methods of paragraph A (equations 5.2.2.1-b and 5.2.2.1-c) are applied at supersonic speeds.

DATCOM METHOD

The supersonic rolling moment due to sideslip for wing-body configurations with straight-tapered wings at low angles of attack and at $M = 1.4$ and higher speeds is approximated by

$$C_{l_\beta} = -0.061\, C_N \frac{C_{N_\alpha}}{57.3}\left[1 + \lambda(1 + \Lambda_{LE})\right]\left(1 + \frac{\Lambda_{LE}}{2}\right)\left(\frac{\tan \Lambda_{LE}}{\beta}\right)\left[\frac{M^2 \cos^2 \Lambda_{LE}}{A} + \left(\frac{\tan \Lambda_{LE}}{4}\right)^{4/3}\right]$$
$$+ \Gamma\left[\frac{C_{l_\beta}}{\Gamma} + \frac{\Delta C_{l_\beta}}{\Gamma}\right] + \Delta C_{l_{\beta_{z_W}}} \quad \text{(per degree)} \qquad 5.2.2.1\text{-e}$$

where

Λ_{LE} is the wing leading-edge sweep in radians.

C_{N_α} is the wing normal-force-curve slope per radian, obtained by using the straight-tapered-wing method of paragraph C of Section 4.1.3.2.

$\frac{C_{l_\beta}}{\Gamma}$ is the wing dihedral effect for uniform geometric dihedral, calculated by using equation 5.1.2.1-d with C_{l_p} (per radian) obtained by using the method of paragraph C of Section 7.1.2.2.

$\frac{\Delta C_{l_\beta}}{\Gamma}$ is the body-induced effect on wing height due to uniform geometric dihedral obtained by using equation 5.2.2.1-b.

$\left(\Delta C_{l_\beta}\right)_{z_W}$ is the increment in C_{l_β} due to the body-induced effect on wing height for configurations with wings located above or below the fuselage center line, obtained by using equation 5.2.2.1-c.

A comparison of test values with results calculated by using the Datcom method for wing-body configurations without dihedral and with wings mounted at the midfuselage location is presented as table 5.2.2.1-D. A comparison of test values with results calculated by using the Datcom method for the effects of dihedral is presented as table 5.2.2.1-E.

It is difficult to assess the validity of the Datcom method for establishing the value of C_{l_β}/C_L, even at small lift coefficients. Test data show that for many configurations the variation of C_{l_β} with C_L at supersonic speeds is nonlinear throughout the lift-coefficient range. Some of the test values listed in table 5.2.2.1-D are questionable, and those configurations for which no test values are listed exhibit nonlinear rolling moment due to sideslip throughout the lift-coefficient range.

Although the data of table 5.2.2.1-E are limited, it appears that the method provides relatively good results for the effect of dihedral on C_{l_β} at supersonic speeds.

Not enough experimental data are available to assess the validity of equation 5.2.2.1-c applied at supersonic speeds for determining the effect of wing vertical location. Equation 5.2.2.1-c has been applied to the configurations of references 19 and 20; the results of these calculations are compared with test values in table 5.2.2.1-F. The calculated values are somewhat less than the test values in all cases.

Sample Problem

Given: The wing-body configuration of reference 19.

Wing Characteristics:

$A = 4.0$ $\quad \lambda = 0.2$ $\quad \Lambda_{LE} = 49.4^\circ$ $\quad \Lambda_{c/2} = 42.5^\circ$

$b = 24.0$ in. $\quad \Gamma = 3^\circ$ $\quad z_w = 0$ (midwing) $\quad$ NASA 65A004 airfoil

Body Characteristics:

$d = 3.33$ in. $\quad d/b = 0.139$ $\quad$ Body of revolution

Additional Characteristics:

$M = 2.01$; $\beta = 1.74$ $\quad C_{N_\alpha} = 2.235$ per rad (test value)

Midwing, no dihedral

Compute:

$$\left(1 + \Lambda_{LE}\right) = 1 + \frac{49.4}{57.3} = 1.862$$

$$[1 + \lambda(1 + \Lambda_{LE})] = [1 + 0.2\,(1.862)] = 1.372$$

$$\left(1 + \frac{\Lambda_{LE}}{2}\right) = \left[1 + \frac{49.4}{2(57.3)}\right] = 1.431$$

$$(\tan \Lambda_{LE}/\beta) = \tan 49.4^{o}/1.74 = 0.6705$$

$$\left[\frac{M^2 \cos^2 \Lambda_{LE}}{A} + \left(\frac{\tan \Lambda_{LE}}{4}\right)^{4/3}\right] = \left[\frac{(2.01)^2 \cos^2 49.4^{o}}{4.0} + \left(\frac{\tan 49.4^{o}}{4}\right)^{4/3}\right] = 0.621$$

Solution:

$$\frac{C_{l_\beta}}{C_N} = -0.061 \frac{C_{N_\alpha}}{57.3} [1 + \lambda(1 + \Lambda_{LE})] \left(1 + \frac{\Lambda_{LE}}{2}\right)\left(\frac{\tan \Lambda_{LE}}{\beta}\right)\left[\frac{M^2 \cos^2 \Lambda_{LE}}{A} + \left(\frac{\tan \Lambda_{LE}}{4}\right)^{4/3}\right]$$

(equation 5.2.2.1-e with $\Gamma = 0$, $z_w = 0$)

$$= -0.061 \frac{2.235}{57.3} [1.372](1.431)(0.6705)[0.621]$$

$$= -0.00195 \text{ per deg}$$

This compares with a test value of −0.0019 per degree from reference 19.

Dihedral effect

Compute:

$$\beta A = (1.74)(4.0) = 6.96$$

$$A \tan \Lambda_{c/2} = (4.0)(\tan 42.5^{o}) = 3.67$$

$$\frac{C_{l_{p\ \text{theory}}}}{A} = -0.0665 \text{ per rad} \quad \text{(figure 7.1.2.2-38, interpolated)}$$

$$\Delta y_\perp = 0.80 \quad \text{(figure 2.2.1-8)}$$

$$\delta_\perp = \tan^{-1} \frac{\Delta y_\perp}{5.85} = \tan^{-1} \frac{0.80}{5.85} = 7.8^{o}$$

$$\frac{C_{l_p}}{(C_{l_p})_{\text{theory}}} = 0.918 \quad \text{(figure 7.1.2.2-40)}$$

$$C_{l_p} = \left[\frac{(C_{l_p})_{\text{theory}}}{A}\right] A \frac{C_{l_p}}{(C_{l_p})_{\text{theory}}} \quad \text{(equation 7.1.2.2-d)}$$

$$= [-0.0665](4.0)(0.918) = -0.244 \text{ per rad}$$

$$\frac{C_{l_\beta}}{\Gamma} = \frac{2}{(57.3)^2}\left(\frac{1+2\lambda}{1+3\lambda}\right)C_{l_p} \quad \text{(equation 5.1.2.1-d)}$$

$$= \frac{2}{(57.3)^2}\left(\frac{1.4}{1.6}\right)(-0.244) = -0.000130 \text{ per deg}^2$$

$$\frac{\Delta C_{l_\beta}}{\Gamma} = -0.0005\sqrt{A}\left(\frac{d}{b}\right)^2 \quad \text{(equation 5.2.2.1-b)}$$

$$= -0.0010\sqrt{4.0}\left(\frac{3.33}{24}\right)^2$$

$$= -0.0000193 \text{ per deg}^2$$

Solution:

$$\Gamma\left(\frac{C_{l_\beta}}{\Gamma} + \frac{\Delta C_{l_\beta}}{\Gamma}\right) \quad \text{(dihedral effect term of equation 5.2.2.1-e)}$$

$$3.0\,[-0.000130 + (-0.0000193)] = -0.000448 \text{ per deg}$$

This compares with a test value of −0.00046 per degree from reference 19.

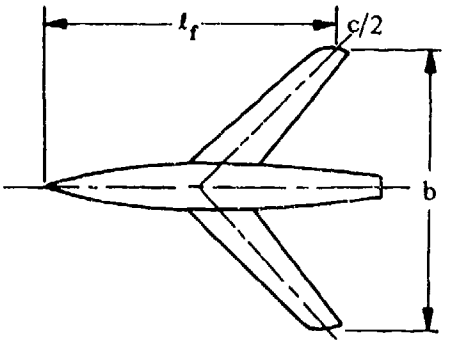

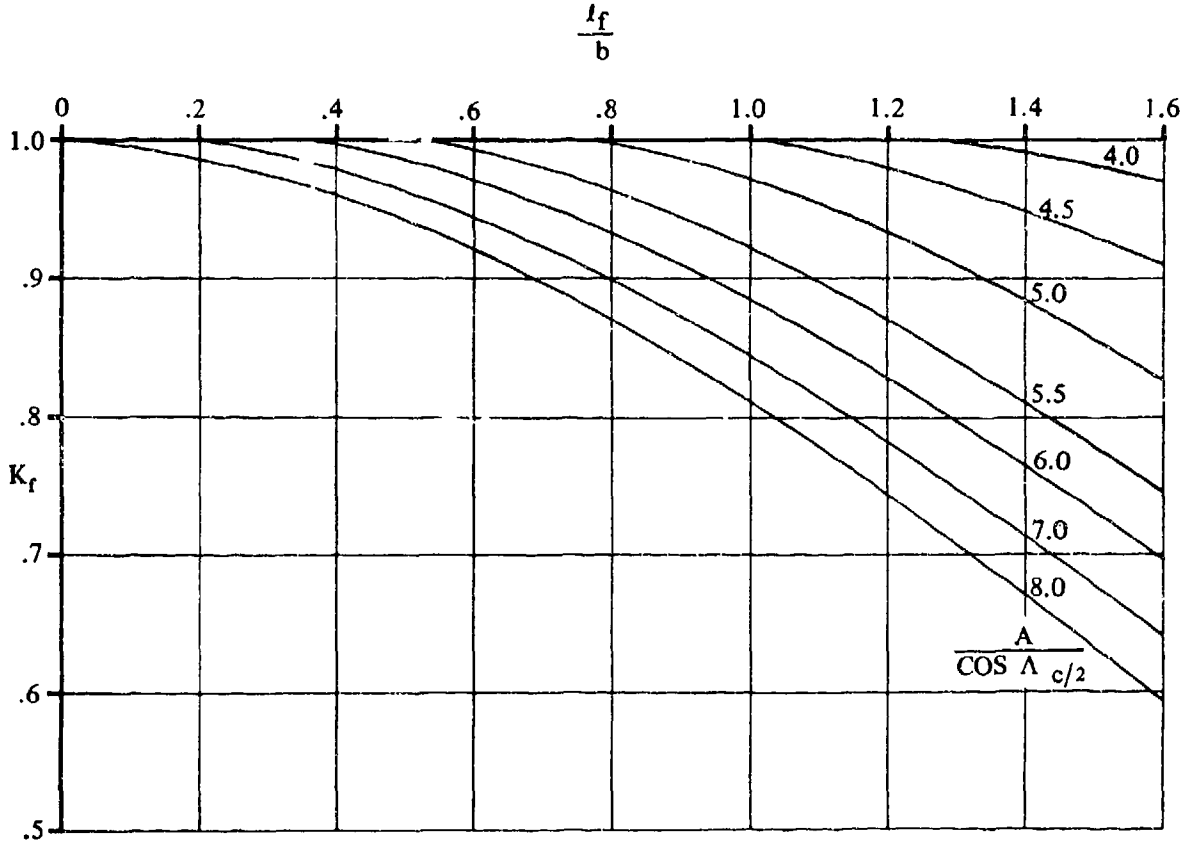

FIGURE 5.2.2.1-26 FUSELAGE CORRECTION FACTOR

5.2.3 WING-BODY SIDESLIP DERIVATIVE C_{n_β}

5.2.3.1 WING-BODY SIDESLIP DERIVATIVE C_{n_β} IN THE LINEAR ANGLE-OF-ATTACK RANGE

The wing-body yawing moment due to sideslip can be considered as the sum of the yawing moments of the body, the wing, and the wing-body interference. The wing contribution is important only at large incidences and is deleted from the solution of wing-body yawing moment due to sideslip. The method provided herein gives the total wing-body sideslip derivative C_{n_β} as the sum of the body and wing-body interference contributions.

The unstable directional stability contribution of the fuselage is dominant in this analysis, and since slender-body theory predicts the body contribution to be essentially independent of Mach number, the method presented is considered to be valid for all speeds.

Experimental investigations have shown that the wing-body interference contribution to the yawing-moment derivative is essentially independent of sweep, taper ratio, and Mach number. Furthermore, the evidence of references 1, 2, and 3 is that the effect of wing vertical position on wing-body yawing moment is small.

The maximum angle of applicability is limited to the linear-lift region. Above this angle-of-attack limitation, separation occurs and both the wing and wing-fuselage interference have an appreciable effect on the wing-body sideslip derivative C_{n_β} as a result of the changes in the magnitude and orientation of the resultant force on the two wing semispans.

DATCOM METHOD

All Speeds

The total wing-body sideslip derivative C_{n_β}, based on the product of total wing area and wing span Sb, and referred to an arbitrary moment center, is given by

$$\left(C_{n_\beta}\right)_{WB} = -K_N K_{R_\ell} \frac{S_{B_S}}{S_W} \frac{\ell_B}{b} \quad \text{(per degree)} \qquad 5.2.3.1\text{-a}$$

where

K_N is an empirical factor related to the sideslip derivative for body plus wing-body interference, obtained from figure 5.2.3.1 -8 as a function of the body geometry.

K_{R_ℓ} is an empirical Reynolds-number factor obtained from figure 5.2.3.1 -9 as a function of the fuselage Reynolds number.

S_{B_S} is the projected side area of the body.

ℓ_B is the length of the body.

A comparison of results calculated by using this method with test data is presented as table 5.2.3.1-A.

It should be noted that the upper limit of the fuselage Reynolds number of the test data is 49.2 million. For configurations at higher full-scale Reynolds numbers the method is expected to give results that are satisfactory for preliminary design.

Sample Problem

1. Given: The wing-body configuration of reference 12.

Body Characteristics:

$\ell_B = 4.1$ ft $\quad S_{B_S} = 1.35$ sq ft $\quad x_m = 2.5$ ft $\quad h = 0.416$ ft

$w = 0.416$ ft $\quad h_1 = 0.315$ ft $\quad h_2 = 0.388$ ft

Wing Characteristics:

$S_W = 2.25$ sq ft $\quad b = 3.0$ ft

Additional Characteristics:

$M = 0.91$ $\quad R_\ell = 3.87 \times 10^6$ per ft

Compute:

$$\frac{x_m}{\ell_B} = \frac{2.5}{4.1} = 0.610$$

$$\frac{\ell_B{}^2}{S_{B_S}} = \frac{(4.1)^2}{1.35} = 12.45$$

$$\sqrt{\frac{h_1}{h_2}} = \sqrt{\frac{0.315}{0.388}} = 0.902$$

$$\frac{h}{w} = \frac{0.416}{0.416} = 1.00$$

K_N = 0.00105 per deg (figure 5.2.3.1-8)

$R_{\ell_{fuselage}} = (3.87 \times 10^6)\,\ell_B = (3.87 \times 10^6)(4.1) = 15.87 \times 10^6$

K_{R_ℓ} = 1.567 (figure 5.2.3.1-9)

Solution:

$$\left(C_{n_\beta}\right)_{WB} = -K_N K_{R_\ell} \frac{S_{B_S}}{S_W} \frac{\ell_B}{b} \quad \text{(equation 5.3.2.1-a)}$$

$$= -(0.00105)(1.567) \frac{1.35}{2.25} \frac{4.1}{3.0}$$

$$= -0.00135 \text{ per deg} \quad \text{(based on } S_W b\text{)}$$

This compares with a test value of −0.00130 per degree from reference 12.

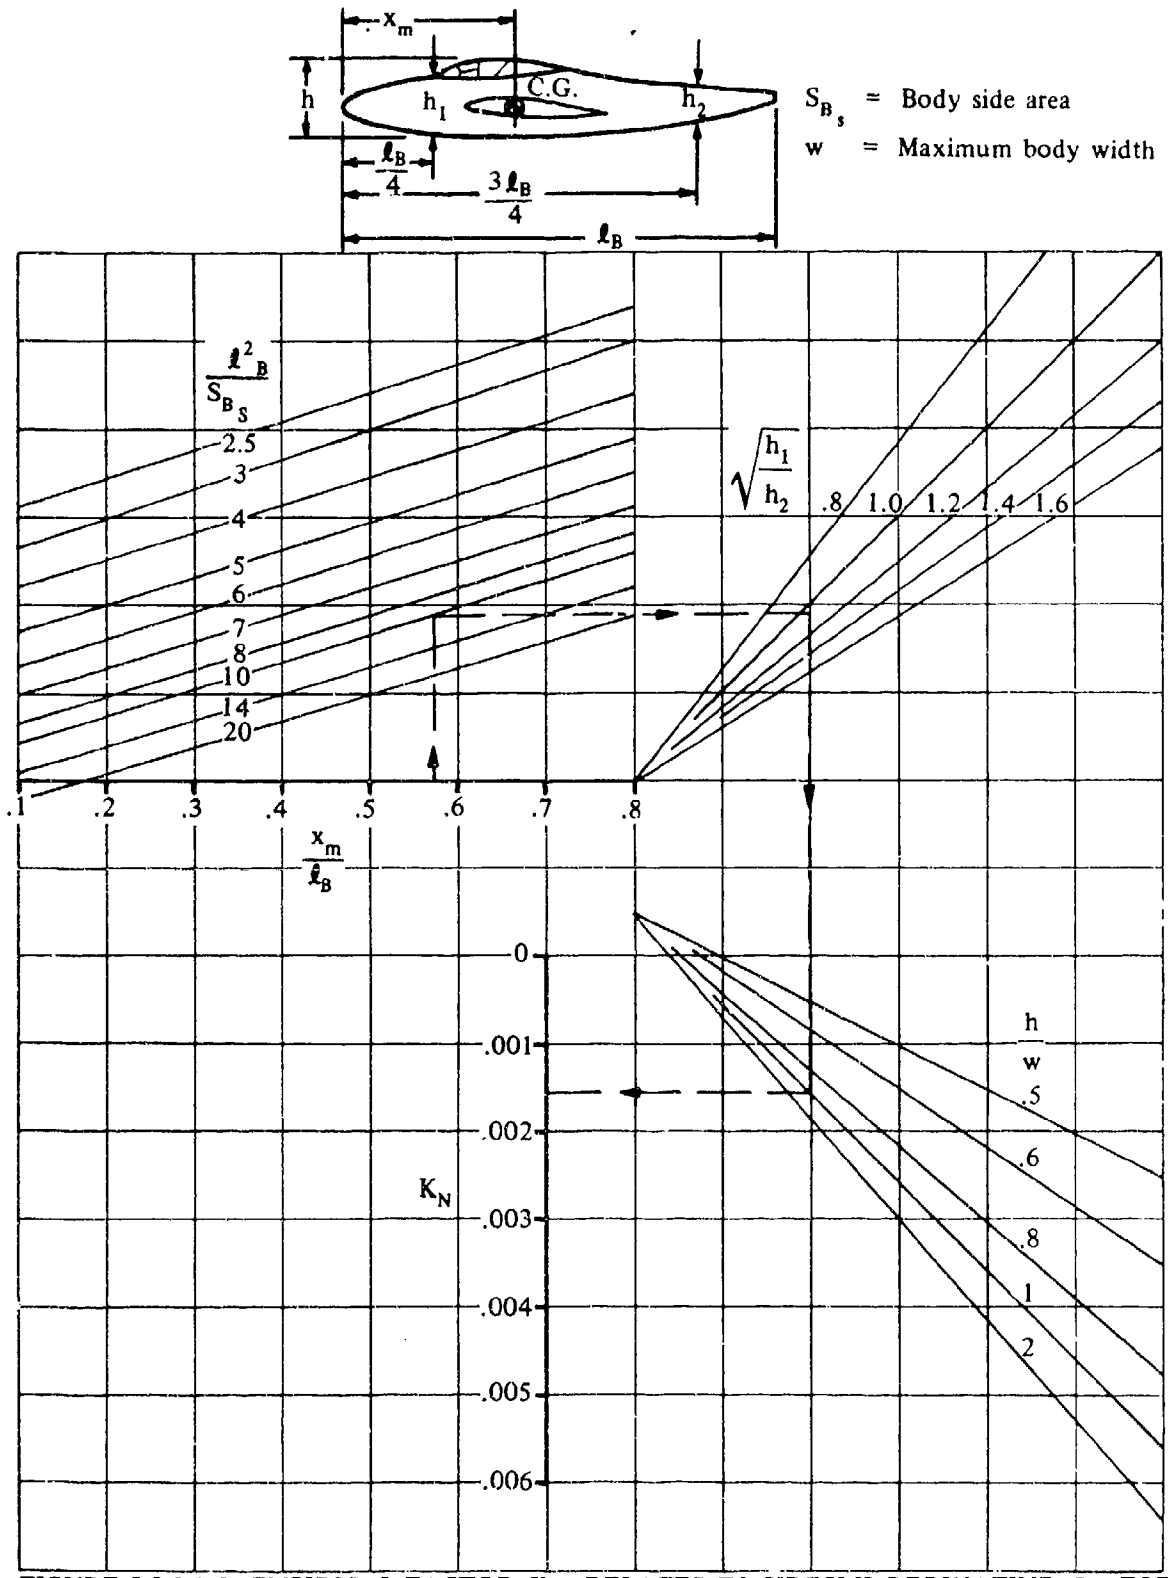

FIGURE 5.2.3.1-8 EMPIRICAL FACTOR K_N RELATED TO SIDESLIP DERIVATIVE C_{n_β} FOR BODY + WING-BODY INTERFERENCE

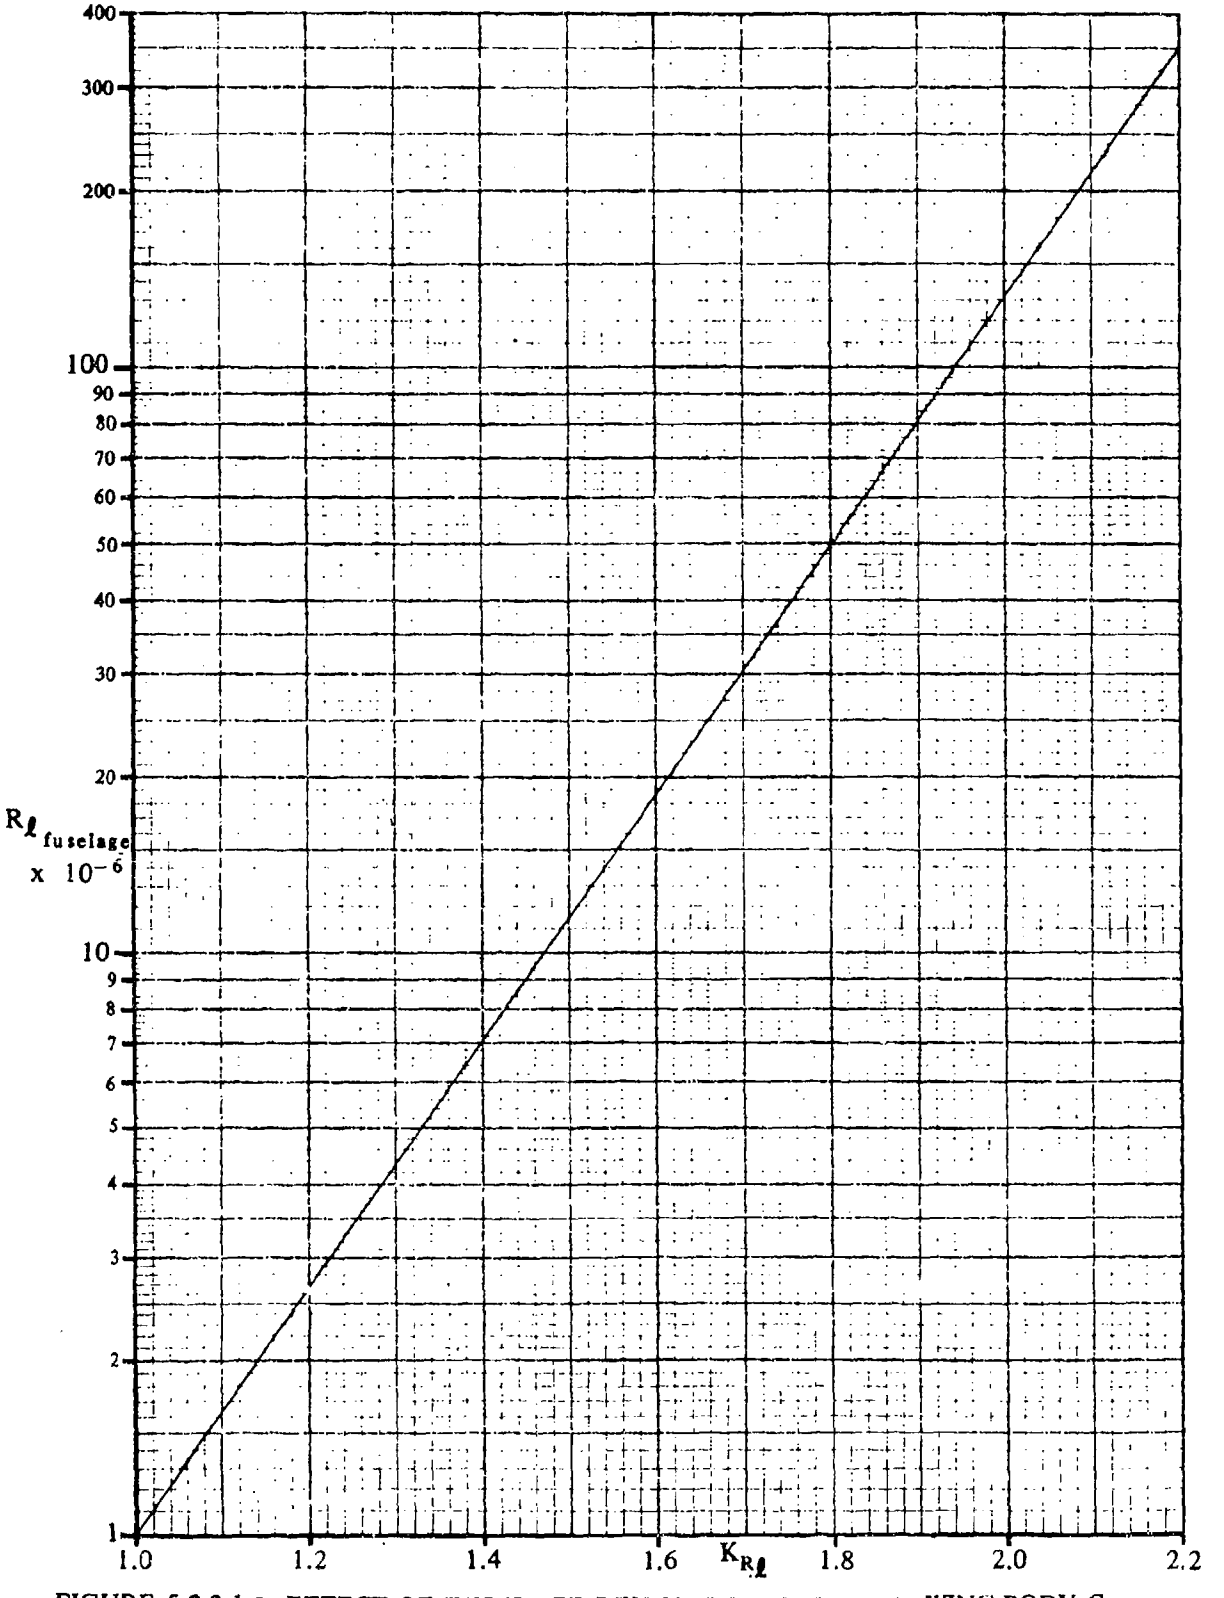

FIGURE 5.2.3.1-9 EFFECT OF FUSELAGE REYNOLDS NUMBER ON WING-BODY C_{n_β}

5.2.3.2 WING-BODY YAWING-MOMENT COEFFICIENT C_n AT ANGLE OF ATTACK

The wing-body yawing moment developed at combined angles is nonlinear with respect to both sideslip and angle of attack because of viscous cross-flow effects and cross-coupling of upwash and sidewash velocities. To obtain the sideslip derivative $C_{n_{\beta_{WB}}}$ it is recommended that $C_{n_{WB}}$ be calculated at several angles of attack for a small sideslip angle ($\beta \leq 4^\circ$). Then at each angle of attack the yawing moment is assumed linear with sideslip for small values of β so that

$$C_{n_{\beta_{WB}}} = \frac{C_{n_{WB}}}{\beta} .$$

A. SUBSONIC

No method is presently available for determining the wing-body yawing moment at large angles of attack and subsonic speeds. The method presented herein is restricted to first-order approximations at relatively low angles of attack.

DATCOM METHOD

It is recommended that the method of Section 5.2.3.1 be used in the linear-lift angle-of-attack range.

B. TRANSONIC

No method is presently available for determining the wing-body yawing moment at large angles of attack and transonic speeds. The method presented herein is restricted to first-order approximations at relatively low angles of attack.

DATCOM METHOD

It is recommended that the method of Section 5.2.3.1 be used in the linear-lift angle-of-attack range.

C. SUPERSONIC

The method for estimating the wing-body yawing-moment coefficient $C_{n_{WB}}$ is based on the theory involved in estimating $C_{Y_{WB}}$ presented in Section 5.2.1.2. Therefore, the comments in that Section applying to the aerodynamics of wing-body interference also apply to this Section but are not repeated here.

To obtain the wing-body yawing-moment coefficient it is necessary to apply the appropriate moment arm to the side-force coefficient of Section 5.2.1.2. The center of pressure of the aerodynamic forces on the body at angle of attack establishes one moment arm. No simple method is available for estimating the body-alone center of pressure. The method suggested herein is necessarily tentative and will be updated as information becomes available. Of course, test values at the appropriate angle of attack are to be preferred. The position at which the wing-body interference side force acts on the body establishes a second moment arm. In the method that follows, this position is expressed as a function of the vertical location of the wing on the body and is based on the assumption that both the pressure and viscous force components of interference act at the same location.

The same limitations apply to the estimation of the yawing moments as to the estimation of the side force: although the wing leading edge should be supersonic, fair results are obtained for subsonic leading edges if the aspect ratio is not too low. Furthermore, correlation of experimental and estimated values of the wing-body interference moment indicates that the Datcom method is in actuality only warranted for cases in which the mid-point of the wing root chord is substantially displaced from the moment reference point.

DATCOM METHOD

The yawing-moment coefficient for wing-body combinations at supersonic speeds is given by the equation

$$C_{n_{WB}} = C_{n_B} + \left[\frac{x_m - \bar{l}_{W(B)}}{b_W}\right] C_{Y_{W(B)}} \qquad 5.2.3.2\text{-a}$$

where

C_{n_B} is the body-alone contribution given by

$$C_{n_B} = \left[\frac{x_m}{l_B} - x_{c.p.}\right] \frac{l_B}{b_W} C_{Y_B} \qquad 5.2.3.2\text{-b}$$

where

x_m is the distance from the body nose to the moment center

l_B is the body length

$x_{c.p.}$ is the distance from the body nose to the body center of pressure, measured in body lengths. This parameter is approximated by $x_{c.p.} = \frac{C_m}{C_L}$

where C_m and C_L are obtained from paragraph C of Sections 4.2.2.2 and 4.2.1.2, respectively, at $\alpha = \alpha'$. The pitching-moment coefficient from Section 4.2.2.2 is referred to the body nose ($x_m = 0$).

b_W is the wing span

C_{Y_B} is the body-alone side-force coefficient obtained from Section 5.2.1.2

$C_{Y_{W(B)}}$ is the side-force interference contribution obtained from Section 5.2.1.2

$\bar{l}_{W(B)}$ is the distance from the body nose to the center of pressure of the wing-induced body side force

For midwing configurations

$$\bar{l}_{W(B)} = l_n + \tfrac{1}{2} c_{r_e} \qquad 5.2.3.2\text{-c}$$

where

l_n is the distance from the body nose to the juncture of the wing leading edge and body

For tangent wing configurations

$$\bar{l}_{W(B)} = l_n + c_{r_e}\left[\frac{x_{l_{(\alpha)}}}{x_{l_{(\alpha=0)}}}\right]\left[\frac{x_{l_{(\alpha=0)}}}{c_{r_e}}\right] \qquad 5.2.3.2\text{-d}$$

where

$x_{l_{(\alpha)}}$ is the distance to the center of pressure of the wing-induced body side force from the juncture of the wing leading edge and the body at the prop- angle of attack

$x_{l_{(\alpha=0)}}$ is the distance to the center of pressure of the wing-induced body side force from the juncture of the wing leading edge and the body at zero angle of attack

$\frac{x_{l_{(\alpha)}}}{x_{l_{(\alpha=0)}}}$ is obtained from figure 5.2.3.2-6

$\frac{x_{l_{(\alpha=0)}}}{c_{r_e}}$ is obtained from figure 5.2.3.2-8

Values for the incremental coefficient resulting from the addition of wings in the mid and high- and low-tangent positions on circular bodies, calculated using the second term on the right-hand side of equation 5.2.3.2-a, are compared with experimental results in figure 5.2.3.2-5. This correlation is somewhat inconclusive in that for the conventional wing locations considered the centers of pressure of the wing-body interference side forces are close to the moment reference point. The resulting small yawing moments are likely no larger than the yawing moments of the wing alone which are neglected in the method. Furthermore, exact knowledge of the wing effects on the body cross-flow load distribution is precluded since the center of pressure of the body cross-flow loading is not accurately known.

Sample Problem

Given: Configuration of the sample problem, paragraph C, Section 5.2.1.2. This configuration is also tested in reference 1 of this Section. Some of the characteristics are repeated. Find the yawing-moment coefficient developed by the wing-body combination at $\alpha = 12^\circ$ and $\beta = 4^\circ$.

Characteristics

$\ell_B = 36.5$ in. $\quad \ell_n = 15.62$ in. $\quad x_m = 20.81$ in. $\quad c_{r_e} = 8.90$ in. $\quad c_{r_e}/d = 2.67$

$b_W = 24.0$ in. $\quad x_{c.p.} = 0.36$ at $\alpha' = 12.65^\circ$ (test results) $\quad M = 2.01$ $\quad \alpha' = 12.65^\circ$

Compute:

Body-alone yawing-moment coefficient C_{n_B}

$C_{Y_B} = -0.0238$ (based on S_W) (sample problem, paragraph C, Section 5.2.1.2)

$$C_{n_B} = \left[\frac{x_m}{\ell_B} - x_{c.p.}\right] \frac{\ell_B}{b_W} C_{Y_B} \qquad \text{(equation 5.2.3.2-b)}$$

$$= (0.57 - 0.36)\ \frac{36.5}{24.0}\ (-0.0238)$$

$$= -0.0076 \text{ (based on } S_W b_W)$$

Wing interference yawing-moment coefficient

$$\frac{x_{l_{(\alpha)}}}{x_{l_{(\alpha=0)}}} = 0.77 \text{ (figure 5.2.3.2-6)}$$

$$\sqrt{M^2 - 1}\left[\frac{d}{c_{r_e}}\right] = \sqrt{(2.01)^2 - 1}\left[\frac{3.33}{8.90}\right] = 0.651$$

$$\frac{x_{l_{(\alpha=0)}}}{c_{r_e}} = 0.90 \text{ (figure 5.2.3.2-8)}$$

$$\bar{\ell}_{W(B)} = \ell_n + c_{r_e}\left[\frac{x_{l_{(\alpha)}}}{x_{l_{(\alpha=0)}}}\right]\left[\frac{x_{l_{(\alpha=0)}}}{c_{r_e}}\right] \qquad \text{(equation 5.2.3.2-d)}$$

$$= 15.62 + 8.90\ (0.77)\ (0.90)$$

$$= 21.78$$

$C_{Y_{W(B)}} = -0.0162$ (based on S_W) (sample problem, paragraph C, Section 5.2.1.2)

Solution:

$$C_{n_{WB}} = C_{n_B} + \left[\frac{x_m - \bar{l}_{W(B)}}{b_W}\right] C_{Y_{W(B)}} \qquad \text{(equation 5.2.3.2-a)}$$

$$= -0.0076 + \frac{20.81 - 21.78}{24.0} (-0.0162)$$

$$= -0.00695 \text{ (based on } S_W b_W)$$

This compares with an experimental value (based on $S_W b_W$) of $C_{n_{WB}} = -0.0070$ from reference 1.

A comparison between calculated and experimental results for this configuration at sideslip angles of 2, 4, and 8 degrees and over an angle-of-attack range to 16 degrees is presented in figure 5.2.3.2 -4.

5.3 TAIL-BODY COMBINATIONS IN SIDESLIP

5.3.1 TAIL-BODY SIDESLIP DERIVATIVE C_{Y_β}

5.3.1.1 TAIL-BODY SIDESLIP DERIVATIVE C_{Y_β} IN THE LINEAR ANGLE-OF-ATTACK RANGE

The contributions of panels present in the empennage to the vehicle sideslip derivative C_{Y_β} are presented in this section for speeds ranging from low subsonic to hypersonic. The methods presented include the mutual interference effects of the wing, body, and the horizontal panels.

A. SUBSONIC

At subsonic speeds the vehicle body and horizontal tail affect the flow on the vertical tail in such a way as to increase the effectiveness of the vertical tail. This phenomenon, known as the "end-plate effect," is frequently represented by an effective change in panel aspect ratio required to give the same lift effectiveness as the actual panel in the presence of the other vehicle components. Interferences also exist between the vertical tail, the body, and any forward lifting surface.

In the literature, these mutual interference effects are treated in various ways. In some cases, the wing-body wake and sidewash effects are treated independently of the body and horizontal-tail end-plate effects. The British are notable for this approach. In other cases, all the interference effects are lumped into a single vertical-tail effectiveness parameter. One of the methods presented herein uses this latter approach.

The effect of each of the vehicle components on the subsonic vertical-tail effectiveness is discussed in the following paragraphs.

Effect of Body Cross Flow

A body in sideslip exhibits a flow characteristic similar to a cylinder in cross flow. For potential flow the peak local velocity occurs at the top of the cylinder and is equal to twice the free-stream cross-flow velocity. Actually, separation exists on the leeward side, reducing the peak velocity from the potential-flow value. In either case, the velocity decays to the free-stream cross-flow value with distance from the body surface. Thus, it is to be expected that tail-body combinations with large bodies and small tails have a greater effectiveness per unit area than combinations with large tails and small bodies. This trend is exhibited by test data. The vertical panel itself causes a load carry-over from the panel onto the body. This carry-over increases the effectiveness of the vertical panel and is included in the methods presented.

Effect of Horizontal Surface

The presence of a horizontal panel in the vicinity of a vertical panel causes a change in the pressure loading of the latter if the horizontal panel is at a height where the vertical panel has an appreciable gradient, i.e., at a relatively high or low position. Test data substantiate the greater effectiveness of horizontal panels in these positions and the relative ineffectiveness of a horizontal panel at the midspan position on the vertical panel.

Effect of Wing-Body Wake and Sidewash

The effect of wing-body wake and sidewash on the effectiveness of the vertical panel is discussed in detail in Section 5.4.1. This effect is implicitly included in only one of the methods presented herein (Method 3).

Several approaches to this problem have been taken in the literature. Reference 1 presents a method accounting for the effects of body size relative to vertical-panel size, and dealing with horizontal-tail height ranging from positions on the body to the top of the vertical. This method appears to be the most accurate one available. It is presented in this Section as Method 1.

Reference 2 contains a method which is also widely used. Included in this method is a chart for twin tails that is presented in this section. The charts give the average lift-curve slope of the two panels. (The interferences and hence the individual lift-curve slope of the panels differ somewhat.)

A different approach is given in reference 3. This method is based on the assumption that the ratio of the increment in side force due to the addition of a vertical panel to the side force developed by the panel alone is the same as the ratio of the increment in apparent mass of the cross section at the base of the empennage with panel added to the apparent mass of the panel alone. The development of the apparent-mass concept is

given in many places in the literature, e.g., reference 4. The panel alone is taken to be the actual panel reflected about a reflection plane. This assumption implies two-dimensional flow and a slender configuration with all surfaces of the empennage lying in the base plane of the configuration. It is shown in reference 3, however, that good accuracy is obtained for nonslender configurations where the longitudinal locations of the separate surfaces are not in the base plane. This method is limited to configurations in which the horizontal surfaces are mounted on the body or configurations with no horizontal surface. The charts for this method are also used for the supersonic method.

There are some additional effects that are not accounted for by these methods. For instance, dorsal fins may cause a considerable error in the values obtained, although the effect of dorsal fins is more pronounced at the higher angles of sideslip. The use of lift-curve slopes for double-delta wings may decrease this error. A method for calculating the lift-curve slope of double-delta wings is presented in Section 4.1.3.2 under the nonstraight-tapered-wing methods. Dihedral in the horizontal surfaces is known to change the pressure loading on the vertical panel and hence its effectiveness. For rapidly converging bodies, flow separation frequently exists at the juncture of the vertical panel with the body. This effect generally decreases the effectiveness of the vertical tail and is not accounted for by the methods included herein. Similar effects can result when the maximum thickness of two orthogonal panels are made to coincide.

DATCOM METHODS

Method 1

Vertical Panels on Plane of Symmetry

The contribution of the vertical panel to the sideslip derivative C_{Y_β} is determined by the following steps (reference 1).

Step 1. The effective aspect ratio of the vertical panel is determined by means of the equation

$$A_{eff} = \frac{(A)_{V(B)}}{(A)_V} (A)_V \left\{ 1 + K_H \left[\frac{(A)_{V(HB)}}{(A)_{V(B)}} - 1 \right] \right\} \qquad 5.3.1.1\text{-a}$$

where

$\frac{(A)_{V(B)}}{(A)_V}$ is the ratio of the aspect ratio of the vertical panel in the presence of the body to that of the isolated panel. This ratio is given in figure 5.3.1.1-22a as a function of span-to-body-diameter ratio and tail taper ratio.

$(A)_V$ is the geometric aspect ratio of the isolated panel with the span and area of the panel measured to the body center line.

$\frac{(A)_{V(HB)}}{(A)_{V(B)}} = \frac{(A)_{V(HB)}}{\frac{(A)_{V(B)}}{(A)_V} (A)_V}$ is the ratio of the vertical-panel aspect ratio in the presence of the horizontal tail and body to that of the panel in the presence of the body alone. This ratio is given in figure 5.3.1.1-22b as a function of the horizontal and vertical position of the horizontal tail on the vertical panel.

K_H is a factor accounting for the relative size of the horizontal and vertical tails, obtained from figure 5.3.1.1-22c.

Step 2. The lift-curve slope of the vertical panel is determined from paragraph A of Section 4.1.3.2, with the effective aspect ratio of the vertical panel determined from equation 5.3.1.1-a.

Step 3. The wake and sidewash effects as represented by the parameter $\left(1 + \frac{\partial\sigma}{\partial\beta}\right) \frac{q_V}{q_\infty}$ are presented in Section 5.4.1 for the appropriate Mach number and vehicle geometry.

Step 4. The increment in C_{Y_β} due to the vertical panel is given by the equation (based on wing area)

$$(\Delta C_{Y_\beta})_{V(WBH)} = -k(C_{L_\alpha})_V \left(1 + \frac{\partial \sigma}{\partial \beta}\right) \frac{q_V}{q_\infty} \frac{S_v}{S_w} \qquad 5.3.1.1\text{-b}$$

where $(C_{L_\alpha})_V$ is obtained from Step 2

$\left(1 + \frac{\partial \sigma}{\partial \beta}\right)\frac{q_V}{q_\infty}$ is obtained from Step 3

k is an empirical factor obtained from figure 5.3.1.1-22d

$\frac{S_v}{S_w}$ is the ratio of the vertical panel area (measured to the body centerline) to the total wing area

This method is substantiated by test data in table 5.3.1.1-B.

Method 2

Twin Vertical Panels

The contribution of twin vertical panels mounted on the tips of a horizontal tail or wing is given by the following steps. This method (from reference 2) includes the effects of the wing-body wake and sidewash.

Step 1. Determine the ratio of the effective to actual aspect ratio, $\frac{A_{eff}}{A}$, from figure 5.3.1.1-24a as a function of the geometric variable shown.

Step 2. Determine the lift-curve slope of the equivalent rectangular vertical panel $(C_{Y_\beta})_{V_{eff}}$ from figure 5.3.1.1-24b; use the effective aspect ratio found in Step 1 and the total trailing-edge angle of the airfoil section.

Step 3. The increment in vehicle sideslip derivative C_{Y_β} due to the twin panels (based on total wing area) is given by the equation

$$(\Delta C_{Y_\beta})_{V(WBH)} = -\frac{(C_{Y_\beta})_{V(WBH)}}{(C_{Y_\beta})_{V_{eff}}} (C_{Y_\beta})_{V_{eff}} \frac{2S_v}{S_w} \qquad 5.3.1.1\text{-c}$$

where $\frac{(C_{Y_\beta})_{V(WBH)}}{(C_{Y_\beta})_{V_{eff}}}$ is obtained from figure 5.3.1.1-24c for the appropriate geometry shown

$(C_{Y_\beta})_{V_{eff}}$ is obtained from Step 2 above

S_v is the area of a single vertical panel

There are not sufficient data existing to substantiate the accuracy of this method, although reference 2 indicates that the method is accurate to within ±10 percent.

Method 3

A third general method is based on the work in reference 3. This method is limited to configurations in which the horizontal tail is mounted on the body or configurations with no horizontal tail. It is discussed in the introduction to this Section. The charts of this method are also used in the supersonic method of paragraph C.

The method as presented for the vertical panel estimates the increment in C_{Y_β} due to the addition of one panel in the empennage and includes the effects of all existing panels on the added panel. An extension of the method to determine the total empennage side force due to sideslip at subsonic speeds which results from the addition of all panels present in the empennage is presented in paragraph A of Section 5.6.1.1.

Contribution of Vertical Panel

The side force-curve slope (based on total wing area) of a vertical panel added to an empennage is given by the equation

$$(\Delta C_{Y_\beta})_p = -K(C_{L_\alpha})_p \frac{S_{p_e}}{S_w} \qquad 5.3.1.1\text{-d}$$

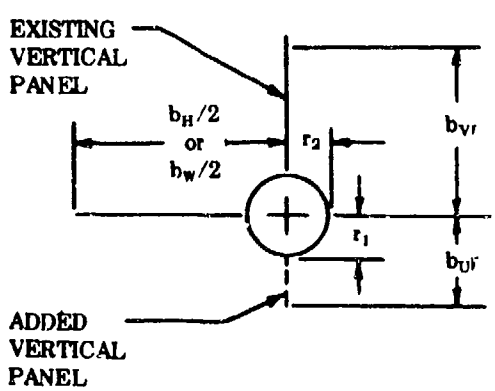
where the subscript $_p$ refers to the added vertical panel (either an upper vertical stabilizing surface V or a lower vertical stabilizing surface U)

$(C_{L_\alpha})_p$ is the lift-curve slope of the isolated vertical panel mounted on a reflection plane from paragraph A of Section 4.1.3.2. For this calculation the aspect ratio must be taken as twice the aspect ratio defined by the average exposed span and exposed area.

S_{p_e} is the area of the exposed vertical panel

K is the apparent mass factor from figures 5.3.1.1-25a through 5.3.1.1-25nn. When using these figures the vertical panel for which the contribution to C_{Y_β} is desired is termed the "added panel" and other panels existing in the empennage are termed the "existing panels" as shown schematically in sketch (a).

The body radii dimensions r_1 and r_2 are defined in the region of the tail panels. If these dimensions change in this region the average values should be used. In general interpolation procedures must be used since the geometry rarely coincides with that of a specific figure. Since the variation of parameters between figures is generally non-linear, graphical interpolation using at least three points is recommended. An index of the K charts and the range of variables covered by each is presented as table 5.3.1.1-A.



SKETCH (a)

Although the sketches on the figures show only the upper vertical panel as the added panel, the added panel can be either the upper or lower vertical panel. Special mention is made of figures 5.3.1.1-25g through 5.3.1.1-25p. Figures 5.3.1.1-25g through 5.3.1.1-25k are used to estimate the K value due to adding an upper vertical stabilizing surface to a body with the horizontal surface in the high tangent position. These figures also apply in estimating the K value due to adding a lower vertical stabilizing surface to a body with a horizontal surface located in the low tangent position. Figures 5.3.1.1-25l through 5.3.1.1-25p are used in the same manner as figures 5.3.1.1-25g through 5.3.1.1-25k except that the horizontal surface is tangent to the body on the side opposite to which the panel is added.

Apparent mass factor solutions for bodies other than circular or elliptic cross sections are not available. In treating bodies of other cross-sectional shapes the assumption is made that the ratio of height to width, r_1/r_2, is the important parameter and that details of the body contour are of secondary importance. This assumption has been used in reference 3, where the body was other than circular or elliptic, and the resulting correlation with experiment was as good as for the cases to which the figures apply directly.

The case of a vertical tail added to an empennage consisting of a horizontal panel located at other than the mid-position on the elliptical body is not covered by the K charts (see table 5.3.1.1-A). To handle such a case, either the body must be considered circular and an interpolation made for horizontal panel height, or the horizontal panel must be assumed located at the mid-position and an interpolation performed between r_1/r_2 ratios. A comparison of the effect of both horizontal panel location and body shape on the K factor should be made in determining the proper approach to the K factor solution.

Contribution of Horizontal Tail

In determining the total empennage side force due to sideslip which results from the addition of all panels present in the empennage the horizontal tail must be added first (see method 3, paragraph A, Section 5.6.1.1). Although the horizontal tail contribution to C_{Y_β} is usually small and for most calculations can be neglected; it can provide a significant contribution to the sideslip derivative C_{l_β}.

The contribution to the sideslip derivative C_{Y_β} (based on total wing area) of a horizontal tail added to a body is given by

$$(\Delta C_{Y_\beta})_{H(B)} = K_{H(B)} (C_{Y_\beta})_B \frac{S_{B_{Ref}}}{S_W} \qquad 5.3.1.1\text{-e}$$

where

$(C_{Y_\beta})_B$ is the side force due to sideslip (based on body reference area, $S_{B_{Ref}}$) obtained from Section 4.2.1.1 by conversion of the body lift-curve slope i.e.; $(C_{Y_\beta})_B = -(C_{L_\alpha})_B$

$K_{H(B)}$ is the apparent mass factor due to the addition of a horizontal tail in the presence of a body for the appropriate tail span and vertical position from figure 5.3.1.1-25oo.

For a horizontal tail mounted at an intermediate position on the body (between mid- and high- or low-tangent position), the following second order interpolation using the equation of an ellipse should be applied

$$K_{H(B)} = K_{\text{High or Low}} \left\{ 1 - \left[1 - \left(\frac{Z_H}{r_1} \right)^2 \right]^{1/2} \right\}$$

A substantiation table comparing experimental data with results calculated by this method is shown in table 5.3.1.1-B. A comparison is made in this table of the relative accuracy of Method 1 and Method 3.

Sample Problems

1. Method 1

Given: The configuration of reference 6 consisting of wing, body, horizontal tail, and vertical tail. Find the effect of adding the vertical tail to the wing-body-horizontal tail combination.

Wing Characteristics

$A_W = 3.0$ $S_W = 576.0$ sq in. $b_W = 41.56$ in. $z_W = 0$ $\Lambda_{c/4_W} = 45^\circ$

Horizontal Tail Characteristics

$A_H = 4.0$ $S_H = 121.6$ sq in. $b_H = 22.42$ in. $z_H = 0$

Vertical Tail Characteristics

$A_V = 1.50$ $S_V = 153.7$ sq in. $b_V = 15.23$ in. $c_{r_V} = 17.40$ in. $\lambda_V = 0.160$

$\Lambda_{c/2_V} = 41.9^\circ$ Airfoil: NACA 0003.5-64

Additional Characteristics

$M = 0.25$ $r_1 = 2.8$ in. $d = 6.0$ in. $x/c_V = 0.55$

Compute:

$(c\ell_\alpha)_V = 6.18$ per rad (Section 4.1.1.2)

$K = \dfrac{c\ell_\alpha}{2\pi} = 0.984$

$b_V/2r_1 = 2.72$

$\dfrac{(A)_{V(B)}}{(A)_V} = 1.47$ (figure 5.3.1.1-22a)

$(A)_{V(B)} = \dfrac{(A)_{V(B)}}{(A)_V}(A)_V = 2.20$

$S_H/S_V = 0.820$

$K_H = 0.83$ (figure 5.3.1.1-22c)

$z_H/b_V = 0$

$\dfrac{(A)_{V(HB)}}{(A)_{V(B)}} = 1.10$ (figure 5.3.1.1-22b)

$S_V/S_W = 0.267$

$z_W/d = 0$

$A_{eff} = (A)_{V(B)}\left\{1 + K_H\left[\dfrac{(A)_{V(HB)}}{(A)_{V(B)}} - 1\right]\right\} = 2.38$ (equation 5.3.1.1-a)

$\dfrac{A_{eff}}{K}\left[\beta^2 + \tan^2 \Lambda_{c/2_V}\right]^{1/2} = 3.193$

$\dfrac{C_{L_\alpha}}{A_{eff}} = 1.08$ (figure 4.1.3.2-49)

$(C_{L_\alpha})_{V(BH)} = \left(\dfrac{C_{L_\alpha}}{A_{eff}}\right)A_{eff} = 2.57$ per rad

$\left(1 + \dfrac{\partial\sigma}{\partial\beta}\right)\dfrac{q_V}{q_\infty} = 0.724 + 3.06\ \dfrac{S_V/S_W}{1 + \cos \Lambda_{c/4_W}} + 0.4\ \dfrac{z_W}{d} + 0.009\ A_W = 1.230$ (equation 5.4.1-a)

$k = 0.87$ (figure 5.3.1.1-22d)

Solution:

$$(\Delta C_{Y_\beta})_{V(WBH)} = -k(C_{L_\alpha})_{V(BH)} \left(1 + \frac{\partial \sigma}{\partial \beta}\right) \frac{q_V}{q_\infty} \frac{S_V}{S_W} \quad \text{(equation 5.3.1.1-b)}$$

$$= -0.734 \text{ per rad}$$

This compares with an experimental value of -0.76 per radian obtained from reference 6.

2. Method 2

Given: A configuration consisting of wing, body, and twin vertical panels mounted on the tips of a horizontal tail. Find the effect of adding the twin vertical panels to the configuration.

Twin Vertical Tail Characteristics

$A_V = 1.39$ $b_V = 5.0$ ft $b'_V = 4.0$ ft $S_V = 18.0$ ft $\phi_{TE_V} = 10°$

Additional Characteristics

$S_W = 144.0$ sq ft $\ell_B = 55.0$ ft $b_H = 12.0$ ft $r_f = 1.50$ ft

Compute:

$b'_V/b_V = 0.80$

$\frac{A_{eff}}{A} = 1.20$ (figure 5.3.1.1-24a)

$A_{eff} = 1.67$

$(C_{Y_\beta})_{V_{eff}} = 2.40$ (figure 5.3.1.1-24b)

$2r_f/b_V = 0.6$

$b_H/\ell_B = 0.22$

$\frac{(C_{Y_\beta})_{V(WBH)}}{(C_{Y_\beta})_{V_{eff}}} = 0.61$ (figure 5.3.1.1-24c)

Solution:

$$(\Delta C_{Y_\beta})_{V(WBH)} = -\frac{(C_{Y_\beta})_{V(WBH)}}{(C_{Y_\beta})_{V_{eff}}} \frac{2S_V}{S_W} \quad \text{(equation 5.3.1.1-c)}$$

$$= -0.366 \text{ per rad}$$

3. Method 3

Given: A configuration of reference 10 consisting of wing, body, horizontal tail, and vertical tail. Find the effect of adding the vertical tail to the wing-body-horizontal tail configuration.

Vertical Tail Characteristics

$A_V = 1.40$ $A_{V_e} = 1.37$ $S_V = 48.6$ sq in. $S_{V_e} = 36.2$ sq in. $\Lambda_{c/2_V} = 39.4°$

$\lambda_V = 0.645$ $\lambda_{V_e} = 0.60$ $b_V = 8.25$ in. NACA 65008 airfoil

Additional Characteristics

$M = 0.13$ $r_1 = 1.20$ $r_2 = 2.65$ $\frac{b_H}{2} = 6.70$ in. $S_W = 324$ sq in.

Compute:

$(c\ell_\alpha)_V = 6.67$ per rad (Section 4.1.1.2)

$K = \frac{(c\ell_\alpha)_V}{2\pi} = 1.06$ (ratio of section lift-curve slope to 2π)

$2A_{V_e} = 2.74$

$\frac{2A_{V_e}}{K}[\beta^2 + \tan^2 \Lambda_{c/2_V}]^{1/2} = 3.26$

$\frac{(C_{L_\alpha})_V}{2A_{V_e}} = 1.08$ per rad (figure 4.1.3.2-49)

$(C_{L_\alpha})_V = (1.08)(2A_{V_e}) = 2.96$ per rad (based on S_{V_e})

Determine the apparent-mass factor due to adding the upper vertical stabilizer to the wing-body-horizontal tail configuration. In this case the empennage consists of the body, horizontal tail, and upper vertical stabilizer. The apparent-mass factor to be found is that due to adding the upper vertical stabilizer to the combination of body and horizontal tail, $K_{V(HB)}$

$\left(\frac{r_1}{r_2}\right) = 0.451$, $\left(r_2/\frac{b}{2}\right)_H = 0.396$, $\left(\frac{r_1}{b}\right)_{\substack{U \\ \text{existing} \\ \text{panel}}} = 1.000$, $\left(\frac{r_1}{b}\right)_{\substack{V \\ \text{added} \\ \text{panel}}} = 0.1455$

Using the above parameters and table 5.3.1.1-A it is seen that $K_{V(HB)}$ is obtained by interpolation from figures 5.3.1.1-25s, -25t, -25u for $r_1/r_2 = 0.333$, 5.3.1.1-25y, -25z, -25aa for $r_1/r_2 = 0.667$; 5.3.1.1-25c, -25d, -25e for $r_1/r_2 = 1.000$. An interpolation between those values of $K_{V(BH)}$ gives, for $r_1/r_2 = 0.451$

$K_{V(BH)} = 1.135$.

Solution

5.3.1.1-7

$(\Delta C_{Y_\beta})_p = -K(C_{L_\alpha})_p \frac{S_{p_e}}{S_W}$ (equation 5.3.1.1-d)

$(\Delta C_{Y_\beta})_{V(WBH)} = -K_{V(HB)} (C_{L_\alpha})_V \frac{S_{V_e}}{S_W}$

$= (-1.135)(2.96)\left(\frac{36.2}{324}\right)$

$= -0.375$ per rad (based on S_W)

This corresponds to an experimental value of -0.367 per radian obtained from reference 10.

B. TRANSONIC

The side force on a vertical panel depends on three general factors. These are the lift characteristics of the panel itself, the effect of the wing-body wake and sidewash, and the interference effects of the body and horizontal surface.

The lift characteristics of the isolated panel at transonic speeds can be estimated by methods such as that described in paragraph B of Section 4.1.3.2. The wake and sidewash, on the other hand, are affected by the detailed geometry of the flow field, which can be radically changed by relatively minor variations in the vehicle geometry. This is true because of the sensitivity of transonic flow to local contour and area distribution changes and because of shock-induced boundary-layer separation. In addition, the vertical panel is usually contained in a small segment of the flow field so that local variations in the field can have pronounced effects upon the resultant forces on the tail. The interference effects of the body and horizontal tail at transonic speeds are likewise sensitive to local configuration geometry and cannot be eliminated.

Because of the above reasons, the vertical tail contribution to the sideslip derivative C_{Y_β} is difficult to estimate reliably, and its value is usually obtained by wind-tunnel testing or estimated from comparison with similar configurations.

DATCOM METHOD

No method is available in the literature for estimating this derivative and none is presented in the Datcom. However, some data in this speed regime can be found in references 11, 12, and 13.

C. SUPERSONIC

The problem of estimating the effectiveness of panels in the empennage in generating side forces due to sideslip at supersonic speeds is complicated by the presence of shock waves. These shock waves cause marked regions of differentiation on the surfaces of an added panel (see sketch b). Each region is characterized by different Mach numbers, pressures, and velocity directions. In addition, vortices from the body and the wake from the forward lifting surfaces can have important effects on the forces generated. The method presented herein, taken from reference 3, does not account for the effects of vortices and wakes. However, these effects are small at low angles of attack.

DATCOM METHOD

The method of this Section is for estimating the increment in C_{Y_β} due to the addition of a panel (either a vertical stabilizer or a horizontal tail) in the empennage. The vertical panel contribution includes the effects of all existing panels on the added panel. An extension of the method to determine the total empennage side force due to sideslip at supersonic speeds which results from the addition of all panels present in the empennage is presented in paragraph C of Section 5.6.1.1.

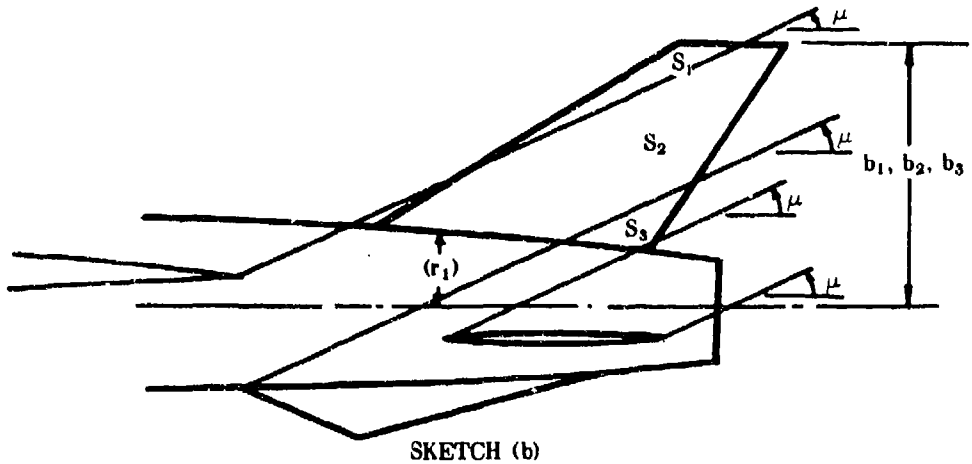
The method is based on the same apparent mass concept as used in Method 3 of paragraph A. A weighted apparent mass factor is obtained for each region defined by a system of Mach lines characteristic of the configuration. The total effective apparent mass K' is then determined and used to obtain the desired force contribution of the added panel.

This method is limited to configurations in which the horizontal tail is mounted on the body or configurations with no horizontal tail.

Contribution of Vertical Panel

When adding a vertical panel to a configuration, the following general procedure is used. However, a more thorough understanding will be gained by studying the sample problems.

Step 1. Construct the Mach lines $\left(\mu = \sin^{-1}\frac{1}{M}\right)$ emenating from the exposed root chord leading and trailing edges of all panels other than that to be added, as shown in sketch (b). (This is an approximation to the horizontal panel flow field boundaries strictly applicable to a flat plate airfoil at zero angle of attack and does not account for the effects of vortices and wakes.)



SKETCH (b)

Step 2. Determine the areas or regions on the added panel affected by each vehicle component, S_1, S_2, S_3, etc.

Step 3. Determine the body-radius-to-semi-span ratios for each region for both the horizontal and vertical surfaces. The vertical span of a given region is taken as the total span of the added panel measured to the body center line, as shown in sketch (b). The semi-span of horizontal surfaces (wings and horizontal tails) is the maximum semi-span of these surfaces. The radius of the body for a given region is taken to be the average radius for that region.

Step 4. The apparent mass factors K for each region are determined from figures 5.3.1.1-25a through 5.3.1.1-25nn using the geometry of each region as determined in Step 3. In determining the K factors for each region any point lying forward of the Mach line from the leading-edge body juncture of a panel does not feel the presence of the panel, and any point lying behind the shock wave drawn from the trailing-edge body juncture of a panel does not feel the presence of the panel. For example, referring to sketch (b), the upper vertical panel is divided into three regions of influence. Region S_1 senses the presence of the body and the wing; region S_2 only the body; and region S_3 the body and the lower vertical stabilizer. Interpolation for the appropriate geometry must frequently be made when using these charts. It is recommended that at least three points be used in these interpolations because of the nonlinearities of the characteristics involved. (See Method 3 of paragraph A for a general discussion on the use of the K charts.)

Step 5. Each apparent mass factor is reduced by the ratio of the area of its region on the added panel (Step2) to the total exposed panel area.

Step 6. The total effective apparent-mass factor for the added panel K′ is then the sum of those calculated for each region (Step 5). For example in the case illustrated in sketch (b), K′ of the upper vertical panel in the presence of wing, body, horizontal tail, and ventral is given as

$$K' = K_{V(WB)} \frac{S_1}{S_{V_e}} + K_{V(B)} \frac{S_2}{S_{V_e}} + K_{V(BU)} \frac{S_3}{S_{V_e}}$$

Step 7. The side-force curve slope (based on total wing area) of a vertical panel added to an empennage is given by

$$(\Delta C_{Y_\beta})_p = -K'(C_{N_\alpha})_p \frac{S_{p_e}}{S_w} \qquad 5.3.1.1\text{-f}$$

where the subscript $_p$ and S_{p_e} are as defined in Method 3 of paragraph A, and $(C_{N_\alpha})_p$ is the normal-force-curve slope of the isolated vertical panel mounted on a reflection plane, from paragraph C of Section 4.1.3.2, based on twice the aspect ratio defined by the average exposed span and exposed area.

Contribution of Horizontal Tail

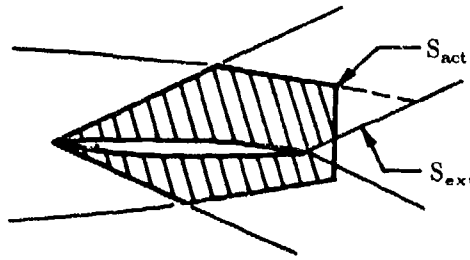
In determining the total empennage side force due to sideslip which results from the addition of all panels present in the empennage the horizontal tail must be added first (see paragraph C, Section 5.6.1.1). Although the horizontal tail contribution to C_{Y_β} is usually small and for most calculations can be neglected; it can provide a significant contribution to the sideslip derivative C_{n_β}.

The contribution to the sideslip derivative C_{Y_β} (based on total wing area) of a horizontal tail added to a body is given by

$$(\Delta C_{Y_\beta})_{H(B)} = K_{H(B)} (C_{Y_\beta})_B \frac{S_{act}}{S_{ext}} \frac{S_{B_{Ref}}}{S_W} \qquad 5.3.1.1\text{-g}$$

where $K_{H(B)}$, $(C_{Y_\beta})_B$, and $S_{B_{Ref}}$ are as defined in Method 3 of paragraph A

$\frac{S_{act}}{S_{ext}}$ is the ratio of the actual projected side area of the fuselage to that of the extended fuselage as determined by Mach lines $\left(\mu = \sin^{-1} \frac{1}{M}\right)$ originating from the leading and trailing edge of the exposed root chord (see sketch (c))

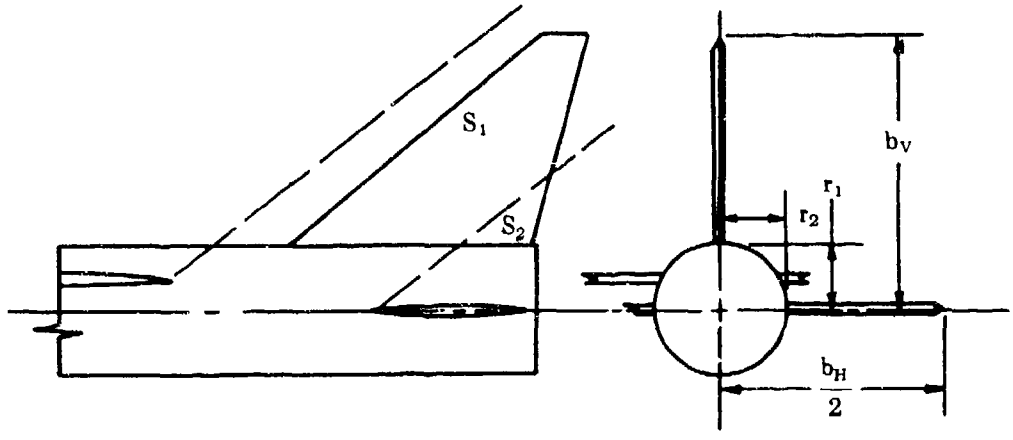


SKETCH (c)

This method is substantiated in table 5.3.1.1-C (from reference 3).

Sample Problems

1. Given: The configuration of reference 16 consisting of wing, body, horizontal tail, and upper vertical stabilize
Find the effect of adding the vertical tail to the wing-body-horizontal tail combination.



Vertical Tail Characteristics

$A_V = 1.59$	$A_{V_e} = 1.48$	$S_V = 35.3$ sq in.	$S_{V_e} = 21.9$ sq in.	$\Lambda_{LE_V} = 50.4^\circ$
$\lambda_V = 0.153$	$\lambda_{V_e} = 0.192$	$b_V = 7.48$ in.	NACA 65A005 airfoil	

Additional Characteristics

$M = 1.61$ $\mu = \sin^{-1}\frac{1}{M} = 38.5°$ $r_1 = 1.78$ in. $r_2 = 1.78$ in.

$\frac{b_H}{2} = 6.06$ in. $S_W = 160.4$ sq in. $S_1 = 19.9$ sq in. $S_2 = 2.0$ sq in.

$z_H = 0$ (horizontal tail on body centerline)

Compute:

$2A_{V_e} \tan \Lambda_{LE_V} = 3.575$

$\beta = \sqrt{M^2 - 1} = 1.265$

$\frac{\tan \Lambda_{LE_V}}{\beta} = 0.955$

$\beta(C_{N_\alpha})_V = 3.90$ per rad (figures 4.1.3.2-56a, -56b, -56c interpolated for $\lambda_{V_e} = 0.192$)

$(C_{N_\alpha})_V = 3.08$ per rad (based on S_{V_e})

Determine the effective apparent mass ratio due to adding the vertical stabilizer to the wing-body-horizontal stabilizer combination. The empennage in this case consists of body, horizontal stabilizer and vertical stabilizer. The effective apparent mass ratio to be found is that due to adding the vertical stabilizer to the body and horizontal tail, $K'_{V(HB)}$.

Referring to the configuration sketch, the region S_1 senses only the body, while S_2 senses both the body and the horizontal stabilizer. Therefore, the effective apparent mass ratio is given by

$$K'_{V(HB)} = K_{V(B)} \frac{S_1}{S_{V_e}} + K_{V(HB)} \frac{S_2}{S_{V_e}}$$

Determine $K_{V(B)}$

$$\left(\frac{r_1}{r_2}\right) = 1.000; \left(\frac{r_1}{b}\right)_{\substack{V \\ \text{added} \\ \text{panel}}} = 0.238; \left(\frac{r_1}{b}\right)_{\substack{U \\ \text{existing} \\ \text{panel}}} = 1.000$$

using the above parameters and table 5.3.1.1-A it is seen that $K_{V(B)}$ is obtained from figure 5.3.1.1-25a

$K_{V(B)} = 1.25$

Determine $K_{V(HB)}$

$$\left(\frac{r_1}{r_2}\right) = 1.000; \left(\frac{r_2}{b_H/2}\right) = 0.293; \left(\frac{r_1}{b}\right)_{\substack{V \\ \text{added} \\ \text{panel}}} = 0.238; \left(\frac{r_1}{b}\right)_{\substack{U \\ \text{existing} \\ \text{panel}}} = 1.000$$

Using the above parameters and table 5.3.1.1-A it is seen that $K_{V(HB)}$ is obtained from figures 5.3.1.1-25b, -25c, and -25d interpolated for $\left(r_2/\frac{b_H}{2}\right) = 0.293$

$K_{V(HB)} = 1.375$

$$K'_{V(HB)} = (1.25)\left(\frac{19.9}{21.9}\right) + (1.375)\left(\frac{2.0}{21.9}\right) = 1.26$$

Solution:

$$(\Delta C_{Y_\beta}) = -K' (C_{N_\alpha})_p \frac{S_{o_o}}{S_W} \quad \text{(equation 5.3.1.1-f)}$$

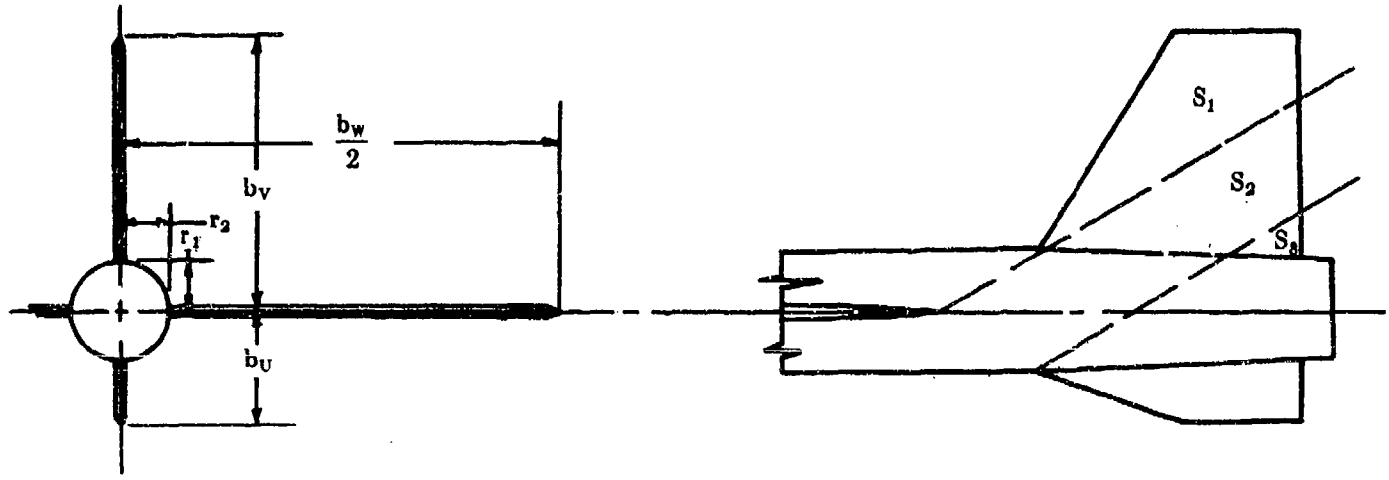
$$(\Delta C_{Y_\beta})_{V(WBH)} = -K'_{V(HB)} (C_{N_\alpha})_V \frac{S_{V_e}}{S_W}$$

$$= (-1.26)\ (3.08)\left(\frac{21.90}{160.4}\right)$$

$$= -0.529 \text{ per rad (based on } S_W)$$

This compares with an experimental value of -0.486 per radian from reference 16.

2. Given: The configuration of reference 18 consisting of wing, body, upper vertical stabilizer and lower vertical stabilizer. Find the effect of adding the upper vertical stabilizing surface to the wing-body-lower vertical stabilizer combination.



Upper Vertical Tail Characteristics

$A_V = 1.29$	$A_{V_e} = 1.12$	$S_V = 43.5$ sq in.	$S_{V_e} = 31.6$ sq in.	$\Lambda_{LE_V} = 32.5°$
$\lambda_V = 0.42$	$\lambda_{V_e} = 0.482$	$b_V = 7.48$ in.	airfoil: wedge nose, slab sides (constant thickness)	

Additional Characteristics

$M = 2.01$	$\mu = \sin^{-1}\frac{1}{M} = 29.8°$		$r_1 = 1.50$ in.	$r_2 = 1.50$ in.
$S_W = 144$ sq in.	$\frac{b_W}{2} = 12.0$ in.	$S_1 = 16.35$ sq in.	$S_2 = 14.10$ sq in.	$S_3 = 1.15$ sq in.
$z_W = 0$ (wing on body centerline)		$b_U = 3.05$ in.		

Compute:

$2A_{V_e} \tan \Lambda_{LE_V} = 1.425$

$\beta = \sqrt{M^2 - 1} = 1.744$

$\frac{\tan \Lambda_{LE_V}}{\beta} = 0.365$

$\beta(C_{N_\alpha})_V = 3.68$ per rad (figures 4.1.3.2-56c, -56d, -56e interpolated for $\lambda_{V_e} = 0.482$)

$(C_{N_\alpha})_V = 2.12$ per rad (based on S_{V_e})

Determine the effective apparent mass ratio due to adding the upper vertical stabilizer to the wing-body-lower vertical stabilizer combination. The empennage in this case consists of body, upper vertical stabilizer and lower vertical stabilizer (ventral). The effective apparent mass ratio to be found is that due to adding the upper vertical stabilizer to the body and ventral, $K'_{V(BU)}$.

Referring to the configuration sketch, the region S_1 senses the wing and the body, S_2 senses only the body and S_3 senses both the body and the ventral. Therefore, the effective apparent mass ratio is given by

$$K'_{V(BU)} = K_{V(WB)} \frac{S_1}{S_{V_e}} + K_{V(B)} \frac{S_2}{S_{V_e}} + K_{V(BU)} \frac{S_3}{S_{V_e}}$$

Determine $K_{V(WB)}$

$$\left(\frac{r_1}{r_2}\right) = 1.000; \left(\frac{r_2}{b_w/2}\right) = 0.125; \left(\frac{r_1}{b}\right)_{\substack{V \\ \text{added} \\ \text{panel}}} = 0.200$$

The ventral surface is not felt in region S_1, therefore

$$\left(\frac{r_1}{b}\right)_{\substack{U \\ \text{existing} \\ \text{panel}}} = 1.000$$

Using the above parameters and table 5.3.1.1-A it is seen that $K_{V(WB)}$ is obtained from figures 5.3.1.1-25b, -25c, -25d interpolated for $(r_2/\frac{b_w}{2}) = 0.125$

$K_{V(WB)} = 1.36$

Determine $K_{V(B)}$

$$\left(\frac{r_1}{r_2}\right) = 1.000; \left(\frac{r_1}{b}\right)_{\substack{V \\ \text{added} \\ \text{panel}}} = 0.200; \left(\frac{r_1}{b}\right)_{\substack{U \\ \text{existing} \\ \text{panel}}} = 1.000 \text{ (region } S_2 \text{ does not sense the ventral)}$$

Using the above parameters table 5.3.1.1-A it is seen that $K_{V(B)}$ is obtained from figure 5.3.1.1-25a

$K_{V(B)} = 1.13$

Determine $K_{V(BU)}$

$$\left(\frac{r_1}{r_2}\right) = 1.000; \left(\frac{r_1}{b}\right)_{\substack{V \\ \text{added} \\ \text{panel}}} = 0.200; \left(\frac{r_1}{b}\right)_{\substack{U \\ \text{existing} \\ \text{panel}}} = 0.492$$

Using the above parameters and table 5.3.1.1-A it is seen that $K_{V(BU)}$ is obtained from figure 5.3.1.1-25a interpolated for $(r_1/b)_U = 0.492$

$$K_{V(BU)} = 1.24$$

$$K'_{V(BU)} = (1.36)\left(\frac{16.35}{31.60}\right) + (1.13)\left(\frac{14.10}{31.60}\right) + (1.24)\left(\frac{1.15}{31.60}\right)$$

$$= 1.253$$

Solution:

$$(\Delta C_{Y_\beta})_p = -K' (C_{N_\alpha})_p \frac{S_{p_e}}{S_w} \quad \text{(equation 5.3.1.1-f)}$$

$$(\Delta C_{Y_\beta})_{V(WBU)} = -K'_{V(BU)} (C_{N_\alpha})_V \frac{S_{V_e}}{S_w}$$

$$= (-1.253)\ (2.12)\left(\frac{31.60}{144.0}\right)$$

$$= -0.583 \text{ per rad (based on } S_w)$$

This compares with an experimental value of -0.601 per radian from reference 18.

D. HYPERSONIC

A general discussion of hypersonic flow is given in paragraph D of Section 4.1.3.3 and in the references cited therein. The application of theories to tail components is complicated by the flow disturbances of forward components (body and wings) in the form of vortices, shock waves, and wakes. In general, these effects have not been generalized and specific configurations must either be compared to similar configurations for which data exist or be submitted to a test program. The recommendations of the Datcom for this speed regime are necessarily tentative and will be updated as information becomes available.

DATCOM METHOD

For configurations in which the tail panels are mounted on the body, it is recommended that the supersonic method described in paragraph C be applied at the higher Mach numbers. However, this method has not been substantiated beyond a Mach number of 6.86 (see table 5.3.1.1-C).

Alternatively, the vertical-panel contribution to C_{Y_β} may be estimated by the hypersonic small-disturbance theory, which gives a local pressure coefficient of

$$C_p = (\beta \pm \delta)^2 \left(\frac{\gamma + 1}{2} \pm \sqrt{\frac{(\gamma + 1)^2}{4} + \frac{4}{(M^2 - 1)(\beta \pm \delta)^2}} \right) \qquad 5.3.1.1\text{-h}$$

where δ is the local slope of the surface of the vertical panel with respect to the vertical plane of symmetry in radians

γ is the ratio of specific heats

β is the sideslip angle in radians

The sign of $(\beta \pm \delta)$ should be chosen to give the correct local angle of sideslip.

The plus sign before the radical in equation 5.3.1.1-h applies to the compression side of the surface and the minus sign to the expansion side. The equation is strictly valid only for sharp-edged sections and for $\delta << 1$. For a slab-sided section the pressure coefficient becomes the side-force coefficient directly (based on exposed panel area).

For very high Mach numbers, Newtonian flow can be assumed. The pressure coefficient for this case is

$$C_p = 2\sin^2(\beta \pm \delta) \qquad 5.3.1.1\text{-i}$$

Care must be taken to assure that portions of the panels that are "blanketed" by forward components, i.e., are not "seen" from the free-stream direction, are not included in the calculation. In these regions the pressure coefficient is assumed to be zero. The pressure coefficient is also assumed to be zero on the leeward side of the panel when the sideslip angle β is greater than the local panel slope δ.

These methods have not been substantiated, since not enough test data are available.

Sample Problem

Given:

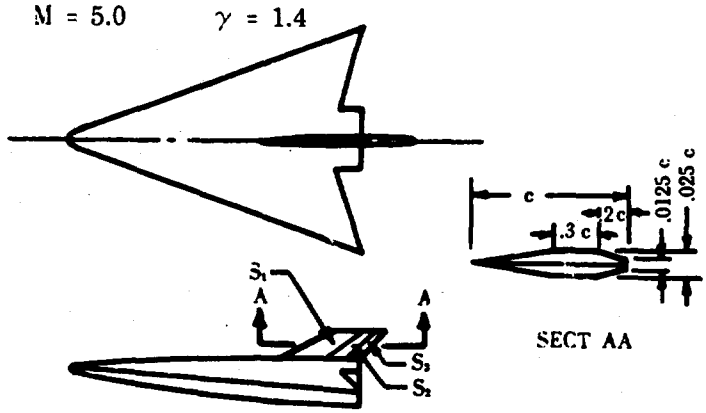
$\frac{S_1}{S_V} = .5$ $\quad \frac{S_3}{S_V} = .2$ $\quad \frac{S_2}{S_V} = .3$ $\quad M = 5.0$ $\quad \gamma = 1.4$

Compute (for $\beta = 1^\circ$):

$$\frac{\gamma + 1}{2} = 1.20$$

$$\frac{(\gamma + 1)^2}{4} = 1.44$$

$$M^2 - 1 = 24$$



Region	$\beta \pm \delta$ (rad)	
	Compression Side*	Expansion Side*
1	.04240	+.00750
2	.01745	−.01745
3	−.01396	−.04886

Values of pressure coefficient, C_p, calculated for each region by means of equation 5.3.1.1-h are listed in the following table (plus signs are used for flow compressions and minus signs for flow expansions in both tables).

Region	C_p	
	Compression Side	Expansion Side
1	.01960	+.00300
2	.00748	−.00674
3	−.00546	−.01728

*For a similar slab-sided surface. In actuality, both sides of region 1 are in compression and both sides of region 3 are in an expansion field.

Solution:

The sum of the pressure coefficients acting on the two sides of a given region is given by the difference of the two pressure coefficients

$$(C_p)_{\substack{\text{compression}\\ \text{side}}} - (C_p)_{\substack{\text{extension}\\ \text{side}}} = \Delta C_p$$

Thus, combining the pressure coefficients for each region and converting to side force coefficient gives

$$\Delta C_Y = \Delta C_{p1} \frac{S_1}{S_V} + \Delta C_{p2} \frac{S_2}{S_V} + \Delta C_{p3} \frac{S_3}{S_V}$$

$$= .0166 \times .5 + .01422 \times .3 + .01182 \times .2$$

$$= .015$$

Therefore

$$(\Delta C_{Y_\beta})_V = -.015 \text{ per degree or } -.86 \text{ per radian}$$

This is essentially the configuration of reference 19.

5.3.1.2 TAIL-BODY SIDE-FORCE COEFFICIENT C_Y AT ANGLE OF ATTACK

The tail-body side force developed at combined angles is nonlinear with respect to both sideslip and angle of attack because of the body-vortex induced sidewash on the upper vertical tail and the cross-coupling of upwash and sidewash velocities. To obtain the sideslip derivative C_{Y_β}, it is recommended that C_Y be calculated at several angles of attack for a small sideslip angle ($\beta \leq 4^\circ$). Then at each angle of attack the side force is assumed linear with sideslip for small values of β so that

$$C_{Y_\beta} \approx \frac{C_Y}{\beta}.$$

A. SUBSONIC

The analysis of tail-body combinations at subsonic speeds and zero angle of attack is described in paragraph A of Section 5.3.1.1. At combined sideslip and angle of attack, however, two other phenomena must be considered: the body-vortex interference, and the cross-coupling effect of sideslip and angle-of-attack induced cross-flow velocities. Unfortunately neither of these phenomena can be estimated at other than supersonic speeds.

The method presented herein is restricted to first-order approximations at relatively low angles of attack.

DATCOM METHOD

It is recommended that the methods of paragraph A of Section 5.3.1.1 be used in the linear-lift angle-of-attack region.

B. TRANSONIC

As stated for the subsonic case the body-vortex interference and cross-coupling of upwash and sidewash velocities due to combined angles cannot be estimated at other than supersonic speeds.

Furthermore, as stated in paragraph B of Section 5.3.1.1, no method is available for estimating the side force on a vertical panel at zero angle of attack.

DATCOM METHOD

No method is available for estimating this coefficient and none is presented in the Datcom.

C. SUPERSONIC

The method of this Section is an extension of that presented as Method 3 of paragraph A and in paragraph C of Section 5.3.1.1. The discussion appearing there also applies here and will not be repeated. At combined sideslip and angle of attack, however, two additional effects must be considered. The cross-coupling effect of sideslip and angle of attack induces cross-flow velocities at the tail panels, and at angle of attack the body sheds vortices which proceed downstream to cause interference at the tail.

The method presented herein does not account for interferences existing between a wing and tail surfaces. If a wing is present in the configuration three additional types of interference exist between the wing and tail panels at supersonic speeds. These interferences produce additional nonlinear effects which are accounted for in paragraph C of Section 5.6.1.2.

DATCOM METHOD

The method presented in this Section for estimating the tail contribution to the sideslip coefficient C_Y is from reference 1, and uses the apparent-mass concept described in Method 3 of paragraph A in Section 5.3.1.1. The method prescribes the order in which the tail panels should be added to the configuration for analysis purposes.

This order is:

The horizontal tail is always added first, but the method is valid only for configurations with a horizontal tail mounted on the body or for configurations with no horizontal tail.

The remaining tail panels are then added, starting with the most aft and working forward (the position is measured in a streamwise direction to the leading edge of the exposed root chord).

The proper weighting of the apparent-mass ratios, which accounts for partial-panel areas affected by existing panels, is outlined in paragraph C of Section 5.3.1.1. The result is an effective apparent-mass factor K'.

For tail-body configurations at angle of attack, the horizontal-tail pressure field is not delineated by Mach lines alone. The pressure field produced is bounded by shock waves at the upper trailing edge and the lower leading edge (at positive angles of attack). If the airfoil is assumed to be thin, it is an easy matter to define the expansion and compression fields by direct application of shock-expansion theory. We assume that the flow in the region of the tail is the two-dimensional shock-expansion field corresponding to the exposed root chord of the horizontal surface. Any effects of horizontal surface-body interference or horizontal surface section in distorting the shock-expansion field are neglected. This method is also used in Section 5.6.1.2 to define the pressure field produced by a wing. The method is described below:

Upper surface of panel:

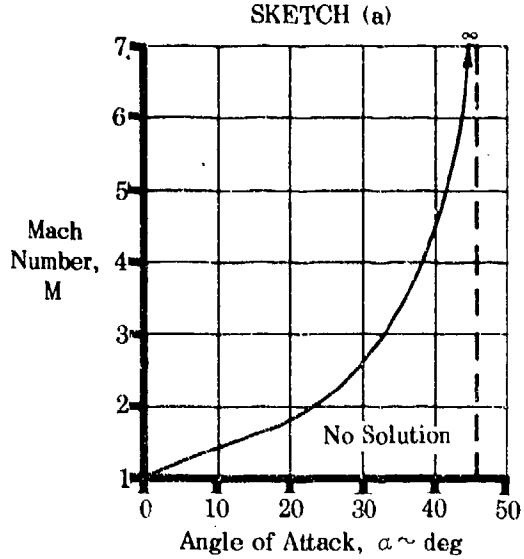
1. Find the leading-edge Mach line $\mu = \sin^{-1} \frac{1}{M_\infty}$ (measured relative to the free stream).
2. Find Mach number M_1 aft of expansion from figure 4.4.1-82. Read ν at M_∞. Then read M_1 at $\nu + \alpha = \nu_1$.
3. Find trailing-edge shock angle. Enter figure 4.4.1-81 at $-\delta' = \alpha$ and read θ_1 at M_1 (measured relative to the chord plane of the horizontal surface).

Lower surface of panel:

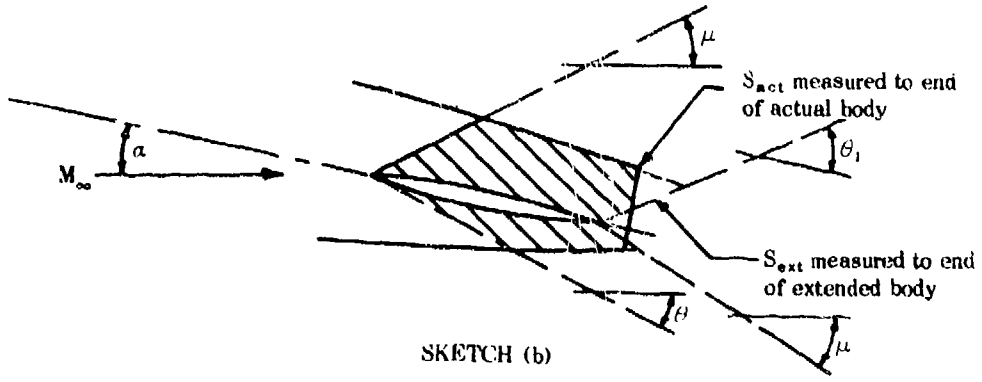
1. Find leading-edge shock angle. Enter figure 4.4.1-81 at $-\delta' = \alpha$ and read θ at M_∞ (measured relative to the free stream).
2. Find Mach number M_2 beneath wing from figure 4.4.1-82. Read ν at M_∞. Then read M_2 at $\nu - \alpha = \nu_2$.
3. Find trailing-edge Mach line (end of expansion), $\mu = \sin^{-1} \frac{1}{M_\infty}$ (measured relative to the free stream).

For a specified initial Mach number there is a maximum value of the angle of attack for which there exists an oblique shock solution. Or, conversely, for a specified angle of attack there is a minimum initial Mach number for which there is an oblique shock solution. The relation between Mach number and angle of attack below which no oblique shock solutions may be obtained is indicated in sketch (a).

SKETCH (a)

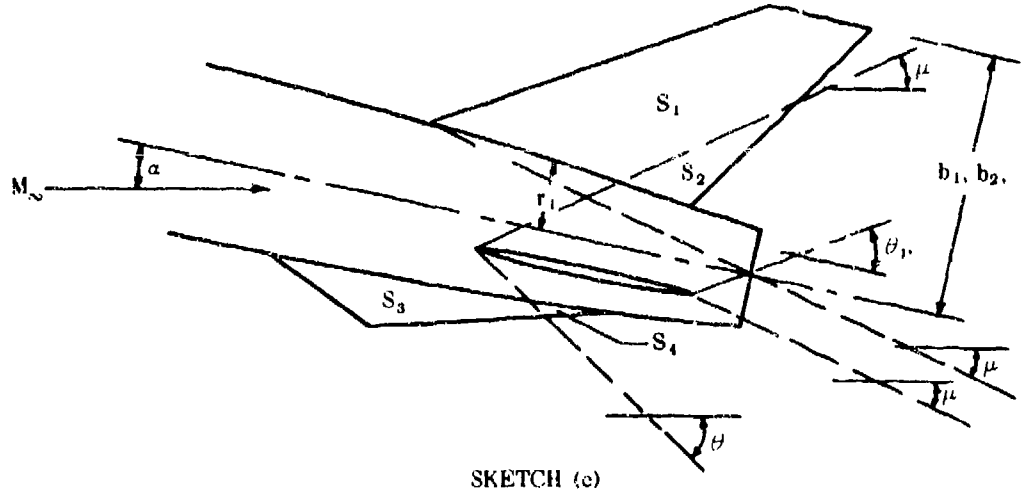


The pressure-field boundaries produced by a horizontal tail are defined in sketch (b) which shows the body area influenced by the horizontal tail. Compare this with sketch (c) of Section 5.3.1.1.



SKETCH (b)

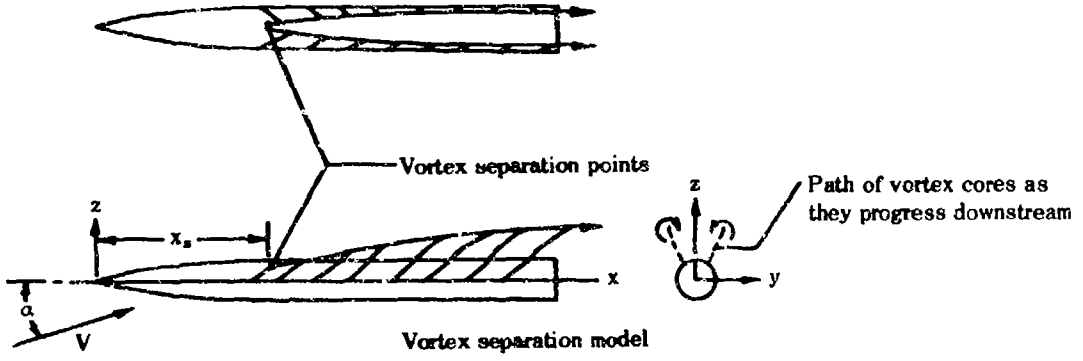
The pressure-field boundaries of a typical tail-body configuration are illustrated in sketch (c). For this example the vertical tail exposed root-chord leading edge is aft of the ventral fin exposed root-chord leading edge; therefore, the ventral fin has no effect on the vertical tail since it is added later. At the angle of attack and Mach number represented the horizontal tail influences both the vertical tail and the ventral fin; however, the vertical tail does not influence the ventral fin.



SKETCH (c)

The modifying effect of angle of attack on the tail contribution to the side-force coefficient is accounted for by the cross-coupling interference factor K_ϕ, developed from slender-body theory in reference 2.

The effect of body-vortex induced sidewash on the upper vertical tail side-force coefficient is calculated using interference factors from references 3 and 4, and vortex strengths and positions from Section 4.3.1.3. A simplified model of body-vortex separation is shown in sketch (d). At some distance x_s behind the body nose a pair of vortices separates from the body. As the vortices progress downstream, they increase in strength as a result of small vortex filaments originating on the body and feeding into the vortex cores. The positions and vortex strengths of a body of revolution are dependent upon angle of attack and the axial distance x behind the body nose. These vortex strengths and positions are presented in Section 4.3.1.3 as functions only of a single nondimensional parameter and the results are presented in the y - z coordinate system. In the method that follows these vortex strengths and positions are resolved into vertical tail reference coordinates for the configuration at combined angle of attack and sideslip. The estimation procedure for finding vortex positions and strengths is restricted to circular bodies; therefore, the Datcom method is not valid for other body shapes.



Vortex separation model

SKETCH (d)

The contribution of the tail panels to the side-force coefficient is determined from the following equation

$$C_{Y_{H(B)V(B)U(B)}} = C_{Y_{H(B)}} + C_{Y_V} + C_{Y_U} \qquad 5.3.1.2\text{-a}$$

where

$C_{Y_{H(B)}}$ is the contribution of the horizontal tail in the presence of the body, calculated by equation 5.3.1.2-b

C_{Y_V} is the contribution of the vertical tail, including body and horizontal tail interference effects, effects of cross-coupling of α and β, and effects of body vortices, and may include ventral fin interference. Calculate by equation 5.3.1.2-c.

C_{Y_U} is the contribution of the ventral fin, including body and horizontal tail interference effects, and effects of cross-coupling of α and β, and may include vertical tail interference. Calculate by equation 5.3.1.2-g. (Ventral fins are not affected by body vortices.)

The following procedure is used in determining the contributions of the tail panels:

Step 1

Determine the contribution of the horizontal tail in the presence of the body. The procedure is completely analogous to that for determining the contribution of the wing in the presence of the body in Section 5.2.1.2. This is always calculated first but cannot be analyzed if the panel is not body-mounted. The equation is

$$C_{Y_{H(B)}} = 2\eta_B K_{H(B)} k(\alpha) \frac{S_B}{S_W} \frac{S_{act}}{S_{ext}} \beta - \frac{c_{d_c}\left(c_{Y_c}\right)_H d}{S_W} \beta(\beta - \alpha') \qquad 5.3.1.2\text{-b}$$

where the first term on the right-hand side is the forebody cross-flow effect and is taken as zero for the midtail case, and the second term on the right-hand side is an approximate effect of the horizontal inhibiting the viscous cross-flow occuring along the body at large angles of attack.

η_B is the Mach number correction to the horizontal tail-body interference coefficient from figure 5.2.1.2-7 using the exposed root chord of the horizontal tail and the average body diameter at the horizontal tail

$K_{H(B)}$ is the horizontal tail-body interference coefficient, or apparent-mass ratio, from figure 5.3.1.1-2500. For tail positions other than midtail ($K_{H(B)} = 0$) or tangent, a nonlinear interpolation is described in Method 3, paragraph A, Section 5.3.1.1.

$k(\alpha)$ is the angle-of-attack correction to the horizontal tail-body interference coefficient obtained from figure 5.2.1.2-8 using the exposed root chord of the horizontal tail and the average body diameter at the horizontal tail. For tail positions other than midtail ($k(\alpha) = 0$) or tangent, a nonlinear interpolation is described in Method 3, paragraph A, Section 5.3.1.1.

$\frac{S_{act}}{S_{ext}}$ is the ratio of the actual projected side area of the fuselage to that of the extended fuselage as illustrated in sketch (b). These areas are bounded by the shock waves and expansion fans of the horizontal tail.

c_{d_c} is the cross-flow drag coefficient, obtained from figure 4.2.1.2-35b, with $M_c = M_\infty \sin \alpha'$

$\left(c_{r_e}\right)_H$ is the exposed root chord of the horizontal tail

β is the sideslip angle in radians

α' is the angle of inclination, $\alpha' = \sqrt{\alpha^2 + \beta^2}$, in radians

Step 2

Determine the vertical tail contribution by

$$C_{Y_V} = C_{Y_{V(K,\phi)}} + C_{Y_{V(\Gamma_B)}} \qquad 5.3.1.2\text{-c}$$

where

$C_{Y_{V(K,\phi)}}$ accounts for horizontal tail-body interference and cross-coupling of α and β acting on the vertical stabilizer, given by equation 5.3.1.2-d

$C_{Y_{V(\Gamma_B)}}$ accounts for the effect of body vortices on the vertical stabilizer, given by equation 5.3.1.2-e

Compute:

$$C_{Y_{V(K,\phi)}} = \left[K'_V - K_{\phi_V}\, \alpha \tan \Lambda_{LE_V}\right] (-C_{N_\alpha})_V\, \beta\, \frac{S_{V_e}}{S_W} \qquad 5.3.1.2\text{-d}$$

where

K'_V is the effective apparent-mass ratio of the vertical tail, as described in paragraph C of Section 5.3.1.1, but refers to sketch (c) of this Section. This factor includes the presence of the horizontal tail; but does not include the presence of the ventral fin if the ventral fin is farther forward than the vertical tail as measured from the leading edges of the exposed root chords.

K_{ϕ_V} is the cross-coupling interference factor of the vertical tail, from figure 5.3.1.2-12

α is the angle of attack in radians

Λ_{LE_V} is the sweepback angle of the vertical tail leading edge

$(C_{N_\alpha})_V$ is the normal-force-curve slope of the vertical tail as defined in paragraph C of Section 5.3.1.1

Compute:

$$C_{Y_{V(\Gamma_B)}} = \Delta i_v \left[\frac{\Gamma_B}{2\pi\, \alpha'\, Vr}\right] \frac{(-C_{N_\alpha})_V\, \alpha'\, S_{V_e}}{\left(\frac{b_V}{r} - 1\right) S_W} \qquad 5.3.1.2\text{-e}$$

where

$\frac{\Gamma_B}{2\pi\, \alpha'\, Vr}$ is the nondimensional vortex strength obtained from figure 4.3.1.3-15 of Section 4.3.1.3 with α replaced by α' in all cases and x taken as the distance from the body nose to the midpoint of the MAC of the exposed panel.

α' is the angle of inclination in radians: $\alpha' = \sqrt{\alpha^2 + \beta^2}$

r is the average radius of the body along the vertical tail exposed root chord

Δi_v is the vortex interference factor:

$\Delta i_v = i_{v_1} - i_{v_2}$. The values of i_{v_1} and i_{v_2} are given in figure 5.3.1.2-13, where they are presented as functions of the positions of the body vortices at the vertical tail

$\frac{z_{v_1}}{b_v}$, $\frac{y_{v_1}}{b_v}$, $\frac{z_{v_2}}{b_v}$, and $\frac{y_{v_2}}{b_v}$ (see sketch (e)). These are given by

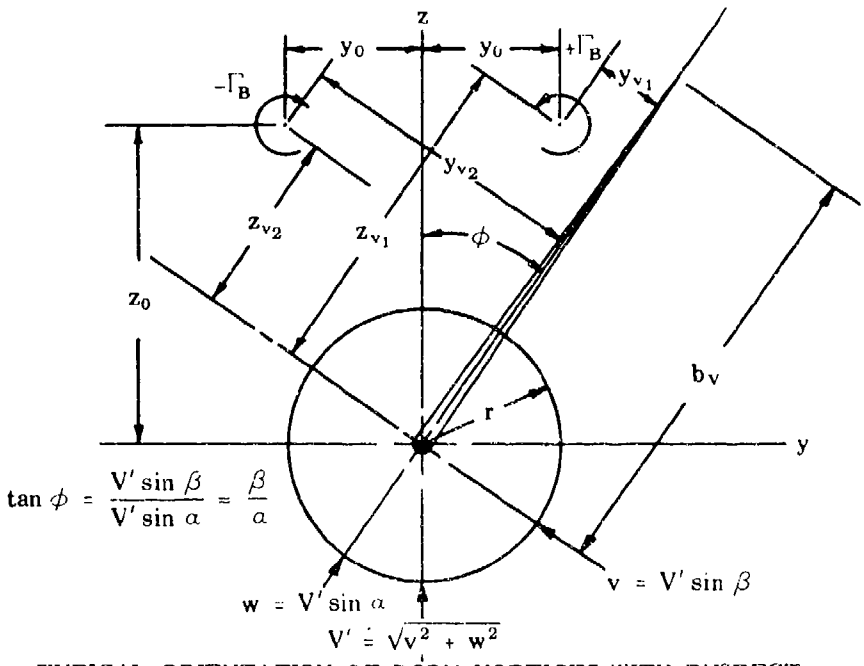
$$\left.\begin{aligned}
\frac{z_{v_1}}{b_v} &= \frac{r}{b_v}\left[\frac{z_0}{r}\cos\phi + \frac{y_0}{r}\sin\phi\right] \\
\frac{y_{v_1}}{b_v} &= \frac{r}{b_v}\left[\frac{z_0}{r}\sin\phi - \frac{y_0}{r}\cos\phi\right] \\
\frac{z_{v_2}}{b_v} &= \frac{r}{b_v}\left[\frac{z_0}{r}\cos\phi - \frac{y_0}{r}\sin\phi\right] \\
\frac{y_{v_2}}{b_v} &= \frac{r}{b_v}\left[\frac{z_0}{r}\sin\phi + \frac{y_0}{r}\cos\phi\right]
\end{aligned}\right\} \quad 5.3.1.2\text{-f}$$

where $\phi = \tan^{-1}\frac{\beta}{\alpha}$

$\frac{z_0}{r}$ is the vertical position of the body vortex in the y - z coordinate system from figure 4.3.1.3-13b

$\frac{y_0}{r}$ is the lateral position of the body vortex in the y - z coordinate system from figure 4.3.1.3-14

In reading these last two figures α must be replaced by α' in all cases and x is taken as the distance from the body nose to the midpoint of the MAC of the exposed panel.



TYPICAL ORIENTATION OF BODY VORTICES WITH RESPECT TO TAIL PLANE FOR CONFIGURATION AT COMBINED ANGLES

SKETCH (e)

Step 3

Determine the ventral fin contribution by

$$C_{Y_U} = C_{Y_{U(K,\Phi)}} = \left[K'_U + K_{\Phi_U} \alpha \tan \Lambda_{LE_U}\right] (-C_{N_\alpha})_U \beta \frac{S_{U_e}}{S_w} \qquad 5.3.1.2\text{-g}$$

where

K'_U is the effective apparent-mass ratio of the ventral fin, as described in paragraph C of Section 5.3.1.1, but refers to sketch (c) of this Section. This factor includes the presence of a horizontal tail; but does not include the presence of the vertical tail if the vertical tail is farther forward than the ventral fin, as measured from the leading edge of the exposed root chords.

K_{Φ_U} is the cross-coupling interference factor of the ventral fin from figure 5.3.1.2-12

Λ_{LE_U} is the sweepback angle of the ventral fin leading edge

$(C_{N_\alpha})_U$ is the normal-force-curve slope of the ventral fin as defined in paragraph C of Section 5.3.1.1

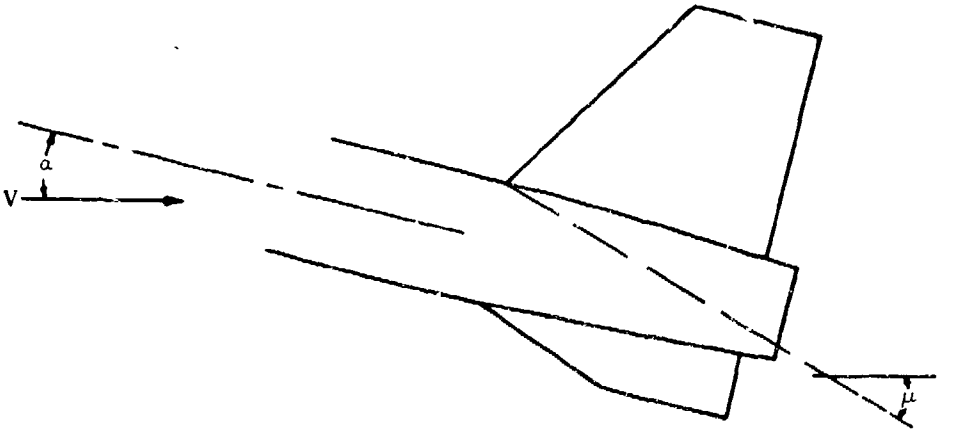
Step 4

All terms are now available for substitution into equation 5.3.1.2-a for finding $C_{Y_{H V(U)}}$.

Values for the incremental coefficient resulting from the addition of upper vertical tails to circular bodies, calculated using equation 5.3.1.2-c, are compared with experimental results in figure 5.3.1.2-11. It is evident from the experimental data that a strong destabilizing effect occurs with increasing angle of attack and that this effect is accurately predicted by the Datcom method over the angle-of-attack range of the tests.

Sample Problem

Given: The configuration of reference 5 consisting of body, vertical tail, and ventral tail. This is the same configuration as that of sample problem 2, paragraph C, Section 5.3.1.1. Find the side-force coefficient developed by the vertical and ventral tails in the presence of a body at $\alpha = 12^\circ$ and $\beta = 4^\circ$.



Body Characteristics

Ogive cylinder, with slight boattail d = 3.33 in. $r_1 = r_2 = 1.5$ in. (average values in region of tail panels)

Vertical Tail Characteristics

$S_{V_e} = 31.6$ sq in. $b_V = 7.48$ in. $\Lambda_{LE_V} = 32.5^\circ$ $A_{V_e} = 1.12$

$\lambda_{V_e} = 0.482$

Ventral Tail Characteristics

S_{U_e} = 8.54 sq in. b_U = 3.05 in. Λ_{LE_U} = 70° A_{U_e} = 0.35

λ_{U_e} = 0.428

Additional Characteristics

M = 2.01 α = 12° = 0.209 rad β = 4° = 0.070 rad

$\alpha' = \sqrt{\alpha^2 + \beta^2}$ = 12.65° = 0.221 rad S_W = 144.0 sq in.

x/r = 21.87 (x measured from nose to 50-percent-chord point of MAC of exposed vertical panel)

At positive angle of attack, vertical-tail exposed root-chord leading edge is aft of ventral-fin exposed root-chord leading edge.

Ventral fin is not influenced by presence of vertical tail at this angle of attack and Mach number.

Compute:

Step 1. Determine the horizontal-tail contribution $C_{Y_{H(B)}}$

$C_{Y_{H(B)}}$ = 0 (horizontal tail off)

Step 2. Determine the vertical tail contribution C_{Y_V}

Vertical tail interference and cross-coupling term $C_{Y_{V(\alpha,\phi)}}$

Determine K'_V = 1.13 (figure 5.3.1.1-25a) at (r_1/r_2) = 1.000; $(r_1/b)_{V_{\text{added panel}}}$ = 0.200; $(r_1/b)_{U_{\text{existing panel}}}$ = 1.000;

Determine K_{ϕ_V} = 0.687 (figure 5.3.1.2-12 at $(r_1/b)_V$ = 0.200)

Determine $(C_{N_\alpha})_V$ using $2A_{V_e}$

$(C_{N_\alpha})_V$ = 2.12 per rad (based on S_{V_e}) (sample problem 2, paragraph C, Section 5.3.1.1)

$$C_{Y_{V(\alpha,\phi)}} = \left[K'_V - K_{\phi_V}\, \alpha \tan \Lambda_{LE_V}\right] (-C_{N_\alpha})_V\, \beta\, \frac{S_{V_e}}{S_W} \qquad \text{(equation 5.3.1.2-d)}$$

$$= [1.13 - (0.687)(0.209)\tan 32.5^\circ]\,(-2.12)\,(0.070)\left(\frac{31.6}{144.0}\right)$$

$$= -0.0339 \text{ (based on } S_W)$$

Effect of body vortices on vertical tail contribution $C_{Y_{V(\Gamma_B)}}$

$\frac{x_a}{r}$ = 10.6 (figure 4.3.1.3-13a at α' = 12.65°)

$\frac{\alpha'(x - x_a)}{r}$ = 0.221 (21.87 - 10.6) = 2.49

$\frac{\Gamma_B}{2\pi\,\alpha' Vr}$ = 0.86 (figure 4.3.1.3-15 at α' = 12.65°)

$\frac{y_0}{r}$ = 0.71 (figure 4.3.1.3-14 at α' = 12.65°)

$\frac{z_0}{r}$ = 1.53 (figure 4.3.1.3-13b at α' = 12.65°)

$$\phi = \tan^{-1}\frac{\beta}{a} = \tan^{-1}\frac{4}{12} = 18.4^\circ$$

Calculate position of vortices at vertical tail

$$\frac{z_{v_1}}{b_v} = \frac{r}{b_v}\left[\frac{z_0}{r}\cos\phi + \frac{y_0}{r}\sin\phi\right] \qquad \text{(equation 5.3.1.2-f)}$$

$$= \frac{1.50}{7.48}\,(1.53\cos 18.4^\circ + 0.71\sin 18.4^\circ)$$

$$= 0.336$$

$$\frac{y_{v_1}}{b_v} = \frac{r}{b_v}\left[\frac{z_0}{r}\sin\phi - \frac{y_0}{r}\cos\phi\right] \qquad \text{(equation 5.3.1.2-f)}$$

$$= \frac{1.50}{7.48}\,(1.53\sin 18.4^\circ - 0.71\cos 18.4^\circ)$$

$$= -0.038$$

$$\frac{z_{v_2}}{b_v} = \frac{r}{b_v}\left[\frac{z_0}{r}\cos\phi - \frac{y_0}{r}\sin\phi\right] \qquad \text{(equation 5.3.1.2-f)}$$

$$= \frac{1.50}{7.48}\,(1.53\cos 18.4^\circ - 0.71\sin 18.4^\circ)$$

$$= 0.246$$

$$\frac{y_{v_2}}{b_v} = \frac{r}{b_v}\left[\frac{z_0}{r}\sin\phi + \frac{y_0}{r}\cos\phi\right] \qquad \text{(equation 5.3.1.2-f)}$$

$$= \frac{1.50}{7.48}\,(1.53\sin 18.4^\circ + 0.71\cos 18.4^\circ)$$

$$= 0.232$$

Find vortex interference factor

$$\left.\begin{aligned} i_{v_1} &= -1.4 \\ i_{v_2} &= -0.9 \end{aligned}\right\} \qquad \text{(figure 5.3.1.2-13a)}$$

$$\Delta i_v = i_{v_1} - i_{v_2} = (-1.4) - (-0.9) = -0.5$$

$$C_{Y_{V(\Gamma_B)}} = \Delta i_v\left[\frac{\Gamma_B}{2\pi\alpha' V_r}\right]\frac{(-C_{N_\alpha})_V\,\alpha' S_{V_e}}{\left(\frac{b_V}{r} - 1\right)S_W} \qquad \text{(equation 5.3.1.2-e)}$$

$$= (-0.5)\,(0.86)\,\frac{(-2.12)\,(0.221)\,(31.6)}{\left(\frac{7.48}{1.5} - 1\right)(144.0)}$$

$$= 0.01104 \text{ (based on } S_W\text{)}$$

Total vertical tail contribution:

$$C_{Y_V} = C_{Y_{V(K,\phi)}} + C_{Y_{V(\Gamma_B)}} \qquad \text{(equation 5.3.1.2-c)}$$

$$= (-0.0339) + (0.01104)$$

$$= -0.0229 \text{ (based on } S_w)$$

Step 3. Determine the ventral tail contribution C_{Y_U}

Ventral fin interference and cross-coupling term $C_{Y_{U(K,\phi)}}$

Determine $K'_U = 2.11$ (figure 5.3.1.1-25a) at $(r_1/r_2) = 1.000$; $(r_1/b)_{U_{\text{added panel}}} = 0.492$; $(r_1/b)_{V_{\text{existing panel}}} = 1.000$

(no horizontal tail, and ventral fin is out of vertical tail influence).

Determine $K_{\phi_U} = 0.535$ (figure 5.3.1.2-12 at $(r_1/b)_U = 0.492$)

Determine $(C_{N_\alpha})_U$ using $2A_{U_e}$

$(C_{N_\alpha})_U = 1.09$ per rad (Section 4.*.3.2; based on S_{U_e})

Total ventral fin contribution:

$$C_{Y_U} = C_{Y_{U(K,\phi)}} = [K'_U + K_{\phi_U} \alpha \tan \Lambda_{LE_U}] (-C_{N_\alpha})_U \beta \frac{S_{U_e}}{S_w} \qquad \text{(equation 5.3.1.2-g)}$$

$$= [2.11 + (0.535)(0.209) \tan 70^\circ] (-1.09)(0.070)\left(\frac{8.54}{144.0}\right)$$

$$= -0.0109 \text{ (based on } S_w)$$

Solution:

$$C_{Y_{HVU(B)}} = C_{Y_{H(B)}} + C_{Y_V} + C_{Y_U} \qquad \text{(equation 5.3.1.2-a)}$$

$$= 0 + (-0.0229) + (-0.0109)$$

$$= -0.0338 \text{ (based on } S_w)$$

5.3.2 TAIL-BODY SIDESLIP DERIVATIVE C_{l_β}

5.3.2.1 TAIL-BODY SIDESLIP DERIVATIVE C_{l_β} IN THE LINEAR ANGLE-OF-ATTACK RANGE

The method of estimating the contribution of panels in the empennage to the sideslip derivative C_{l_β} is similar to that for estimating the contribution of panels in the empennage to C_{n_β}. That is, the side force generated by an added panel is multiplied by an appropriate moment arm in order to obtain the rolling-moment contribution.

A refinement is required in the case of the contribution of a vertical panel (either an upper or lower vertical panel), since the pressure field that is generated by the vertical panel is reflected on the surface of the horizontal tail. These induced loads on the horizontal tail are perpendicular to this surface and therefore do not significantly affect the vehicle yawing moments or side forces. They do, however, contribute to the rolling moments and hence must not be neglected. The rolling-moment contribution of the horizontal tail is positive (opposes that due to the vertical panel) when the horizontal surface is in the low position with respect to the vertical panel. The rolling-moment contribution has no effect when the horizontal tail is mounted near the midspan of the vertical panel and is negative for the horizontal surface in the high position.

At subsonic speeds these contributions are usually small, and reasonable results are obtained when they are neglected. (Actually they would be quite difficult to estimate.) At transonic speeds they can be quite pronounced, because the pressure field of the entire horizontal surface is strongly influenced by the presence of the vertical panel. At supersonic speeds the interferences are restricted to regions on the horizontal surfaces within the boundaries defined by the shock-wave pattern of the vertical panel. As the Mach number increases, the region of influence decreases because the shock pattern becomes more swept. It is to be expected, therefore, that this horizontal-tail effect will become less significant as the supersonic Mach number increases.

Because of the complexity of the problem, no method for predicting the effects of panels in the empennage at transonic speeds is presented, and the method presented for supersonic speeds does not account for the horizontal-tail contribution. However, the effect of the presence of a horizontal tail is accounted for at supersonic speeds in computing the contribution of a vertical panel.

A. SUBSONIC

The contribution of panels in the empennage to the vehicle sideslip derivative C_{l_β} is based on the values of the panel contribution to C_{Y_β} estimated by the methods of Paragraph A. of Section 5.3.1.1.

In addition to the pressure forces induced on the horizontal tail by the vertical tail, there can be other forces for a configuration having either significant twist and/or dihedral on the horizontal tail. If the horizontal tail is large relative to the wing, the effects of twist and/or dihedral may be worthy of consideration. To consider these effects on the horizontal tail, the method of Section 5.1.2.1 is used; i.e., treating the horizontal tail as an isolated wing. (Caution should be exercised to make certain that the horizontal-tail contribution to C_{l_β} is converted to the same reference area and

length $S_W b_W$ as the wing-body contribution, before adding them together.) However, since the horizontal-tail contribution is very small for most configurations in the subsonic speed regime, the method presented here neglects this contribution.

As mentioned above, reasonable results are obtained at subsonic speeds when the horizontal-tail contribution is neglected. However, in using Method 3 of Paragraph A, Section 5.3.1.1, if a horizontal tail is present in the empennage, its effect on the vertical-tail contribution must be accounted for by proper use of the apparent-mass factor (K) charts. If Method 1 or Method 2 of Paragraph A, Section 5.3.1.1 is used, the effect of a horizontal tail on the vertical-tail contribution is implicitly accounted for by the method.

DATCOM METHOD

The contribution of a vertical panel to the sideslip derivative C_{l_β} is estimated by

$$\left(\Delta C_{l_\beta}\right)_p = \left(\Delta C_{Y_\beta}\right)_p \frac{z_p \cos\alpha - \ell_p \sin\alpha}{b_W} \qquad 5.3.2.1\text{-a}$$

where

p is the subscript referring to the added vertical panel (either an upper vertical stabilizing surface V or a lower vertical stabilizing surface U).

$\left(\Delta C_{Y_\beta}\right)_p$ is the side force due to sideslip of the added vertical panel determined as follows:

For configurations with horizontal panels mounted on the body or with no horizontal panels, use Method 1 or Method 3 of Paragraph A, Section 5.3.1.1.

For configurations with horizontal panels mounted on the vertical panel, use Method 1 of Paragraph A, Section 5.3.1.1.

For twin-vertical-panel configurations, use Method 2 of Paragraph A, Section 5.3.1.1.

z_p is the distance in the z-direction (normal to the longitudinal body axis) between the moment reference center (usually the vehicle center of gravity) and the MAC of the added panel, positive for the panel above the body.

ℓ_p is the distance parallel to the longitudinal body axis between the moment reference center (usually the vehicle center of gravity) and the quarter-chord point of the MAC of the added panel, positive for the added panel behind the moment reference center. The aerodynamic center of the vertical panel could be used, but the inaccuracies of the basic method do not warrant this degree of refinement.

b_W is the span of the wing.

All geometry used in determining the moment arms for the above method is based on the vertical panel extended to the body center line.

For a wingless configuration, b_W is replaced by the vehicle reference length and $(\Delta C_{Y_\beta})_p$ is based on the vehicle reference area.

Results calculated at zero angle of attack by this method are compared to experimental data in Table 5.3.2.1-A. The detailed geometry of the configurations used in this table is given in Table 5.3.1.1-B. It should be noted that the values of ΔC_{Y_β} used in Table 5.3.2.1-A are not test data, but are calculated by the method of Section 5.3.1.1. The errors inherent in estimating ΔC_{Y_β} are therefore implicitly included in Table 5.3.2.1-A. However, the errors due to ΔC_{Y_β} and those due to the moment arm can be separated by comparing the errors for a given configuration from Table 5.3.1.1-B (for ΔC_{Y_β}) with those of Table 5.3.2.1-A (for ΔC_{l_β}).

Sample Problems

1. Given: The configuration of Reference 1 consisting of a wing, body, horizontal tail, and upper vertical tail. This is the same configuration as that of Sample Problem 1, Paragraph A, Section 5.3.1.1. Some of the characteristics are repeated.

Wing Characteristics:

$S_W = 576.0$ sq in. $\quad b_W = 41.56$ in. $\quad z_W = 0$

Additional Characteristics:

$M = 0.25 \quad \ell_V = 24.89$ in. (c.g. to $(\bar{c}/4)_V$) $\quad z_V = 5.78$ in. (c.g. to $(MAC)_V$)

$\alpha = 0, 2°, 4°, 6°$

Compute:

$\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$ = −0.734 per rad (based on S_W) (Sample Problem 1, Paragraph A, Section 5.3.1.1)

Solution:

$$\left(\Delta C_{l_\beta}\right)_p = \left(\Delta C_{Y_\beta}\right)_p \frac{z_p \cos\alpha - \ell_p \sin\alpha}{b_W} \quad \text{(Equation 5.3.2.1-a)}$$

$$\left(\Delta C_{l_\beta}\right)_{V(WBH)} = \left(\Delta C_{Y_\beta}\right)_{V(WBH)} \frac{z_V \cos\alpha - \ell_V \sin\alpha}{b_W}$$

$$= -0.734 \left(\frac{5.78 \cos\alpha - 24.89 \sin\alpha}{41.56}\right) \text{ per rad (based on } S_W b_W)$$

Test results from Reference 1 are listed in Column 6 of the calculation table.

(1) α (deg)	(2) $z_V \cos\alpha$ (in.)	(3) $\ell_V \sin\alpha$ (in.)	(4) $\frac{z_V \cos\alpha - \ell_V \sin\alpha}{b_W}$ [(2) − (3)]/41.56	(5) $(\Delta C_{l_\beta})_{V(WBH)}$ −0.734 (4) (per rad)	(6) $(\Delta C_{l_\beta})_{V(WBH)}$ (test) (per rad)

6	5.750	2.600	0.0758	−0.0556	−0.0464

2. Given: The configuration of Reference 2 consisting of a wing, body, horizontal tail, and vertical tail. This is the same configuration as that of Sample Problem 3, Paragraph A, Section 5.3.1.1. Some of the characteristics are repeated.

Wing Characteristics:

S_W = 324 sq in. $\quad b_W$ = 36.0 in. $\quad z_W$ = 0

Additional Characteristics:

M = 0.13 $\quad \ell_V$ = 16.70 in. (c.g. to $(\bar{c}/4)_V$) $\quad z_V$ = 3.78 in. (c.g. to $(MAC)_V$)

α = 0, 2°, 4°, 6°

Compute:

$\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$ = −0.375 per rad (based on S_W) (Sample Problem 3, Paragraph A, Section 5.3.1.1)

Solution:

$$\left(\Delta C_{l_\beta}\right)_p = \left(\Delta C_{Y_\beta}\right)_p \frac{z_p \cos\alpha - \ell_p \sin\alpha}{b_W} \quad \text{(Equation 5.3.2.1-a)}$$

$$\left(\Delta C_{l_\beta}\right)_{V(WBH)} = \left(\Delta C_{Y_\beta}\right)_{V(WBH)} \frac{z_V \cos\alpha - \ell_V \sin\alpha}{b_W}$$

$$= -0.375\left(\frac{3.78\cos\alpha - 16.70\sin\alpha}{36.0}\right) \text{ per rad (based on } S_W b_W)$$

Test results from Reference 2 are listed in Column 6 of the calculation table.

(1) α (deg)	(2) $z_V \cos\alpha$ (in.)	(3) $\ell_V \sin\alpha$ (in.)	(4) $\frac{z_V \cos\alpha - \ell_V \sin\alpha}{b_W}$ [(2) − (3)]/36.0	(5) $(\Delta C_{l_\beta})_{V(WBH)}$ −0.375 (4) (per rad)	(6) $(\Delta C_{l_\beta})_{V(WBH)}$ (test) (per rad)

B. TRANSONIC

A brief discussion of the flow phenomena associated with a vertical panel at transonic speeds is given in Paragraph B of Section 5.3.1.1. The rolling moments due to the vertical panel are partly determined by the transonic lift-curve-slope characteristics of the isolated tail and partly by the wake and wash characteristics of the wing-body combination. In addition, the impingement on the horizontal-tail surface of the pressure field generated by the vertical panel can cause rolling moments. This latter effect can be large, since the pressure field at transonic speeds is frequently strong and is propagated to large distances from the source. The entire horizontal surface is therefore usually immersed in the field of the vertical panel.

DATCOM METHOD

Because of the complexity of the problem, no explicit method is available in the literature for estimating the contribution of a vertical panel to C_{l_β} at transonic speeds and none is presented in the Datcom. Some examples of the limited data available in the literature are shown in Figure 5.3.2.1-13.

C. SUPERSONIC

The procedure for estimating the rolling-moment contribution due to vertical panels at supersonic speeds is essentially the same as that at subsonic speeds. That is, the rolling-moment contribution of a vertical panel is based on the sideslip derivative ΔC_{Y_β} as obtained from Section 5.3.1.1. The problem of estimating the forces generated on vertical panels is complicated by the presence of shock waves. This effect is discussed in Paragraph C of Section 5.3.1.1.

As stated in the introduction to this section, no method is available for determining the horizontal-tail contribution to the derivative C_{l_β}. However, the effect of the horizontal tail on the vertical-tail contribution is accounted for by proper use of the apparent-mass factor (K) charts in determining the vertical-panel side force.

This method is limited to configurations in which the horizontal tail is mounted on the body or configurations with no horizontal tail.

DATCOM METHOD

The contribution of a vertical panel to the sideslip derivative C_{l_β} at supersonic speeds is given by Equation 5.3.2.1-a.

$$\left(\Delta C_{l_\beta}\right)_p = \left(\Delta C_{Y_\beta}\right)_p \frac{z_p \cos\alpha - \ell_p \sin\alpha}{b_W}$$

where the subscript p, z_p, and b_W are defined in Paragraph A, and

$\left(\Delta C_{Y_\beta}\right)_p$ is the side force due to sideslip of an added vertical panel obtained from Paragraph C of Section 5.3.1.1. (If a horizontal panel is present, its effect on the vertical panel must be included.)

ℓ_p is the distance parallel to the longitudinal body axis between the moment reference center and the 50-percent-chord point of the MAC of the added vertical panel, positive for the panel aft of the moment reference center. The aerodynamic center of the vertical panel could be used, but the inaccuracies of the basic method do not warrant this degree of refinement.

All geometry used in determining the moment arms of the vertical panels is based on the exposed panel.

For a wingless configuration the remarks following the Datcom method of Paragraph A above are also applicable here.

Results calculated at zero angle of attack by this method are compared to experimental data in Table 5.3.2.1-B. The detailed geometry of the configurations used in this table is given in Table 5.3.1.1-C. It should be noted that the values of ΔC_{Y_β} used in Table 5.3.2.1-B are calculated by the method of Paragraph C of Section 5.3.1.1.

Sample Problems

1. Given: The configuration of Reference 3 consisting of a wing, body, horizontal tail, and upper vertical stabilizer. This is the same configuration as that of Sample Problem 1, Paragraph C, Section 5.3.1.1. Some of the characteristics are repeated.

   Wing Characteristics:

   $S_W = 160.4$ sq in. $\quad b_W = 25.31$ in. $\quad z_W = 0$

   Additional Characteristics:

   $M = 1.61 \quad \ell_V = 11.40$ in. (c.g. to $(\bar{c}/2)_{V_e}$) $\quad z_V = 4.0$ in. (c.g. to $(MAC)_{V_e}$)

   $\alpha = 0, 2^\circ, 4^\circ, 6^\circ$

Compute:

$\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$ = −0.529 per rad (based on S_W) (Sample Problem 1, Paragraph C, Section 5.3.1.1)

Solution:

$$\left(\Delta C_{l_\beta}\right)_p = \left(\Delta C_{Y_\beta}\right)_p \frac{z_p \cos\alpha - \ell_p \sin\alpha}{b_W} \quad \text{(Equation 5.3.2.1-a)}$$

$$\left(\Delta C_{l_\beta}\right)_{V(WBH)} = \left(\Delta C_{Y_\beta}\right)_{V(WBH)} \frac{z_V \cos\alpha - \ell_V \sin\alpha}{b_W}$$

$$= 0.529 \left(\frac{4.0 \cos\alpha - 11.40 \sin\alpha}{25.31}\right) \quad \text{per rad (based on } S_W b_W\text{)}$$

Test values from Reference 3 are listed in Column 6 of the calculation table.

① α (deg)	② $z_V \cos\alpha$ (in.)	③ $\ell_V \sin\alpha$ (in.)	④ $\frac{z_V \cos\alpha - \ell_V \sin\alpha}{b_W}$ [② − ③]/25.31	⑤ $\left(\Delta C_{l_\beta}\right)_{V(WBH)}$ −0.529 ④ (per rad)	⑥ $\left(\Delta C_{l_\beta}\right)_{V(WBH)}$ (test) (per rad)

D. HYPERSONIC

A general discussion of hypersonic flows is given in the introduction to Paragraph D of Section 4.1.3.5 and in several standard texts. No explicit method exists for estimating the contribution of an added tail panel to the sideslip derivative C_{l_β} at hypersonic speeds.

The supersonic method for estimating the derivative $\left(\Delta C_{Y_\beta}\right)_p$ (Paragraph C, Section 5.3.1.1) has been substantiated to reasonably high Mach numbers (6.86) and can be used for estimating the contribution of an added vertical panel, as in Paragraph C above. However, the method should be applied with caution, since the basic assumptions are increasingly violated as the Mach number increases. The hypersonic small-disturbance theory and Newtonian theory can also be used to estimate the forces and therefore the moments on the vertical panel. Newtonian flow, however, is limited to the upper range of hypersonic Mach numbers.

DATCOM METHODS

Method 1

Extended Supersonic Method

The method described in Paragraph C of this section can be used up to Mach numbers of approximately 7.

Method 2

Hypersonic Small-Disturbance Theory

Equation 5.3.2.1-a can be used to estimate hypersonic values of the vertical-panel contribution $(\Delta C_{l_\beta})_V$, where $(\Delta C_{Y_\beta})_V$ in this equation is obtained from Equation 5.3.1.1-h, and ℓ_p is determined as in Paragraph C above.

Method 3

Newtonian Theory

Equation 5.3.2.1-a is again used, but the vertical-panel contribution $(\Delta C_{Y_\beta})_V$ in this equation is based upon the use of Equation 5.3.1.1-i for this case, and ℓ_p is determined as in Paragraph C above. This method is most successful in the upper range of hypersonic Mach numbers.

Because of the general lack of test data in this speed regime, no substantiation tables are presented.

Sample Problem

Method 2

Given: The configuration of Reference 5. This is the same configuration as that of the sample problem, Paragraph D, Section 5.3.1.1. Some of the characteristics are repeated.

Wing Characteristics:

$S_W = 19.15$ sq in. $\quad b_W = 5.60$ in. $\quad z_W = 0$

Additional Characteristics:

$M = 5.0 \quad z_V = 0.795$ in. (c.g. to $(MAC)_{V_e}$) $\quad \alpha = 0$

Compute:

$$\frac{z_V}{b_W} = \frac{0.795}{5.60} = 0.142$$

$\left(\Delta C_{Y_\beta}\right)_V$ = −0.86 per rad (based on S_W) (Sample Problem, Paragraph D, Section 5.3.1.1)

Solution:

$$\left(\Delta C_{l_\beta}\right)_V = \left(\Delta C_{Y_\beta}\right)_p \frac{z_p \cos\alpha - \ell_p \sin\alpha}{b_W} \quad \text{(Equation 5.3.2.1-a)}$$

$$\left(\Delta C_{l_\beta}\right)_V = \left(\Delta C_{Y_\beta}\right)_V \frac{z_V}{b_W} \quad (\alpha = 0)$$

$$= -0.86\,(0.142)$$

$$= -0.122 \text{ per rad (based on } S_W b_W)$$

This corresponds to an experimental value (based on $S_W b_W$) of −0.1146 per radian obtained from Reference 5.

3.3 TAIL-BODY SIDESLIP DERIVATIVE C_{n_β}

5.3.3.1 TAIL-BODY SIDESLIP DERIVATIVE C_{n_β} IN THE LINEAR ANGLE-OF-ATTACK RANGE

The contribution of panels present in the empennage to the vehicle sideslip derivative C_{n_β} is estimated by the methods of this Section. The methods generally include the interference effects of other vehicle components.

Detailed discussion of the various aerodynamic aspects of adding tail panels to flight vehicles is given in Section 5.3.1.1 and is not repeated here.

A. SUBSONIC

The methods of estimating the contribution of panels present in the empennage to the sideslip derivative C_{n_β} are based on the methods for estimating the contribution of panels present in the empennage to the sideslip derivative C_{Y_β} in Section 5.3.1.1. The moment arm through which the panel side force acts can be taken as (a) the distance parallel to the longitudinal axis between the vehicle center of gravity and the quarter-chord point of the mean aerodynamic chord of the panel or (b) the distance parallel to the longitudinal axis between the vehicle center of gravity and the actual aerodynamic center of the panel. In most cases the former approximation is used, since the inaccuracies of estimating the side force of the panel do not warrant the refinements of (b). For short-coupled configurations, however, where the tail-length distance is relatively short and the size of the panel may be large, significant differences between results estimated by (a) and (b) may result; in such cases (b) is recommended.

DATCOM METHOD

Method 1

Simplified Method

The contribution of a panel to the sideslip derivative C_{n_β} at subsonic speeds is given by

$$(\Delta C_{n_\beta})_p = -(\Delta C_{Y_\beta})_p \frac{\ell_p}{b_w} \qquad 5.3.3.1\text{-a}$$

where the subscript $_p$ refers to panels present in the empennage

$(\Delta C_{Y_\beta})_p$ is the side force due to sideslip of the added panel determined as follows:

For configurations with the horizontal panel mounted on the body, or with no horizontal panel, use Method 1 or Method 3 of paragraph A, Section 5.3.1.1.

For configurations with the horizontal panel mounted on the vertical, use Method 1 of paragraph A, Section 5.3.1.1.

For twin-vertical panel configurations, use Method 2 of paragraph A, Section 5.3.1.1.

ℓ_p is the distance parallel to the longitudinal axis between the moment reference center (usually the vehicle center of gravity) and the quarter-chord point of the MAC of the added panel, positive for the added panel behind the moment reference center.

b_w is the span of the wing

Method 2

Refined Method

In this case the contribution of a panel to the sideslip derivative C_{n_β} is given by

$$(\Delta C_{n_\beta})_p = -(\Delta C_{Y_\beta})_p \frac{[\ell_p + (x_{a.c.})_p]}{b_w} \qquad 5.3.3.1\text{-b}$$

where $(\Delta C_{Y_\beta})_p$, ℓ_p, and b_W are defined in Method 1 above, and

$(x_{c.c.})_p$ is the distance between the quarter-chord point of the MAC of the added panel as determined from paragraph A of Section 4.1.4.2, positive for the a.c. behind the quarter-chord point. (In determining the vertical panel a.c. use the aspect ratio of the panel mounted on an infinite reflection plane.)

All geometry for the added panel of these methods is based on the panel extended to the body centerline.

Methods 1 and 2 of paragraph A, Section 5.3.1.1 lump the total empennage increment in C_{Y_β} into a single parameter. On the other hand, Method 3 gives the increment due to the addition of one panel (either a horizontal or vertical panel) including the mutual aerodynamic interference effects of all other panels present. An extension of Method 3 to determine the total empennage side force due to sideslip at subsonic speeds which results from the addition of all panels present in the empennage is presented in paragraph A of Section 5.5.1.1.

For a wingless configuration, b_W is replaced by the reference length for the vehicle, and $(\Delta C_{Y_\beta})_p$ is based on the vehicle reference area.

Table 5.3.3.1-A compares results calculated by Method 1 with test data. The test cases for this table are the same as those used for table 5.3.1.1-B. Pertinent detailed information for table 5.3.3.1-A is therefore found in table 5.3.1.1-B and is not repeated.

Sample Problems

1. Method 1

Given: The configuration of reference 1, consisting of wing, body, horizontal tail, and upper vertical tail. This is the same configuration as that of sample problem 1, paragraph A, Section 5.3.1.1. Some of the characteristics are repeated. Find the effect of adding the vertical tail to the wing-body-horizontal tail configuration.

Wing Characteristics

S_W = 576.0 sq in. b_W = 41.56 in. z_W = 0

Additional Characteristics

M = 0.25 ℓ_V = 24.89 in. (c.g. to $(\bar{c}/4)_V$)

Compute:

$$\frac{\ell_V}{b_W} = \frac{24.89}{41.56} = 0.599$$

$(\Delta C_{Y_\beta})_{V(WBH)}$ = -0.734 per rad (based on S_W) (sample problem 1, paragraph A, Section 5.3.1.1)

Solution:

$$(\Delta C_{n_\beta})_p = -(\Delta C_{Y_\beta})_p \frac{\ell_p}{b_W} \qquad \text{(equation 5.3.3.1-a)}$$

$$(\Delta C_{n_\beta})_{V(WBH)} = -(\Delta C_{Y_\beta})_{V(WBH)} \frac{\ell_V}{b_W}$$

$$= -(-0.734)(0.599)$$

$$= 0.440 \text{ per rad (based on } S_W b_W)$$

This compares with an experimental value of 0.415 per radian obtained from reference 1.

2. Method 1

Given: The configuration of reference 2, consisting of wing, body, horizontal tail, and vertical tail. This is the same configuration as that of sample problem 3, paragraph A, Section 5.3.1.1. Some of the characteristics are repeated. Find the effect of adding the vertical tail to the wing-body-horizontal tail combination.

Wing Characteristics

S_w = 324 sq in. b_w = 36.0 in. z_w = 0

Additional Characteristics

M = 0.13 ℓ_v = 16.70 in. (c.g. to $(\bar{c}/4)_v$)

Compute:

$$\frac{\ell_v}{b_w} = \frac{16.7}{36.0} = 0.464$$

$(\Delta C_{Y_\beta})_{V(WBH)}$ = -0.375 per rad (based on S_w) (sample problem 3, paragraph A, Section 5.3.1.1)

Solution:

$$(\Delta C_{n_\beta})_v = -(\Delta C_{Y_\beta})_v \frac{\ell_v}{b_w} \qquad \text{(equation 5.3.3.1-a)}$$

$$(\Delta C_{n_\beta})_{V(WBH)} = -(\Delta C_{Y_\beta})_{V(WBH)} \frac{\ell_v}{b_w}$$

$$= -(-0.375)\,(0.464)$$

$$= 0.174 \text{ per rad (based on } S_w b_w)$$

This compares with an experimental value of 0.178 per radian obtained from reference 2.

B. TRANSONIC

A brief discussion of the flow phenomena associated with forces generated on a vertical panel at transonic speeds is given in paragraph B of Section 5.3.1.1. As in the case for the vertical tail contribution to C_{Y_β}, the transonic characteristics of the sideslip derivative C_{n_β} are closely associated with the transonic lift-curve-slope characteristics of the isolated panel (see introduction to paragraph B of Section 4.1.3.2).

DATCOM METHOD

No method is available for estimating the contribution of a tail panel to the sideslip derivative C_{n_β} and none is presented in the Datcom. Figure 5.3.3.1-11 presents some available information for this derivative.

C. SUPERSONIC

As in the subsonic case, the method of estimating supersonic values of $(\Delta C_{n_\beta})_v$ is based on the values of $(\Delta C_{Y_\beta})_v$ estimated by the method of Section 5.3.1.1. The problem of estimating the forces generated on vertical panels is complicated by the presence of shock waves. See paragraph C of Section 5.3.1.1 for a detailed description of this method. The moment arm through which the added vertical panel side force acts can be taken as (a) the distance parallel to the longitudinal axis between the vehicle center of gravity and the 50-percent-chord point of the mean aerodynamic center of the vertical panel, or (b) the distance parallel to the longitudinal axis between the vehicle center of gravity and the actual aerodynamic center of the vertical panel. For short-coupled configurations the latter approximation is, of course, more accurate. At supersonic speeds the centroid of area of the region of interference approximates the moment arm in the case of the increment gained by adding a horizontal surface.

This method is limited to configurations in which the horizontal tail is mounted on the body or configurations with no horizontal tail.

DATCOM METHODS

Method 1

Simplified Method

The contribution of an added panel (either a horizontal or vertical panel) to the sideslip derivative C_{n_β} at supersonic speeds is given by equation 5.3.3.1-a

$$(\Delta C_{n_\beta})_p = -(\Delta C_{Y_\beta})_p \frac{\ell_p}{b_W}$$

where the subscript p and b_W are defined in paragraph A, and

$(\Delta C_{Y_\beta})_p$ is the side force due to sideslip of an added panel obtained from paragraph C of Section 5.3.1.1

ℓ_p is the distance parallel to the longitudinal axis between the vehicle moment center and the 50-percent-chord point of the MAC of an added vertical panel, positive for the vertical panel aft of the vehicle moment center. In the case of the increment gained by adding a horizontal panel, ℓ_p is the distance parallel to the longitudinal axis between the vehicle moment center and the centroid of area of the region of interference, positive for the horizontal panel aft of the vehicle moment center. (See sketch (c) of Section 5.3.1.1 for definition of area of region of interference.)

Method 2

Refined Method

For a more refined estimate of the contribution of an added panel to the sideslip derivative C_{n_β}, equation 5.3.3.1- is used

$$(\Delta C_{n_\beta})_p = -(\Delta C_{Y_\beta})_p \frac{[\ell_p + (x_{a.c.})_p]}{b_W}$$

where $(\Delta C_{Y_\beta})_p$, ℓ_p, and b_W are defined in Method 1 above, and

$(x_{a.c.})_p$ is the distance parallel to the longitudinal axis between the 50-percent-chord point of the MAC of an added vertical panel and the aerodynamic center of the added panel obtained from paragraph C of Section 4.1.4.2, positive for the a.c. behind the 50-percent-chord point. (In determining the vertical panel a.c. use the aspect ratio of the isolated panel mounted on an infinite reflection plane.)

In the case of the increment gained by adding a horizontal panel, the moment arm is treated as in Method 1 above.

All geometry used in determining the moment arms of the vertical panels in the above methods is based on the exposed panel.

For a wingless configuration the remarks following the Datcom methods of paragraph A above are also applicable here.

Table 5.3.3.1-B compares results obtained by Method 1 with experimental data. The test configurations used in this table are the same as those used in Table 5.3.1.1-C. Detailed geometric variables are given in this latter table.

Sample Problems

1. Method 1

Given: The configuration of reference 3 consisting of wing, body, horizontal tail, and upper vertical stabilizer. This is the same configuration as that of sample problem 1, paragraph C, Section 5.3.1.1. Some of the characteristics are repeated. Find the effect of adding the vertical tail to the wing-body-horizontal tail combination.

Wing Characteristics

S_w = 160.4 sq in. b_w = 25.31 in. z_w = 0

Additional Characteristics

M = 1.61 ℓ_v = 11.40 in. (c.g. to $(\bar{c}/2)_{v_e}$)

Compute:

$$\frac{\ell_v}{b_w} = \frac{11.40}{25.31} = 0.450$$

$(\Delta C_{Y_\beta})_{V(WBH)}$ = -0.529 per rad (based on S_w) (sample problem 1, paragraph C, Section 5.3.1.1)

Solution:

$$(\Delta C_{n_\beta})_p = -(\Delta C_{Y_\beta})_p \frac{\ell_p}{b_w} \qquad \text{(equation 5.3.3.1-a)}$$

$$(\Delta C_{n_\beta})_{V(WBH)} = -(\Delta C_{Y_\beta})_{V(WBH)} \frac{\ell_v}{b_w}$$

$$= -(-0.529)\,(0.450)$$

$$= 0.238 \text{ per rad (based on } S_w b_w)$$

This compares with an experimental value of 0.218 per radian obtained from reference 3.

2. Method 1

Given: The configuration of reference 4 consisting of wing, body, upper vertical stabilizer, and lower vertical stabilizer. This is the same configuration as that of sample problem 2, paragraph C, Section 5.3.1.1. Some of the characteristics are repeated. Find the effect of adding the upper vertical stabilizer to the wing-body-lower vertical stabilizer combination.

Wing Characteristics

S_w = 144.0 sq in. b_w = 24.0 in. z_w = 0

Additional Characteristics

M = 2.01 ℓ_v = 12.00 in. (c.g. to $(\bar{c}/2)_{v_e}$)

Compute:

$$\frac{\ell_v}{b_w} = \frac{12.00}{24.0} = 0.500$$

$(\Delta C_{Y_\beta})_{V(WBU)}$ = -0.583 per rad (based on S_w) (sample problem 2, paragraph C, Section 5.3.1.1)

Solution:

$$(\Delta C_{n_\beta})_p = -(\Delta C_{Y_\beta})_p \frac{\ell_p}{b_w} \qquad \text{(equation 5.3.3.1-a)}$$

$$(\Delta C_{n_\beta})_{V(WBU)} = -(\Delta C_{Y_\beta})_{V(WBU)} \frac{\ell_v}{b_w}$$

$$= -(-0.583)\,(0.500)$$

$$= 0.2915 \text{ per rad (based on } S_w b_w)$$

This compares with an experimental value of 0.277 per radian obtained from reference 4.

D. HYPERSONIC

A general discussion of hypersonic flows is given in the introduction to paragraph D of Section 4.1.3.3 and in several standard texts. No explicit method exists for estimating the contribution of an added tail panel to the sideslip derivative C_{n_β} at hypersonic speeds.

The supersonic method for estimating the derivative $(\Delta C_{Y_\beta})_p$ (paragraph C, Section 5.3.1.1) has been substantiated to reasonably high Mach numbers (6.86) and can be used for estimating $(\Delta C_{n_\beta})_p$ as in paragraph C above. However, the method should be applied with caution, since the basic assumptions are increasingly violated as the Mach number increases. The hypersonic small-disturbance theory and Newtonian Theory can also be used to estimate the forces and therefore the moments on the vertical panel. Newtonian flow, however, is limited to the upper range of hypersonic Mach numbers.

DATCOM METHODS

Method 1

Extended Supersonic Method

The method described in paragraph C can be used up to Mach numbers of approximately 7.

Method 2

Hypersonic Small-Disturbance Theory

Equation 5.3.3.1-a or 5.3.3.1-b can be used to estimate hypersonic values of $(\Delta C_{n_\beta})_V$, where $(\Delta C_{Y_\beta})_V$ is obtained from equation 5.3.1.1-h and ℓ_p is as defined in paragraph C above. This method is generally limited to small angles of flow deflection.

Method 3

Newtonian Theory

Equation 5.3.3.1-a or 5.3.3.1-b can be used, but $(\Delta C_{Y_\beta})_V$ is obtained by using equation 5.3.1.1-i to determine C_p in this case. ℓ_p is as defined in paragraph C above. This method is most successful at the high hypersonic Mach numbers.

Because of the general lack of test data in this speed regime, no substantiation table is presented.

Method 2

Sample Problem

Given: The configuration of reference 5. This is the same configuration as that of the sample problem, paragraph D, Section 5.3.1.1. Some of the characteristics are repeated. Find the effect of adding the vertical stabilizer to the wing-body configuration.

Wing Characteristics

S_W = 19.15 sq in. $\quad b_W$ = 5.60 in.

Additional Characteristics

M = 5.0 $\quad \ell_V$ = 2.79 in. (c.g. to $(\bar{c}/2)_{V_e}$)

Compute:

$$\frac{\ell_V}{b_W} = \frac{2.79}{5.60} = 0.499$$

$(\Delta C_{Y_\beta})_V$ = -0.86 per rad (based on S_W) (sample problem, paragraph D, Section 5.3.1.1)

Solution:

$$(\Delta C_{n_\beta})_p = -(\Delta C_{Y_\beta})_p \frac{\ell_p}{b_W} \qquad \text{(equation 5.3.3.1-a)}$$

$$(\Delta C_{n_\beta})_V = -(\Delta C_{Y_\beta})_V \frac{\ell_V}{b_W}$$

$= -(-0.36)\,(0.499)$

$= 0.430$ per rad (based on $S_w b_w$)

This corresponds to an experimental value of 0.59 per radian obtained from reference 5.

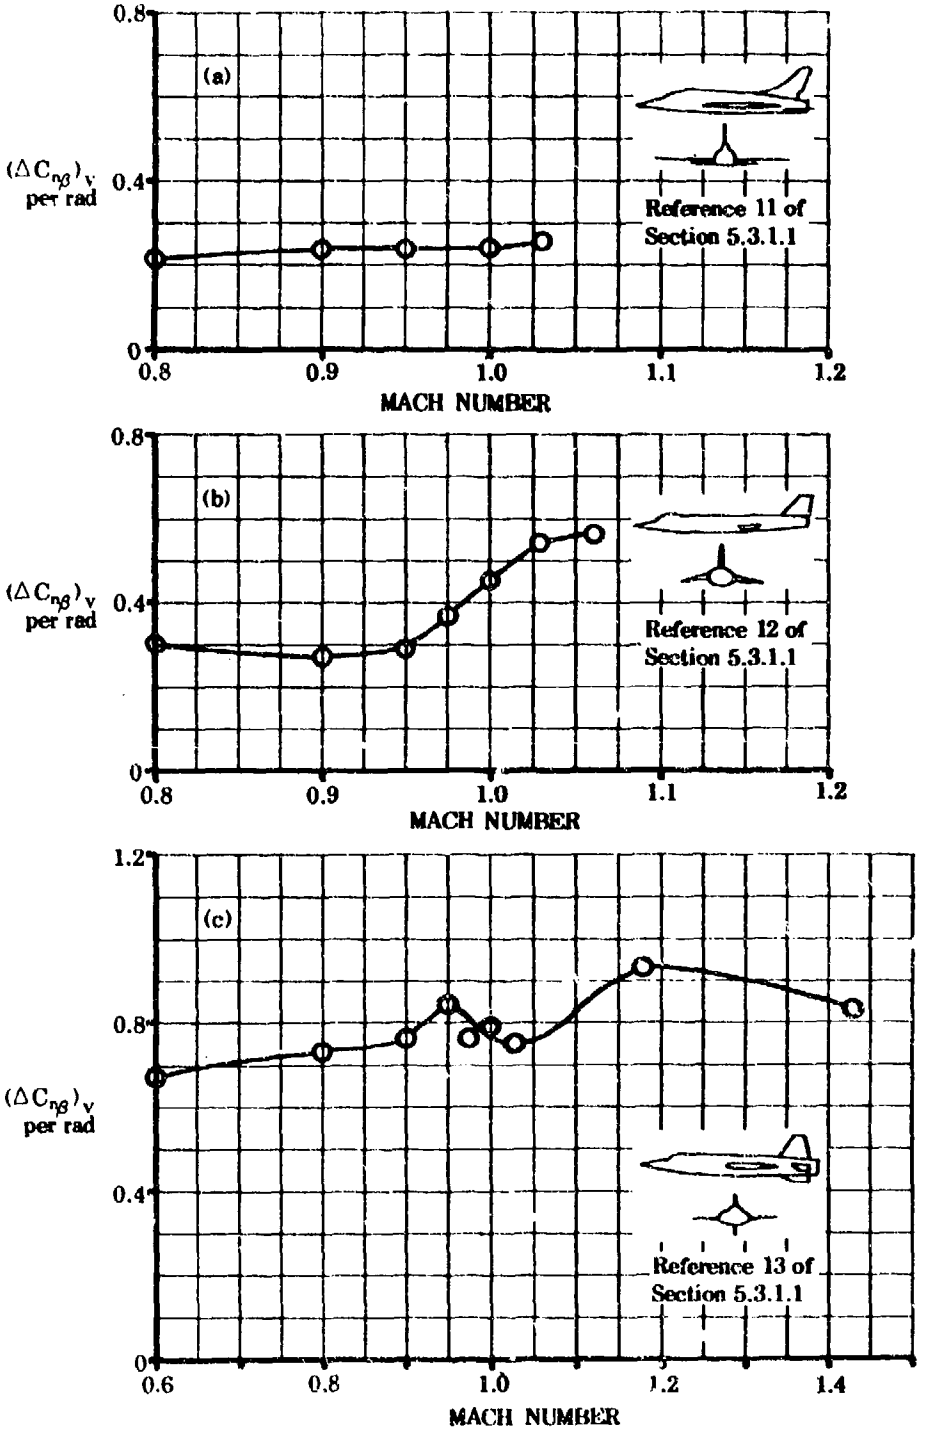

FIGURE 5.3.3.1-11. TYPICAL TRANSONIC DATA

5.3.3.2 TAIL-BODY YAWING-MOMENT COEFFICIENT C_n AT ANGLE OF ATTACK

The tail-body yawing moment developed at combined angles is nonlinear with respect to both sideslip and angle of attack because of the body-vortex induced sidewash on the upper vertical tail and the cross-coupling of upwash and sidewash velocities. To obtain the derivative C_{n_β}, it is recommended that C_n be calculated at several angles of attack for a small sideslip angle ($\beta \leq 4^o$). Then, at each angle of attack, the yawing moment is assumed linear with sideslip for small values of β so that

$$C_{n_\beta} \approx \frac{C_n}{\beta}$$

A. SUBSONIC

The comments appearing in Paragraph A of Section 5.3.1.2 apply here also. The method presented herein is restricted to first-order approximations at relatively low angles of attack.

DATCOM METHOD

It is recommended that the method of Paragraph A of Section 5.3.3.1 be used in the linear-lift angle-of-attack range.

B. TRANSONIC

The comments appearing in Paragraph B of Section 5.3.1.2 apply here also and will not be repeated.

DATCOM METHOD

No method is available for estimating this coefficient at angle of attack and none is presented in the Datcom.

C. SUPERSONIC

The comments in Paragraph C of Section 5.3.1.2 apply here also. As noted therein, the method for determining the side-force coefficient at angle of attack does not account for wing-tail interference effects. The yawing-moment coefficient at angle of attack for a configuration including a wing at supersonic speeds must be obtained from Paragraph C of Section 5.6.3.2.

DATCOM METHOD

The method for estimating the empennage contribution to the yawing moment at combined angles is essentially that of Section 5.3.1.2. The yawing-moment coefficient is obtained simply by applying the proper moment arms to the various side-force coefficients that comprise the total tail contribution. As noted in Section 5.3.1.2, the method is limited to circular bodies, and to the analysis of horizontal-tail effects only when the surface is body-mounted.

The contribution of the tail panels to the yawing-moment coefficient is given as

$$(C_n)_{HVU(B)} = -\frac{\ell_H \cos\alpha + z_H \sin\alpha}{b_W}(C_Y)_{H(B)} - \frac{\ell_V \cos\alpha + z_V \sin\alpha}{b_W}(C_Y)_V$$

$$-\frac{\ell_U \cos\alpha + z_U \sin\alpha}{b_W}(C_Y)_U \qquad 5.3.3.2\text{-a}$$

where

$(C_Y)_{H(B)}$ is defined under Equation 5.3.1.2-a.

$(C_Y)_V$ is defined under Equation 5.3.1.2-a.

$(C_Y)_U$ is defined under Equation 5.3.1.2-a.

ℓ_H is the distance from the moment reference center to the center of pressure of the horizontal-tail interference side force, measured parallel to the longitudinal axis. The c.p. is taken at the centroid of the interference area, indicated by shading in Sketch (a) of Section 5.3.1.2.

z_H is the distance to the center of pressure of the horizontal-tail interference side force, measured from, and normal to, the longitudinal axis. z_H is positive when the c.p. is above the longitudinal axis. (The c.p. location is as assumed above.)

ℓ_V is the distance from the moment reference center to the center of pressure of the upper vertical tail, measured parallel to the longitudinal axis.

z_V is the distance to the center of pressure of the upper vertical tail, measured from, and normal to, the longitudinal axis. z_V is positive when the c.p. is above the longitudinal axis.

ℓ_U is the distance from the moment reference center to the center of pressure of the ventral fin, measured parallel to the longitudinal axis.

z_U is the distance to the center of pressure of the ventral fin, measured from, and normal to, the longitudinal axis. z_U is negative when the c.p. is below the longitudinal axis.

For the vertical panels the center of pressure is taken as the 50-percent-chord point of the mean aerodynamic chord of the exposed panel.

Values for the incremental coefficient resulting from the addition of upper vertical tails to circular bodies, calculated using the Datcom method, are compared with experimental results in Figure 5.3.3.2-4. It is evident from the experimental data that a strong destabilizing effect occurs with increasing angle of attack, and that this effect is fairly accurately predicted by the Datcom method over the angle-of-attack range of the tests.

Sample Problem

Given: Configuration of Sample Problem, Paragraph C, Section 5.3.1.2. No horizontal tail. Some characteristics are repeated. Find the yawing-moment coefficient developed by a vertical tail and a ventral fin.

Wing Characteristics:

$\alpha = 12°$ $\quad S_W = 144.0$ sq in.

Additional Characteristics:

$\ell_V = 12.0$ in. $\quad \ell_U = 12.0$ in. $\quad b_W = 24.0$ in. $\quad z_V = 4.15$ in. $\quad z_U = -2.15$ in.

$\left.\begin{aligned}(C_Y)_V &= -0.0229 \\ (C_Y)_U &= -0.0109\end{aligned}\right\}$ (based on S_W) (Sample Problem, Paragraph C, Section 5.3.1.2)

$M = 2.01$

Solution:

$$(C_n)_{VU(B)} = -\frac{\ell_V \cos\alpha + z_V \sin\alpha}{b_W}(C_Y)_V - \frac{\ell_U \cos\alpha + z_U \sin\alpha}{b_W}(C_Y)_U$$ (Equation 5.3.3.2-a, horizontal tail off)

$$= -\frac{12.0 \cos 12° + 4.15 \sin 12°}{24.0}(-0.0229) - \frac{12.0 \cos 12° - 2.15 \sin 12°}{24.0}(-0.0109)$$

$= 0.0171$ (based on $S_W b_W$)

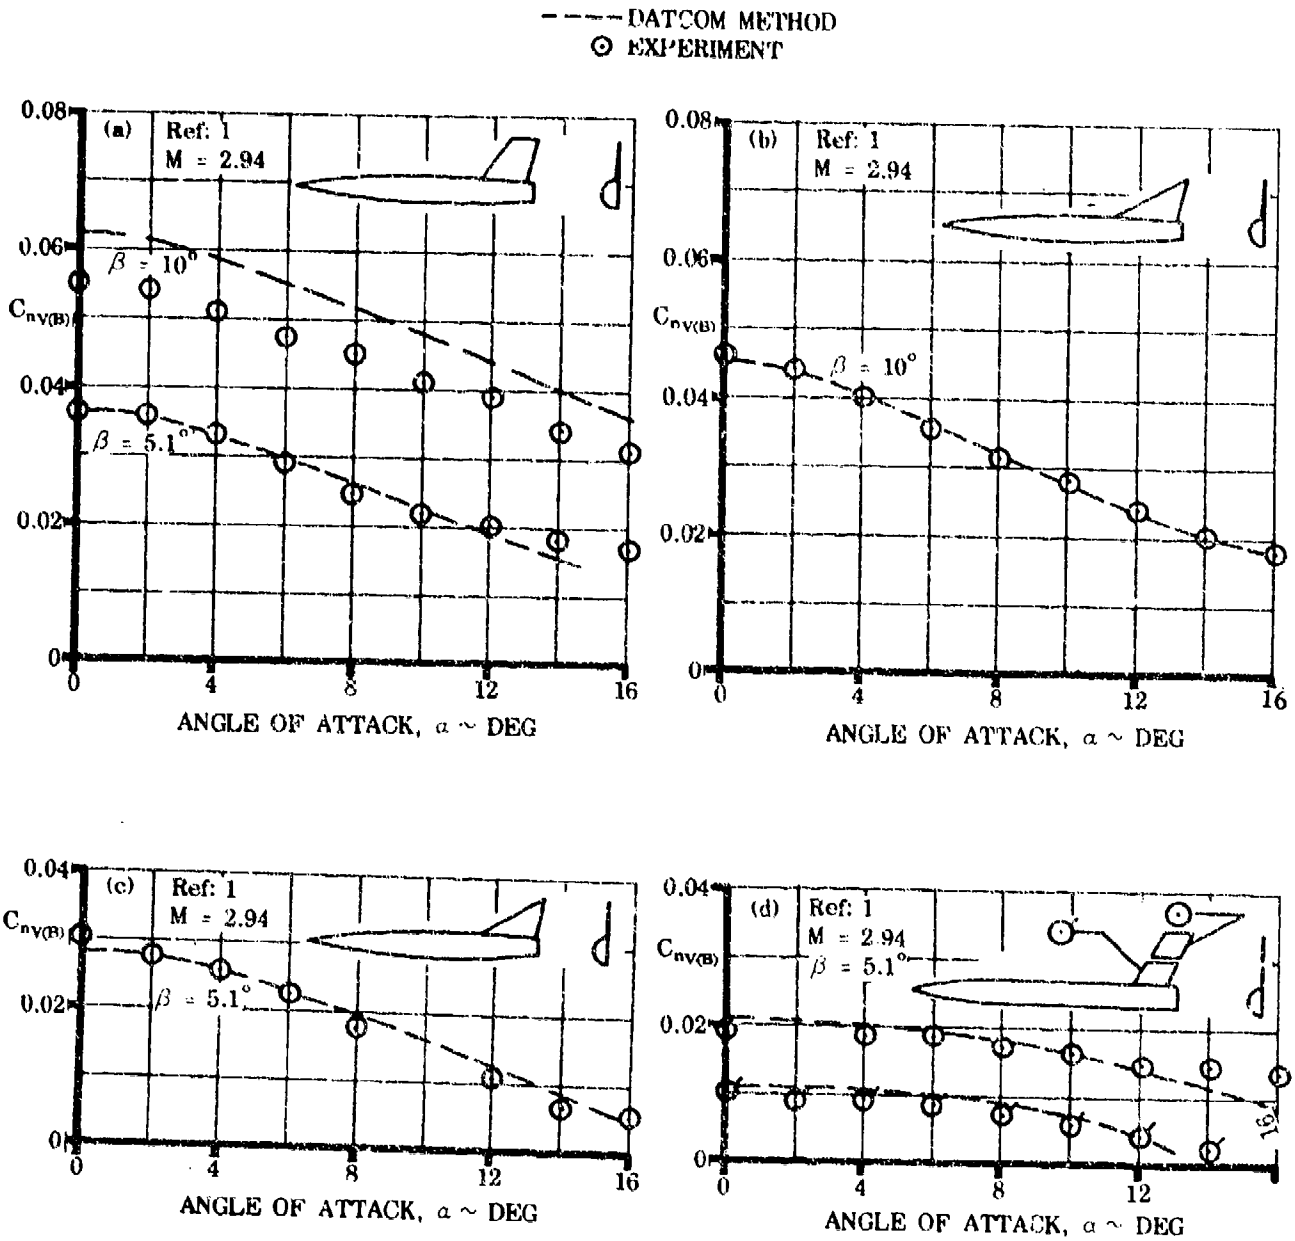

FIGURE 5.3.3.2-4 COMPARISON OF EXPERIMENTAL AND CALCULATED YAWING-MOMENT COEFFICIENT INCREMENTS DUE TO ADDING A VERTICAL TAIL TO A BODY

5.4 FLOW FIELDS IN SIDESLIP

5.4.1 WING-BODY WAKE AND SIDEWASH IN SIDESLIP

For a wing-body combination there are two contributions to the sidewash present at a vertical tail – that due to the body and that due to the wing.

The sidewash due to a body arises from the side force developed by a body in yaw. As a result of this side force a vortex system is produced, which in turn induces lateral-velocity components at the vertical tail. This sidewash from the body causes a destabilizing flow in the airstream beside the body. Above and below the fuselage, however, the flow is stabilizing.

The sidewash arising from a wing in yaw is small compared to that of a body. The flow above the wake center line moves inboard and the flow below the wake center line moves outboard.

For conventional aircraft the combination of the wing-body flow fields is such as to cause almost no sidewash effect below the wake center line.

At subsonic speeds an empirical equation is presented that gives the total sidewash effect directly, i.e., the combined sidewash angle and dynamic-pressure loss.

At supersonic speeds no generalized method is available.

DATCOM METHOD

A. SUBSONIC

A simple algebraic equation is presented that predicts the combined sidewash and dynamic-pressure parameter:

$$\left(1 + \frac{\partial\sigma}{\partial\beta}\right) \frac{q_V}{q_\infty}$$

This empirically derived expression is

$$\left(1 + \frac{\partial\sigma}{\partial\beta}\right) \frac{q_V}{q_\infty} = 0.724 + 3.06 \frac{\frac{S_V}{S_W}}{1 + \cos\Lambda_{c/4\,W}} + .4 \frac{z_W}{d} + 0.009A_W \qquad 5.4.1\text{-a}$$

where

σ is the sidewash at the vertical tail, positive out the left wing

S_V is the vertical tail area, including the submerged area to the fuselage center line, square feet

z_W is the distance, parallel to the Z-axis, from wing root quarter-chord point to fuselage center line, feet. This value is positive for the quarter-chord point below the fuselage center line.

d is the maximum fuselage depth, feet

A comparison of test data with results calculated from Equation 5.4.1-a is shown in Table 5.4.1-A.

5.5 LOW-ASPECT-RATIO WINGS AND WING-BODY COMBINATIONS IN SIDESLIP

During recent years much work has been done on problems associated with the design and operation of advanced flight vehicles. These vehicles include re-entry configurations and those designed for hypersonic cruise. The requirement that these vehicles operate within the atmosphere at hypersonic speeds necessitates the use of configurations that are not well suited for subsonic flight at low altitudes. For the most part, the configurations proposed for this type of mission feature extremely low aspect ratios of the order of two or less, and thick, generously rounded lifting surfaces. These configurations also often have large blunt bases.

The use of conventional subsonic theories and related test data does not result in adequate estimates of the aerodynamic characteristics for this type of vehicle. The methods presented in this section for estimating the aerodynamic characteristics of advanced flight vehicles at subsonic speeds are necessarily semiempirical in nature. The methods are based on test data, which have been correlated with the aid of the extension of available theory. A large portion of the material is related to delta or modified-delta configurations, since a major portion of the pertinent theory and test results relates to these planforms.

In the following group of sections (5.5.1, 5.5.2, and 5.5.3) methods are presented for estimating the side force, rolling moment, and yawing moment on specific types of advanced flight vehicles over the linear sideslip-angle range and at angles of attack up to 20°.

The pertinent aerodynamic forces and moments acting on the vehicle are illustrated on figure 5.5-6. These forces and moments are presented in a normal-force axis system that is introduced in Section 4.8. The reference axes are oriented with respect to the particular configuration under consideration such that the normal force is zero at zero angle of attack and also so that the rolling moment due to sideslip is zero for zero normal force.

The axis designated $X' - X'$ in figure 5.5-6 is the zero-normal-force reference axis defined in Section 4.8 as the axis passing through the centroid of the base area and the most forward point on the vehicle nose. If this axis is parallel to the free stream, the normal force acting on the body is zero by definition, and the zero-normal-force angle of attack α_{N_0} is specified (see Section 4.8.1.1).

Although the position of the axes such that the normal force is zero at zero angle of attack is readily determined, there is no accurate way of establishing the position of the axes for an arbitrary configuration such that the rolling moment due to sideslip is zero at zero normal force.

In the sections that follow, the position of the axis which results in zero rolling moment due to sideslip at zero normal force has been defined by using available test data. The required axis position, represented by axis $0 - 0$ of figure 5.5-6, is parallel to the $X' - X'$ axis and located at a distance Δ from $X' - X'$, where Δ is given by

$$\Delta = \left[\frac{K'_{l_{\beta_{X'X'}}}}{K_{Y_\beta}} \right]_{N_0} b$$

The data in the following sections are presented with respect to this "zero normal force – zero rolling moment" axis system. In this axis system the normal-force coefficient, angle of attack, side-force derivative with respect to sideslip, rolling-moment derivative with respect to sideslip, and yawing-moment derivative with respect to sideslip are designated by C_N', α', K_{Y_β}, K'_{l_β}, and K'_{n_β}, respectively.

The lateral-directional characteristics for the defined body-axis system are related to the more familiar stability-axis system by

$$K_{Y_\beta} = C_{Y_\beta}$$

$$K'_{l_\beta} = C_{l_\beta} \cos \alpha' - C_{n_\beta} \sin \alpha' - K_{Y_\beta} \frac{\Delta}{b}$$

$$K'_{n_\beta} = C_{n_\beta} \cos \alpha' + C_{l_\beta} \sin \alpha'$$

For symmetrical configurations (symmetry about the Z = 0 plane)

$$\alpha' = \alpha$$

$$K'_{l_\beta} = K_{l_\beta}$$

$$K'_{n_\beta} = K_{n_\beta}$$

A general notation list is included in this section for all sections included under Section 5.5.

Sketches showing planform geometry for nearly all configurations analyzed in Sections 5.5.1.1 through 5.5.3.2 are presented in table 4.8-A

5.5.1 WING, WING-BODY SIDESLIP DERIVATIVE K_{Y_β}

5.5.1.1 WING, WING-BODY SIDESLIP DERIVATIVE K_{Y_β} AT ZERO NORMAL FORCE

A. SUBSONIC

This section presents a method, taken from reference 1, for estimating the sideslip derivative K_{Y_β} at zero normal force for delta and modified-delta configurations at subsonic speeds.

The side force at zero normal force is assumed to be composed of two parts, side force due to skin friction and side force due to the pressures acting on the configuration. For thin configurations (essentially zero side area) the side force can be taken as equal to the skin-friction drag of the wing. As the thickness is increased, the influence of pressure distribution is introduced and the side force increases. However, this increase would be expected to be relatively small until the thickness becomes large enough so that the flow separates, causing the pressure drag to become appreciable. It is reported in reference 1 that many attempts were made to relate this phenomenon to existing theories, but without success. The available theories are usually appropriate only when the flow is attached or when the point of separation is known, as in the case of a thin, sharp-leading-edged delta wing. For the case of a moderately thick delta wing, the cross-flow components associated with sideslip tend to induce separation in an unpredictable manner. Therefore, the method presented is based on an empirical correlation of available test data.

The design chart presented was obtained by relating the sideslip derivative at zero normal force to the side area of the configuration. For zero side area, $K_{Y_{\beta N_0}}$ is taken to be equal to the incompressible skin-friction coefficient of the wing. For the purpose of the Datcom, the skin-friction coefficient of the wing is taken as $C_f = 0.006$. Therefore, for a wing with zero side area, $K_{Y_{\beta N_0}} = -0.006$ per radian.

Factors which might be expected to influence side force, but which are not isolated in the analysis, include planform geometry, aspect ratio, section thickness, and camber.

DATCOM METHOD

The zero-normal-force sideslip derivative $K_{Y_{\beta N_0}}$ of a delta or modified-delta configuration, based on planform area, is obtained from the procedure outlined in the following steps:

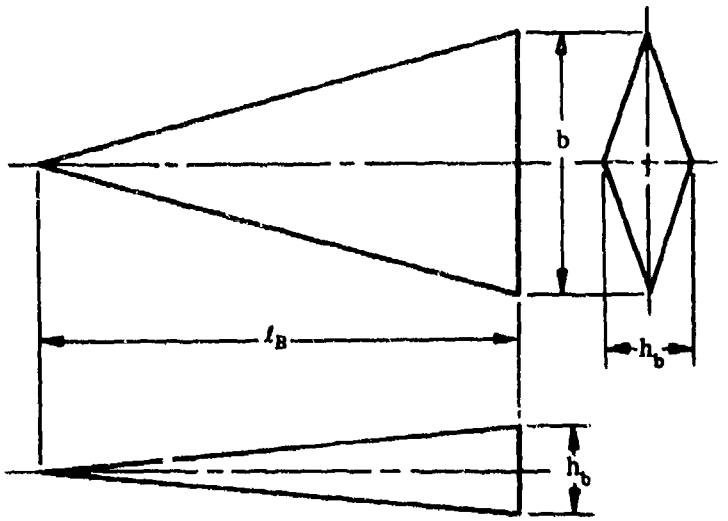
Step 1. From the configuration geometry determine the projected side area of the configuration S_{B_S} and the planform area S.

Step 2. Obtain $K_{Y_{\beta N_0}}$ as a function of S_{B_S}/S from figure 5.5.1.1-6 .

Values of the zero-normal-force sideslip derivative calculated by using this method are compared with test results in table 5.5.1.1-A. It should be noted that a considerable amount of scatter was involved in the data correlation used to define the design chart. A more accurate correlation was not obtainable because of the limited availability of test data and the uncertainties in the test results.

Sample Problem

Given: The delta-series configuration of reference 6 designated D-2. This is a sharp-edged delta model with a symmetrical diamond-shape cross section and a blunt trailing edge.



ℓ_B = 23.0 in.

b = 12.374 in.

h_b = 4.32 in.

Compute:

$$S = \frac{1}{2}\ell_B b$$

$$= \frac{1}{2}(23.0)(12.374) = 142.3 \text{ sq in.}$$

$$S_{B_S} = \frac{1}{2}\ell_B h_b = \frac{1}{2}(23.0)(4.32) = 49.68 \text{ sq. in.}$$

$$\frac{S_{B_S}}{S} = \frac{49.68}{142.3} = 0.349$$

Solution:

$K_{Y_{\beta_{N_0}}}$ = −0.110 per rad (based on S) (figure 5.5.1.1-6)

This compareds with a test value of −0.122 per radian from reference 6.

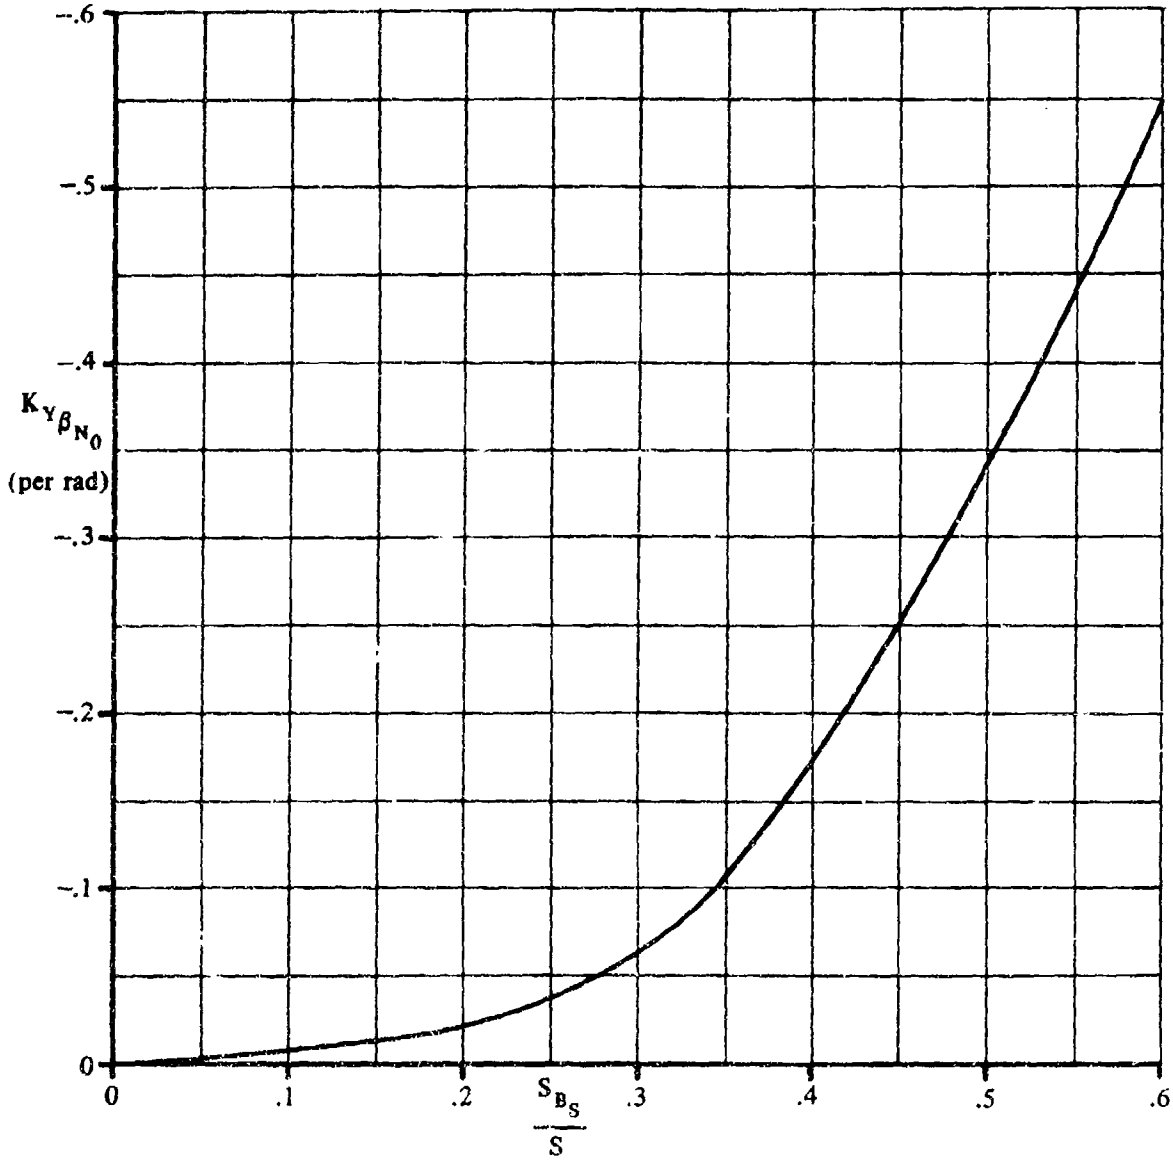

FIGURE 5.5.1.1-6 SIDE-FORCE DERIVATIVE WITH RESPECT TO SIDESLIP AT ZERO NORMAL FORCE – DELTA AND MODIFIED DELTA CONFIGURATIONS

5.5.1.2 WING, WING-BODY SIDESLIP-DERIVATIVE K_{Y_β} VARIATION WITH ANGLE OF ATTACK

A. SUBSONIC

This section presents a method for estimating the effects of angle of attack on the sideslip derivative K_{Y_β} of a delta or modified-delta planform re-entry configuration.

The Datcom method is taken from reference 1. An empirical correlation is presented for estimating K_{Y_β} at $\alpha' = 20^o$, and this correlation has been related to the normal-force coefficient to estimate K_{Y_β} at intermediate angles of attack.

Leading-edge shape was shown to have an important influence on the side force as well as on its variation with angle of attack. A lifting delta wing is characterized by two vortices that extend aft of the nose, at or somewhat inboard of the wing tips. These vortices move with respect to the wing as it is sideslipped, tending to remain fixed with respect to the free stream. Minimum pressures and, as a result, maximum local lifts, are observed in the area immediately below the cores of these vortices. It would, therefore, be expected that the side force produced by sideslipping a delta wing would depend to a significant degree upon the shape of the wing below the vortices. For example, if the minimum pressure acts on a region where the surface of the wing is sloped so that the contribution to side force is large, the value of K_{Y_β} would be expected to differ from that observed on a configuration with flat upper surfaces. During the study reported in reference 1 available test results were analyzed in an attempt to isolate this phenomenon; however, the results were not conclusive. Therefore, the influence of cross-sectional shape other than that related to leading-edge rounding or leading-edge angle is not included in the correlation curve presented in the Datcom method.

Test data show that K_{Y_β} tends to become more negative as angle of attack is increased for wings with small leading-edge radii, while the opposite is true for configurations with generously rounded leading edges. This phenomenon can be explained as follows: On a lifting delta wing the upper-surface pressures on the up-stream leading edge decrease as the sideslip angle is increased and the upper-surface pressures acting on the down-stream edge increase. If the leading-edge radius is large so that the flow does not separate readily, and so that these pressures are effective over a relatively large area, the change in K_{Y_β} due to increases in $C_N{}'$ is positive. For sharper leading edges, the combination of the flow separating readily at the leading edges and the small side area in the vicinity of the minimum pressures at the up-stream leading edge results in a reduction in K_{Y_β} as $C_N{}'$ is increased. This observation led to the development of the estimation procedure. Since the change in K_{Y_β} with C_N depends upon the pressure distribution produced by the lifting process, it was assumed that a correlation procedure could be developed that relates K_{Y_β} to the normal-force coefficient. The expression used in the correlation procedure is

$$K_{Y_\beta} = K_{Y_{\beta_{N_0}}} + \left(K_{Y_{\beta_{20}}} - K_{Y_{\beta_{N_0}}}\right)\left[\frac{C_{N'}}{C_{N'_{20}}}\right]^2$$

Semiempirical correlation curves based on the above expression and test values at $\alpha' = 20^o$ are presented in the Datcom method for delta and modified-delta wings with either round or sharp leading edges. These design charts are considered valid for sideslip angles between $\pm 5^o$ and angles of attack up to 20^o.

DATCOM METHOD

The variation of the sideslip derivative K_{Y_β} with angle of attack for a delta or modified-delta configuration at low speeds, based on planform area, is obtained from the procedure outlined in the following steps:

Step 1. Determine the effective leading-edge angle $\delta_{e_\perp}$ for sharp leading edges or the effective leading-edge radius $R_{\frac{1}{3}LE}$ for round leading edges. These parameters are functions of the configuration geometry in a plane normal to the leading edge at $\frac{1}{3}c_r$ from the nose. The applicable configuration geometry is illustrated on figures 4.8.1.2-11a and 4.8.1.2-11b.

Step 2. Determine the variation of sideslip derivative with angle of attack by

$$K_{Y_\beta} = K_{Y_{\beta_{N_0}}} + \left[\frac{\Delta K_{Y_\beta}}{(C_N')^2}\right]_{20} (C_N')^2 \qquad 5.5.1.2\text{-a}$$

where

$K_{Y_{\beta_{N_0}}}$ is the side force due to sideslip at zero normal force obtained by using the method of Section 5.5.1.1.

C_N' is the normal-force coefficient at angle of attack obtained by using the method of Section 4.8.1.2.

$\left[\frac{K_{Y_\beta}}{(C_N')^2}\right]_{20}$ is the semiempirical correlation factor for the sideslip derivative K_{Y_β} for delta and modified-delta configurations. It is presented as a function of effective leading-edge radius $R_{\frac{1}{3}LE}$ and S_{B_S}/S for configurations with round leading edges in figure 5.5.1.2-8, and as a function of effective leading-edge angle $\delta_{e_\perp}$ and S_{B_S}/S for configurations with sharp leading edges in figure 5.5.1.2-9.

S_{B_S}/S is the ratio of the projected side area of the configuration to the planform area.

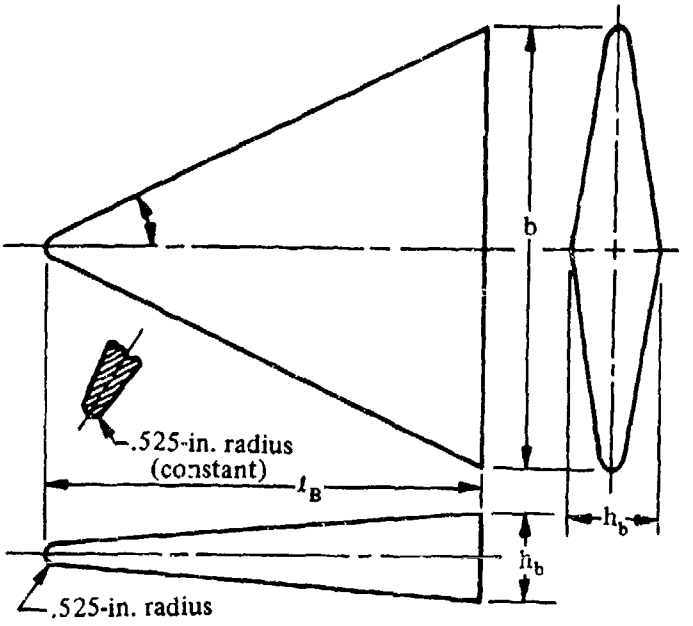
It should be noted that a considerable amount of scatter was involved in the data correlation used to define the design charts. In the case of sharp-leading-edged configurations it was necessary to estimate the nature of the effect of leading-edge angle on the basis of very few test data. Therefore, the accuracy of the design chart for sharp leading edges (figure 5.5.1.2-9) is questionable.

Nonlinearities in the variation of side force with sideslip may appear if the upper-surface slope is such that spanwise components of normal force, due to the negative pressures under the vortex, appear only for a limited range of sideslip angles. As indicated in the introduction, the available data are not sufficient to allow isolation of this effect. However, it should be realized that a constant value of K_{Y_β} valid for $\beta = \pm 5^o$ may not be a useful representation of the physical phenomena involved.

The variation of the sideslip derivative K_{Y_β} with normal force calculated by this method is compared with test data in table 5.5.1.2-A.

Sample Problem

Given: A delta model with a symmetrical diamond cross section, a blunt trailing edge, and round leading edges. This is model D-6 of reference 6. This is the configuration of sample problem 1 of Section 4.8.1.2.



$A = 1.868$ $b = 22.116$ in.

$S = 261.95$ sq in.

$R_{\frac{1}{3}LE} = 0.525$ in.

$S_{B_S} = 61.82$ sq in.

The following variation of C_N' with α' from sample problem 1 of Section 4.8.1.2:

α	0	5°	10°	15°	20°
C_N'	0	0.2017	0.4122	0.6323	0.8618

Compute:

$S_{B_S}/S = 61.82/261.95 = 0.236$

$K_{Y\beta_{N_0}} = -0.030$ per rad (figure 5.5.1.1-6)

$R_{\frac{1}{3}LE}/b = 0.525/22.116 = 0.0237$

$\left[\frac{\Delta K_{Y_\beta}}{(C_N')^2}\right]_{20} = -0.095$ per rad (figure 5.5.1.2-8)

Solution:

$$K_{Y_\beta} = K_{Y_{\beta_{N_0}}} + \left[\frac{\Delta K_{Y_\beta}}{(C_{N'})^2}\right]_{20} (C_{N'})^2 \quad \text{(equation 5.5.1.2-a)}$$

$$= -0.030 + (-0.095)\ (C_{N'})^2$$

①	②	③	④	⑤
α (deg)	$C_{N'}$ (given)	$(C_{N'})^2$ ②^2	$-0.095\,(C_{N'})^2$ -0.095 ③	K_{Y_β} (based on S) (per rad) $-0.030 +$ ④
0	0	0	0	−0.030
5	0.2017	0.041	−0.004	−0.034
10	0.4122	0.170	−0.016	−0.046
15	0.6323	0.400	−0.038	−0.068
20	0.8618	0.743	−0.071	−0.101

The calculated results are compared with test values in sketch (a) and in table 5.5.1.2-A.

5.5.2 WING, WING-BODY SIDESLIP DERIVATIVE K'_{l_β}

5.5.2.1 WING, WING-BODY SIDESLIP DERIVATIVE K'_{l_β} NEAR ZERO NORMAL FORCE

A. SUBSONIC

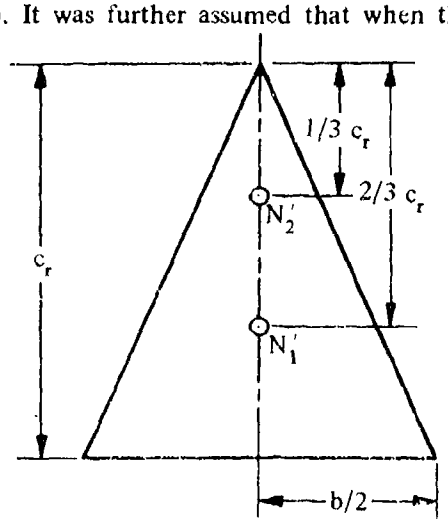
This section presents a method for estimating the sideslip derivative K'_{l_β} near zero normal force for delta and modified-delta configurations at subsonic speeds.

The subsonic rolling moment due to sideslip of a thin delta wing of vanishing aspect ratio ($A < 1$) with sharp leading edges and a pointed nose can be satisfactorily predicted at low lift coefficients by using the method presented in Section 5.1.2.1. However, this procedure is inadequate for proposed re-entry configurations. These configurations range in aspect ratio from low values of the order of 1/2 up to 2, and, for the most part, have thick, generously rounded lifting surfaces and blunt nose shapes.

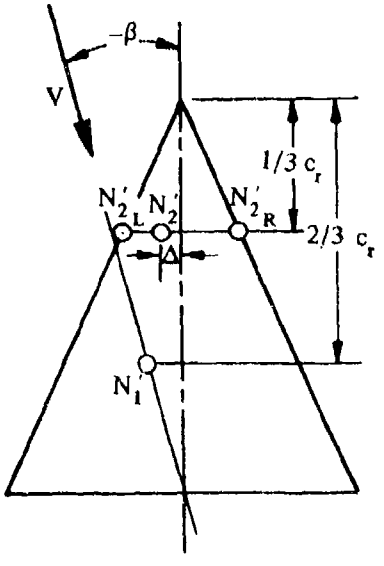
The Datcom method is taken from reference 1. The method is semiempirical and was developed by first describing the pertinent aerodynamic phenomena in terms of a conceptual model and then using available experimental data to adjust the final theoretical results.

In determining the rolling moment due to sideslip of thin delta wings near zero normal force, it was necessary to define the spanwise variation of the normal-force loading due to sideslip, the longitudinal and lateral shifts in the configuration center of pressure due to sideslip, and the effect of sideslip on the total normal force. Briefly, the analysis proceeded as follows: From symmetry considerations and experimental results it was concluded that the total normal force is independent of sideslip angle near zero sideslip. Experimental data also show that the longitudinal position of the center of pressure does not change as the wing is sideslipped through small sideslip angles. Therefore, it was concluded that the change in K'_{l_β} results because of the spanwise shifts in normal force. It was then assumed that the normal force acting on a pure delta wing at zero sideslip can be divided into two components, one distributed uniformly over the planform and the other concentrated at the leading edge. The magnitude of the concentrated component at any spanwise station is proportional to the local chord. In accordance with this concept, the resultant of the uniform load acts at a point 2/3 of the root chord aft of the wing apex, and the resultant of the leading-edge component acts at a point 1/3 of the root chord aft of the wing apex (see sketch (a)). It was further assumed that when the wing is sideslipped, the center of

SKETCH (a)



pressure of the uniform load moves normal to the root chord so as to maintain a line from the trailing edge of the root chord to the center of pressure in a plane parallel to the free stream. It was also assumed that the center of pressure of the leading-edge component moves normal to the root chord some distance Δ that is a function of the angle of sideslip (see sketch (b)). Any rolling-moment



GEOMETRY FOR DEFINING THE EFFECT OF SIDESLIP ON CENTER-OF-PRESSURE POSITION – PURE DELTA WING

SKETCH (b)

contribution from the leading-edge component results from a normal-force differential between the right and left leading-edge components. The lateral position of their center of pressure is determined by balancing their rolling moments about the roll axis. By using the results given in reference 2 for the variation of the leading-edge component of normal force and the configuration geometry described by sketches (a) and (b), an expression was derived for the rolling moment due to sideslip of a thin delta wing near zero normal force. Finally, test data were used to refine the derived expression.

The final correlation is presented as figure 5.5.2.1-8a in the Datcom.

The effect of nose blunting was determined by analyzing a simplified model wherein a portion of the nose of a pure delta wing is removed by a straight cut normal to the root chord. The lateral center-of-pressure movement predicted by this technique is different from that observed, since actual nose blunting usually consists of rounding the forward part of the wing rather than cutting it off sharply. Therefore, an empirical factor was applied, based on the results of reference 3, to compensate for this difference.

It would be expected that thickness would influence rolling moment due to sideslip. The difference in the pressure distribution on the upper and lower surfaces of a lifting delta wing and the variation of the center-of-pressure locations due to thickness should result in an increment of rolling moment due to sideslip. However, during the study reported in reference 1, it was not possible to isolate the expected thickness effects with any degree of confidence. Therefore, the Datcom method does not include an increment showing the effect of thickness on rolling moment.

The Datcom method is considered valid for normal-force coefficients up to 0.3.

DATCOM METHOD

The rolling moment due to sideslip near zero normal force for delta and modified-delta configurations, based on the product of the planform area and span Sb, at low speeds is given by

$$K'_{l\beta_{N_0}} = C_{N'} \left\{ \left[\frac{K'_{l\beta_{N_0}}}{C_{N'}} \right]_{\Delta} + \Delta \left[\frac{K'_{l\beta}}{C_{N'}} \right]_{B} \right\} \quad \text{(per radian)} \qquad 5.5.2.1\text{-a}$$

where

$C_{N'}$ is the normal-force coefficient.

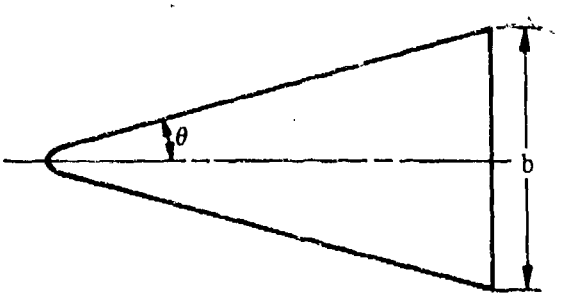
$\left[\frac{K'_{l\beta_{N_0}}}{C_{N'}} \right]_{\Delta}$ is the ratio of the sideslip derivative $K'_{l\beta}$ at zero normal force to the normal-force coefficient for a pointed-nose delta configuration. This parameter is obtained from figure 5.5.2.1-8a as a function of the wing semiapex angle θ.

$\Delta \left[\frac{K'_{l\beta}}{C_{N'}} \right]_{B}$ is the increment of the ratio of sideslip derivative $K'_{l\beta}$ to the normal-force coefficient, due to nose blunting. This parameter is obtained from figure 5.5.2.1-8b as a function of the configuration semiapex angle θ and the aspect ratio. The semiapex angle is measured as illustrated on figure 5.5.2.1-8b and the aspect ratio is that of the blunt-nose configuration.

A comparison of the rolling moment due to sideslip near zero normal force calculated by this method with test data is presented as table 5.5.2.1-A.

Sample Problem

Given: A blunt-nose delta-wing model with a symmetrical cross section and a blunt trailing edge. This is model D-5 of reference 7.



A = 1.076 θ = 15° S = 160.19 sq in. b = 13.13 in.

Compute:

$$\left[\frac{K'_{l\beta_{N_0}}}{C_{N'}}\right]_\Delta = -0.65 \text{ per rad} \quad \text{(figure 5.5.2.1-8a)}$$

$$1 - \frac{4 \tan \theta}{A} = 1 - \frac{4 \tan 15^\circ}{1.076} = 0.0041$$

$$\Delta\left[\frac{K'_{l\beta}}{C_{N'}}\right]_B = 0.033 \text{ per rad} \quad \text{(figure 5.5.2.1-8b)}$$

Solution:

$$\frac{K'_{l\beta}}{C_{N'}} = \left\{\left[\frac{K'_{l\beta_{N_0}}}{C_{N'}}\right]_\Delta + \Delta\left[\frac{K'_{l\beta}}{C_{N'}}\right]_B\right\} \quad \text{(equation 5.5.2.1-a)}$$

$$= -0.65 + 0.033$$

$$= -0.617 \text{ per rad (based on Sb)}$$

This compares with a test value of −0.556 per radian from reference 7.

5.5.2.2 WING, WING-BODY SIDESLIP-DERIVATIVE K'_{l_β} VARIATION WITH ANGLE OF ATTACK

A. SUBSONIC

This section presents a method, taken from reference 1, for estimating the sideslip-derivative K'_{l_β} variation with angle of attack for delta and modified-delta configurations at subsonic speeds.

The variation of K'_{l_β} with angle of attack for a thin delta wing is based on the conceptual model described briefly in Section 5.5.2.1, and the semiempirical technique used to obtain the variation of normal force with angle of attack is that described in reference 2. It is shown in reference 2 that the longitudinal position of the center of pressure and the distribution of the load over the surface of an unyawed, thin delta wing are both independent of angle of attack. As noted in Section 5.5.2.1, experimental data also show that the longitudinal position of the center of pressure does not change as the wing is sideslipped through small sideslip angles. Therefore, it was concluded that the ratio of the normal-force component that is considered to act at the leading edge to that uniformly distributed over the wing (see discussion in Section 5.5.2.1) does not change, and that the change in K'_{l_β} with angle of attack results because of the spanwise shift in one or both of these normal-force components as the angle of attack is increased. In accordance with these considerations, the variation of the sideslip derivative K'_{l_β} with angle of attack is related to the normal-force coefficient by

$$\frac{\left(K'_{l_\beta}/C_{N'}\right)_{\text{linear}}}{\left(K'_{l_\beta}/C_{N'}\right)_{\text{nonlinear}}} = \frac{\left(C_{N'}\right)_{\text{linear}}}{\left(C_{N'}\right)_{\text{nonlinear}}}$$

The technique used to obtain a correlation of normal force in reference 2 (see Section 4.8.1.2) was then applied to determine a reference value for K'_{l_β} at $\alpha' = 20^\circ$. The correlation parameters used were leading-edge radius and leading-edge angle for thin delta wings with round and sharp leading edges, respectively. It was then assumed that the variation of $K'_{l_\beta}/C_{N'}$ within the angle-of-attack range from 0 to 20° is parabolic. It should be noted that as the leading-edge radius approaches zero, the rolling-moment coefficient with respect to sideslip approaches the same value as for a sharp leading edge. Therefore, a configuration with a small leading-edge radius can be analyzed as one having a sharp leading edge.

As wing thickness is increased, the pressure distribution on the upper and lower surfaces of a sideslipping delta wing at angle of attack become significantly different. A couple will be introduced due to this pressure distribution and a corresponding rolling-moment increment will result. An empirical correlation, taken from reference 1, is presented to account for this thickness effect. This correlation is based on data at $\alpha' = 20^\circ$ only; however, it is applied over the angle-of-attack range from 0 to 20° in the Datcom.

The increment in rolling-moment coefficient with respect to sideslip due to nose blunting is assumed invariant with angle of attack. Therefore, the effect of nose blunting is taken as that presented in Section 5.5.2.1.

The Datcom method is considered valid for sideslip angles between ±10° and angles of attack up to 20°.

DATCOM METHOD

The sideslip-derivative K'_{l_β} variation with angle of attack for a delta or modified-delta configuration at subsonic speeds, based on the product of planform area and span Sb, is obtained from the procedure outlined in the following steps:

Step 1. Determine the effective leading-edge angle $\delta_{e_\perp}$ for sharp leading edges or the effective leading-edge radius $R_{\frac{1}{3}\,LE}$ for round leading edges. These parameters are functions of the configuration geometry in a plane normal to the leading edge at $\frac{1}{3} c_r$ from the nose. The applicable configuration geometry is illustrated on figure 4.8.1.2-11a and 4.8.1.2-11b.

Step 2. Determine the ratio $\left[\frac{K'_{l_{\beta_{N_0}}}}{C_{N'}}\right]_\Delta$ of the sideslip derivative K'_{l_β} near zero normal force to the normal-force coefficient for a thin, pointed-nose delta wing. This parameter is obtained from figure 5.5.2.1-8a as a function of the wing semiapex angle θ.

Step 3. Determine the calculated value of $K'_{l_\beta}/C_{N'}$ at $\alpha' = 20^o$ by

$$\left[\left(\frac{K'_{l_\beta}}{C_{N'}}\right)_{calc}\right]_{20} = \frac{1}{1 + \frac{0.152}{\tan\theta}} \left[\frac{K'_{l_{\beta_{N_0}}}}{C_{N'}}\right]_\Delta \quad \text{(per radian)} \qquad 5.5.2.2\text{-a}$$

where θ is the semiapex angle in degrees and $\left[\frac{K'_{l_{\beta_{N_0}}}}{C_{N'}}\right]_\Delta$ is obtained from step 2.

Step 4. Obtain the empirical correlation factor for the ratio of K'_{l_β} to normal-force coefficient at $\alpha' = 20^o$. This parameter is expressed as $\frac{\left(K'_{l_\beta}/C_{N'}\right)_{20}}{\left[\left(K'_{l_\beta}/C_{N'}\right)_{calc}\right]_{20}}$ and is presented as a function of the effective leading-edge radius for configurations with round leading edges in figure 5.5.2.2-12a, and as a function of leading-edge angle for configurations with sharp leading edges in figure 5.5.2.2-12b.

Step 5. Obtain the empirical correlation factor for the increment in the ratio of K'_{l_β} to normal-force coefficient due to thickness effects at $\alpha' = 20^o$. This parameter is expressed as $\Delta \frac{\left(K'_{l_\beta}/C_{N'}\right)_{20}}{\left[\left(K'_{l_\beta}/C_{N'}\right)_{calc}\right]_{20}}$ and is presented in figure 5.5.2.2-13 as a function of the ratio of the projected side area of the configuration to the planform area S_{B_S}/S.

Step 6. Determine the ratio of the increment in sideslip derivative K'_{l_β} to the normal-force coefficient due to nose blunting $\Delta\left[\frac{K'_{l_\beta}}{C_{N'}}\right]_B$ from figure 5.5.2.1-8b as a function of the configuration semiapex angle θ and the aspect ratio. The semiapex angle is measured as illustrated on figure 5.5.2.1-8b and the aspect ratio is that of the blunt-nose configuration.

Step 7. Using the terms obtained in steps 2 through 6 determine the variation of the ratio of $K'_{l_\beta}/C_{N'}$ with α' by

$$\frac{K'_{l_\beta}}{C_{N'}} = \left[\frac{K'_{l_{\beta_{N_0}}}}{C_{N'}}\right]_\Delta \left[1 - \left(\frac{\alpha'}{20}\right)^2\right] + \left(\left\{ \frac{\left(K'_{l_\beta}/C_{N'}\right)_{20}}{\left[\left(K'_{l_\beta}/C_{N'}\right)_{calc}\right]_{20}} + \Delta \frac{\left(K'_{l_\beta}/C_{N'}\right)_{20}}{\left[\left(K'_{l_\beta}/C_{N'}\right)_{calc}\right]_{20}} \right\} \left[\left(\frac{K'_{l_\beta}}{C_{N'}}\right)_{calc}\right]_{20} + \Delta\left[\frac{K'_{l_\beta}}{C_{N'}}\right]_B \right)\left(\frac{\alpha'}{20}\right)^2 \quad \text{(per radian)}$$

5.5.2.2-b

where α' is in degrees.

Step 8. Determine the variation of K'_{l_β} with angle of attack by

$$K'_{l_\beta} = \left(\frac{K'_{l_\beta}}{C_{N'}}\right) C_{N'} \qquad \text{5.5.2.2-c}$$

where $\left(K'_{l_\beta}/C_{N'}\right)$ is from step 7 and $C_{N'}$ is the normal-force coefficient at angle of attack obtained from Section 4.8.1.2.

The variation of the sideslip derivative K'_{l_β} with angle of attack calculated by this method is compared with test data in table 5.5.2.2-A. The variations of $C_{N'}$ with angle of attack, used to obtain the calculated values of K'_{l_β} in table 5.5.2.2-A, were calculated by using the method of Section 4.8.1.2.

It should be noted that a considerable amount of scatter was involved in the data correlation used to define the design charts. In the case of sharp-leading-edged configurations it was necessary to estimate the nature of the effect of leading-edge angle on the basis of very few test data. Therefore, the accuracy of the design chart used for sharp leading edges (figure 5.5.2.2-12b) is questionable.

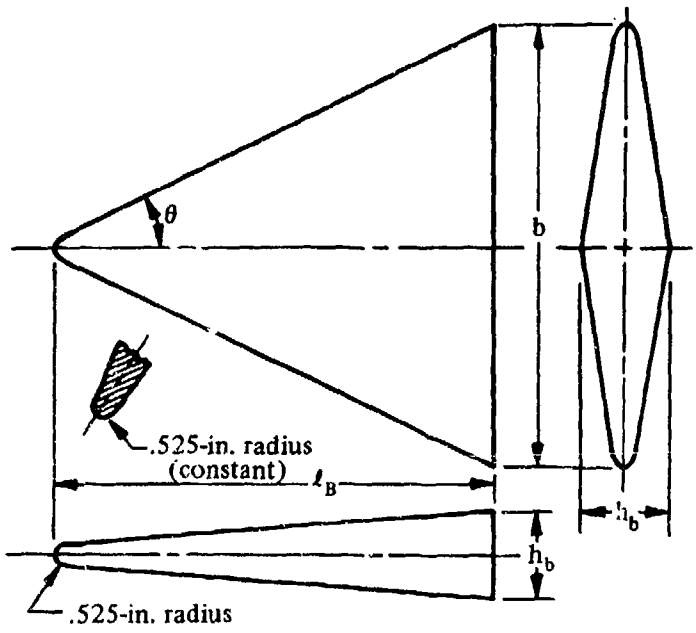
The lift distribution over a lifting delta wing is such that maximum local lifts occur in the area immediately below the cores of the shed vortices (see discussion in Section 5.5.1.2). Since these vortices do not move with the wing as it is sideslipped, the region of high local lift may act on the surface at one sideslip angle while the wing-vortex which produces it may be outboard of the leading edge at

another. Therefore, nonlinearities in the variation of rolling moment with sideslip may exist with low-aspect-ratio delta planforms. The available data are not sufficient to allow isolation of this effect. However, it should be realized that a constant value of K'_{l_β} valid for $\beta = \pm 10^o$ may not be a useful representation of the physical phenomena involved.

Sample Problems

1. Round Leading Edge

Given: A delta wing model of reference 6 designated D-6. This is the configuration of sample problem 1 of Section 4.8.1.2.



$A = 1.868$ $b = 22.116$ in. $S = 261.95$ sq in. $S_{B_S} = 61.82$ sq in.

$R_{\frac{1}{3}\,LE} = 0.525$ in. $\theta = 25^o$ $h_b = 4.32$ in.

The following variation of $C_{N'}$ with α' from sample problem 1 of Section 4.8.1.2:

α'	0	5^o	10^o	15^o	20^o
$C_{N'}$	0	0.2017	0.4122	0.6323	0.8618

Compute:

$$\left[\frac{K'_{l_{\beta_{N_0}}}}{C_{N'}}\right]_\Delta = -0.36 \text{ per rad} \quad \text{(figure 5.5.2.1-8a)}$$

$$\left[\left(\frac{K'_{l_\beta}}{C_{N'}}\right)_{calc}\right]_{20} = \frac{1}{1+\frac{0.152}{\tan\theta}}\left[\frac{K'_{l_{\beta_{N_0}}}}{C_{N'}}\right]_\Delta \quad \text{(equation 5.5.2.2-a)}$$

$$= \frac{1}{1+\frac{0.152}{\tan 25^\circ}} \quad (-0.36)$$

$$= -0.271 \text{ per rad}$$

$$R_{\frac{1}{3}LE}/b = 0.525/22.116 = 0.0237$$

$$\frac{\left(K'_{l_\beta}/C_{N'}\right)_{20}}{\left[\left(K'_{l_\beta}/C_{N'}\right)_{calc}\right]_{20}} = 0.655 \quad \text{(figure 5.5.2.2-12a)}$$

$$S_{B_S}/S = 61.82/261.95 = 0.236$$

$$\Delta\frac{\left(K'_{l_\beta}/C_{N'}\right)_{20}}{\left[\left(K'_{l_\beta}/C_{N'}\right)_{calc}\right]_{20}} = 0.10 \quad \text{(figure 5.5.2.2-13)}$$

$$1-\frac{4\tan\theta}{A} = 1-\frac{4\tan 25^\circ}{1.868} = 0.0015$$

$$\Delta\left[\frac{K'_{l_\beta}}{C_{N'}}\right]_B = 0.005 \text{ per rad} \quad \text{(figure 5.5.2.1-8b)}$$

$$\frac{K'_{l_\beta}}{C_{N'}} = \left[\frac{K'_{l_{\beta_{N_0}}}}{C_{N'}}\right]_\Delta\left[1-\left(\frac{\alpha'}{20}\right)^2\right] + \left(\left\{\frac{\left(K'_{l_\beta}/C_{N'}\right)_{20}}{\left[\left(K'_{l_\beta}/C_{N'}\right)_{calc}\right]_{20}} + \Delta\frac{\left(K'_{l_\beta}/C_{N'}\right)_{20}}{\left[\left(K'_{l_\beta}/C_{N'}\right)_{calc}\right]_{20}}\right\}\left[\left(\frac{K'_{l_\beta}}{C_{N'}}\right)_{calc}\right]_{20} + \Delta\left[\frac{K'_{l_\beta}}{C_{N'}}\right]_B\right)\left(\frac{\alpha'}{20}\right)^2 \quad \text{(equation 5.5.2.2-b)}$$

$$= (-0.36)\left[1 - \left(\frac{\alpha'}{20}\right)^2\right] + \left(\{0.655 + 0.10\}[-0.271] + 0.005\right)\left(\frac{\alpha'}{20}\right)^2$$

$$= -0.36 + 0.36\left(\frac{\alpha'}{20}\right)^2 - 0.200\left(\frac{\alpha'}{20}\right)^2$$

$$= -0.36 + 0.160\left(\frac{\alpha'}{20}\right)^2 \text{ per rad}$$

Solution:

$$K'_{l_\beta} = \left(\frac{K'_{l_\beta}}{C_{N'}}\right) C_{N'} \quad \text{(equation 5.5.2.2-c)}$$

$$= \left[-0.36 + 0.160\left(\frac{\alpha'}{20}\right)^2\right] C_N \text{ per rad}$$

①	②	③	④	⑤	⑥

5.5.3 WING, WING-BODY SIDESLIP DERIVATIVE K'_{n_β}

5.5.3.1 WING, WING-BODY SIDESLIP DERIVATIVE K'_{n_β} AT ZERO NORMAL FORCE

A. SUBSONIC

This section presents a method, taken from reference 1, for estimating $K'_{n_{\beta_{N_0}}}$, the yawing-moment coefficient with respect to sideslip at zero normal force, for delta and modified-delta configurations at subsonic speeds.

The yawing moment due to sideslip is estimated by determining the side force due to sideslip and determining its effective point of application. The side force due to sideslip at zero normal force is estimated by using the method of Section 5.5.1.1.

The nature of the side force, and consequently the location of the center of pressure, is basically different for thin and for thick wings. As noted in Section 5.5.1.1, the side force at zero normal force is assumed to be composed of two parts, side force due to skin friction and side force due to the pressure acting on the configuration. For thin wings the side force is produced primarily by skin friction, and the side-force center of pressure can be related to the wing planform. As the wing thickness is increased, the side force is produced primarily by the difference in pressure distribution between the right and left sides. While the wing planform area would be expected to influence this pressure distribution, the side-area distribution has a major effect. In accordance with these considerations, the skin-friction drag component is assumed to act at the centroid of the planform area and the pressure-drag component at the center of pressure of the side area of the configuration.

An empirical correlation was used to determine the position of the resultant of the side-force components. It was assumed that the center-of-pressure position of the pressure component depends primarily on the shape of the side area and that the influence of other geometric parameters can be neglected. Test data indicated that nose shape has an important influence on this center-of-pressure location, and the final correlation is presented as a function of the ratio of the side area forward of the 20-percent root-chord point (see figure 5.5.3.1-6) to the total side area.

The zero-normal-force sideslip derivative $K_{Y_{\beta_{N_0}}}$ for very thin wings is taken to be equal to the incompressible skin-friction coefficient of the wing, which is taken as $C_f = 0.006$, so that $K_{Y_{\beta_{N_{0_{\substack{\text{thin}\\\text{wing}}}}}}} = -0.006$ per radian, based on planform area. This value is maintained constant for thicker wings, since the side force due to pressure is much greater than that produced by friction and a more accurate value of it is not required.

DATCOM METHOD

The zero-normal-force sideslip derivative $K'_{n_{\beta_{N_0}}}$ of a delta or modified-delta configuration, based on the product of planform area and span Sb, and taken about an axis at the nose of the configuration, is determined from the procedure outlined in the following steps:

Step 1. From the configuration geometry determine the following:

S_{B_S} the projected side area of the configuration

$(S_{B_S})_{.2c_r}$ the projected side area of the configuration forward of 0.2 c_r

$x_{centroid_W}$ the distance from the nose of the configuration to the centroid location of the wing planform, positive aft of the nose

$x_{centroid_{S_{B_S}}}$ the distance from the nose of the configuration to the centroid location of the projected side area, positive aft of the nose

Step 2. Determine $K'_{n_{\beta_{N_0}}}$ by

$$K'_{n_{\beta_{N_0}}} = \left(K_{Y_{\beta_{N_0}}} + 0.006\right) \frac{(x_{c.p.})_p}{x_{centroid_{S_{B_S}}}} \frac{x_{centroid_{S_{B_S}}}}{b} - 0.006 \frac{x_{centroid_W}}{b} \text{ (per radian)} \qquad 5.5.3.1\text{-a}$$

where

$K_{Y_{\beta_{N_0}}}$ is the side-force coefficient due to sideslip at zero normal force, obtained from Section 5.5.1.1.

$\frac{(x_{c.p.})_p}{x_{centroid_{S_{B_S}}}}$ is the ratio of the center-of-pressure location of the pressure component of side force to the centroid location of the projected side area.

This parameter is obtained from figure 5.5.3.1-6 as a function of $(S_{B_S})_{.2c_r}/S_{B_S}$.

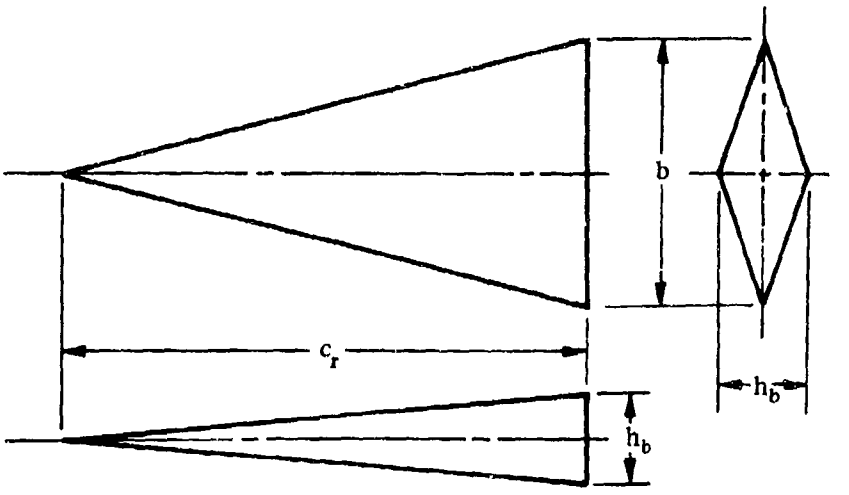
b is the wing span.

A comparison of $K'_{N_{\beta N_0}}$ calculated by using this method with test results is presented as table 5.5.3.1-A. The sideslip derivatives $K_{Y_{\beta N_0}}$, used to obtain the calculated values of $K'_{n_{\beta N_0}}$ in table 5.5.3.1-A, were calculated by using the method of Section 5.5.1.1.

It should be noted that a considerable amount of scatter was involved in the data correlation used to define the center-of-pressure location of the pressure component of side force. For configurations with values of $(S_{B_S})_{.2c_r}/S_{B_S}$ greater than approximately 0.15, the location of $(x_{c.p.})_p$ is not well established.

Sample Problem

Given: A delta-series configuration of reference 6 designated D-2.



$S = 142.3$ sq in. $\quad S_{B_S} = 49.68$ sq in. $\quad \left(S_{B_S}\right)_{.2c_r} = 1.99$ sq in.

$c_r = 23.0$ in. $\quad b = 12.374$ in. $\quad h_b = 4.32$ in.

Compute:

$S_{B_S}/S = 49.68/142.3 = 0.349$

$K_{Y_{\beta_{N_0}}} = -0.110$ per rad (figure 5.5.1.1-6)

$x_{centroid_W} = 2c_r/3 = 2(23.0)/3 = 15.33$ in.

$x_{centroid_{S_{B_S}}} = 2c_r/3 = 15.33$ in.

$\left(S_{B_S}\right)_{.2c_r}/S_{B_S} = 1.99/49.68 = 0.040$

$\dfrac{(x_{c.p.})_p}{x_{centroid_{S_{B_S}}}} = 1.04$ (figure 5.5.3.1-6)

Solution:

$$K'_{n_{\beta_{N_0}}} = \left(K_{Y_{\beta_{N_0}}} + 0.006\right) \frac{(x_{c.p.})_p}{x_{centroid_{S_{B_S}}}} \frac{x_{centroid_{S_{B_S}}}}{b} - 0.006 \frac{x_{centroid_W}}{b} \quad \text{(equation 5.5.3.1-a)}$$

$$= (-0.110 + 0.006)\,(1.04)\,\frac{15.33}{12.374} - 0.006\,\frac{15.33}{12.374}$$

$$= -0.1414 \text{ per rad (based on Sb)}$$

This compares with a test value of −0.1485 per radian from reference 6.

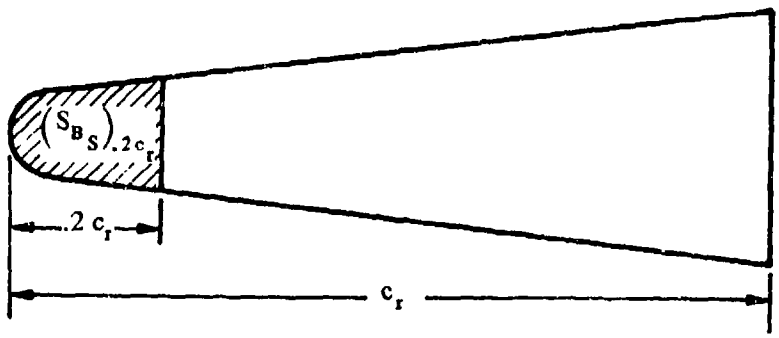

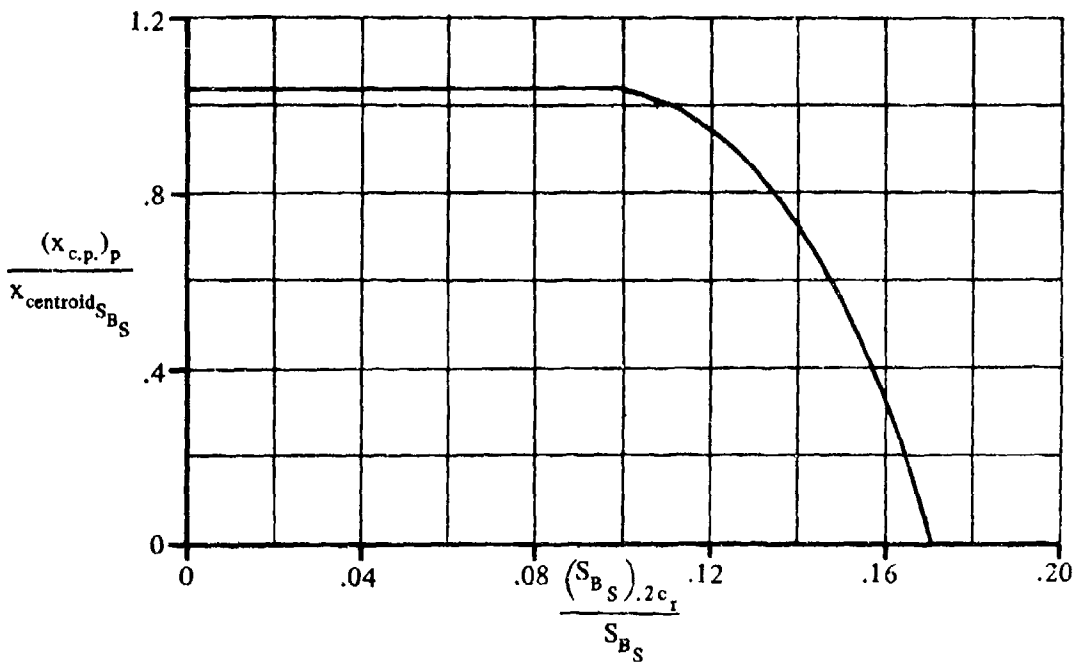

FIGURE 5.5.3.1-6 SIDE-FORCE CENTER OF PRESSURE DELTA AND MODIFIED DELTA CONFIGURATIONS

5.5.3.2 WING, WING-BODY SIDESLIP-DERIVATIVE K'_{n_β} VARIATION WITH ANGLE OF ATTACK

A. SUBSONIC

This section presents a method, taken from reference 1, for estimating the sideslip-derivative K'_{n_β} variation with angle of attack for delta and modified-delta configurations at subsonic speeds.

Although the pressure distribution over a configuration is altered as a result of the lifting process, test data show that side-force center-of-pressure location is not affected appreciably by normal force. Therefore, the change in directional stability is attributed to the change in side force due to sideslip as angle of attack is increased.

Because the location of the side-force center of pressure is considered to be independent of angle of attack, the relationships established in Section 5.5.3.1 for determining the location of the side-force center of pressure at zero normal force are also applicable to this section. Furthermore, the nature of the breakdown of the side force at zero normal force may also be applied at any angle of attack, and the expression for determining the directional stability at angle of attack is the same as that presented in Section 5.5.3.1 for determining K'_{n_β} at zero normal force.

The Datcom method is considered valid for sideslip angles between $\pm 5^o$ and angles of attack from 0 to 20^o.

DATCOM METHOD

The variation of the sideslip derivative K'_{n_β} with angle of attack, based on the product of planform area and span Sb and referred to a moment center at the nose of the configuration, for a delta or modified-delta configuration at subsonic speeds is given by

$$K'_{n_\beta} = \left(K_{Y_\beta} + 0.006\right)\frac{\left(x_{c.p.}\right)_p}{x_{centroid_{S_{B_S}}}}\frac{x_{centroid_{S_{B_S}}}}{b} - 0.006\frac{x_{centroid_W}}{b} \text{ (per radian)} \qquad 5.5\,3.2\text{-a}$$

where K_{Y_β} is the side force due to sideslip at angle of attack, obtained from Section 5.5.1.2, and all the remaining terms are described in Section 5.5.3.1.

A comparison of the variation of K'_{n_β} with normal-force variation calculated by using this method with test data is presented as table 5.5.3.2-A.

The comments pertaining to nonlinearities in the variation of side force with sideslip in Section 5.5.1.2 also apply to the side-force center-of-pressure location.

Sample Problem

Given: A delta-series model of reference 6 designated D-2. This is the configuration of the sample problem of Section 5.5.3.1.

$S = 142.3$ sq in. $\quad S_{B_S} = 49.68$ sq in. $\quad (S_{B_S})_{.2c_r} = 1.99$ sq in.

$c_r = 23.0$ in. $\quad b = 12.374$ in. $\quad \delta_{e_\perp} = 58^\circ$

The following results from the sample problem of Section 5.5.3.1:

$$K_{Y_{\beta_{N_0}}} = -0.110 \text{ per rad} \qquad \frac{(x_{c.p.})_p}{x_{centroid_{S_{B_S}}}} = 1.04$$

$$x_{centroid_{S_{B_S}}} = x_{centroid_W} = 15.33 \text{ in.} \qquad S_{B_S}/S = 0.349$$

Compute:

$$\left[\frac{\Delta K_{Y_\beta}}{(C_{N'})^2}\right]_{20} = 0.335 \text{ per rad} \quad \text{(figure 5.5.1.2-9)}$$

$$K_{Y_\beta} = K_{Y_{\beta_{N_0}}} + \left[\frac{\Delta K_{Y_\beta}}{(C_{N'})^2}\right]_{20} (C_{N'})^2 \quad \text{(equation 5.5.1.2-a)}$$

$$= -0.110 + (0.335)(C_{N'})^2$$

① $C_{N'}$	② $(C_{N'})^2$ ① ^{2}	③ $(0.335)(C_{N'})^2$ 0.335 ②	④ K_{Y_β} (based on S) −0.110 + ③
0	0	0	−0.110

5.6 WING-BODY-TAIL COMBINATIONS IN SIDESLIP

5.6.1 WING-BODY-TAIL SIDESLIP DERIVATIVE C_{Y_β}

5.6.1.1 WING-BODY-TAIL SIDESLIP DERIVATIVE C_{Y_β} IN THE LINEAR ANGLE-OF-ATTACK RANGE

The information contained in this Section is for estimating the side-force-curve slope C_{Y_β} of wing-body-tail combinations at low angles of attack. In general, it consists of a synthesis of material presented in other Sections. The method of Section 5.3.1.1 based on the apparent-mass concept for the determination of increments in C_{Y_β} due to the addition of one panel to an empennage is extended herein to determine the total empennage sideslip derivative C_{Y_β} at low angles of attack resulting from the addition of all the panels present in the empennage. The methods presented include the mutual interference effects of other vehicle components.

The main contributions to the derivative C_{Y_β} will come from the fuselage and the vertical stabilizers. The wing contribution is a function of α^2 and can usually be neglected at low angle of attack. A discussion of the various aerodynamic aspects associated with the build-up of vehicle components in relation to side force are discussed in Sections 5.2.1.1 and 5.3.1.1 and are not repeated here.

The methods presented herein are based on the procedure of totaling the coefficient of the wing-body configuration and the incremental coefficient of the total empennage resulting from the addition of all panels present in the empennage.

A. SUBSONIC

Three methods of estimating the subsonic derivative C_{Y_β} of a complete configuration are presented, differing in their treatment of the incremental coefficient of the total empennage. Methods 1 and 2 treat the mutual interference effects of the wing-body wake and sidewash independently of the body and horizontal tail end-plate effects and lump the total empennage increment into a single parameter. On the other hand, Method 3 utilizes a build-up procedure to determine the total empennage increment wherein the mutual interference effects are lumped into a single effectiveness parameter for each panel in the empennage.

DATCOM METHODS

Method 1

For configurations with a single vertical stabilizer and with horizontal-stabilizer height ranging from positions on the body to the top of the vertical stabilizer or configurations with a single vertical stabilizer and with no horizontal stabilizer the side force due to sideslip is given by

$$C_{Y_\beta} = (C_{Y_\beta})_{WB} + (\Delta C_{Y_\beta})_{VOLBD} \qquad 5.6.1.1\text{-a}$$

where

$(C_{Y_\beta})_{WB}$ is obtained from Section 5.2.1.1

$(\Delta C_{Y_\beta})_{VOLBD}$ is the total empennage increment in C_{Y_β} obtained from Method 1, paragraph A, Section 5.3.1.1

Method 2

For configurations with twin vertical panels mounted on the tips of a horizontal tail or wing the side force due to sideslip is given by equation 5.6.1.1-a

$$C_{Y_\beta} = (C_{Y_\beta})_{WB} + (\Delta C_{Y_\beta})_{VOLBD}$$

where

$(\Delta C_{Y_\beta})_{VOLBD}$ is the total empennage increment in C_{Y_β} obtained from Method 2, paragraph A, Section 5.3.1.1

Method 3

The estimation of the total empennage side-force derivative by this method is based on the apparent-mass concept for the determination of increments in C_{Y_β} due to the addition of one panel to an empennage, presented as Method 3 of paragraph A of Section 5.3.1.1. That method is extended herein to determine the total sideslip derivative C_{Y_β} resulting from the addition of all panels present in the empennage. The method is limited to configurations in which the horizontal tail is mounted on the body or configurations with no horizontal tail.

The total empennage contribution to C_{Y_β} is obtained by adding the increments gained by successive additions of the panels in the empennage to the wing-body configuration. The order of build-up should proceed as follows:

1. Determine the increment in C_{Y_β} due to adding the horizontal stabilizer to the wing-body configuration, $(\Delta C_{Y_\beta})_{H(WB)}$
2. Determine the increment in C_{Y_β} due to adding the upper vertical stabilizing surface to the combination of wing, body, and horizontal stabilizer, $(\Delta C_{Y_\beta})_{V(WBH)}$
3. Determine the increment in C_{Y_β} due to adding the lower vertical stabilizing surface to the combination of wing, body, horizontal stabilizer, and upper vertical stabilizer, $(\Delta C_{Y_\beta})_{(V)(WBHV)}$

The side force due to sideslip for the complete configuration is given by

$$C_{Y_\beta} = (C_{Y_\beta})_{WB} + \Sigma_p (\Delta C_{Y_\beta})_p \qquad 5.6.1.1\text{-b}$$

where the subscript p refers to the panels present in the empennage

$(C_{Y_\beta})_{WB}$ is obtained from Section 5.2.1.1

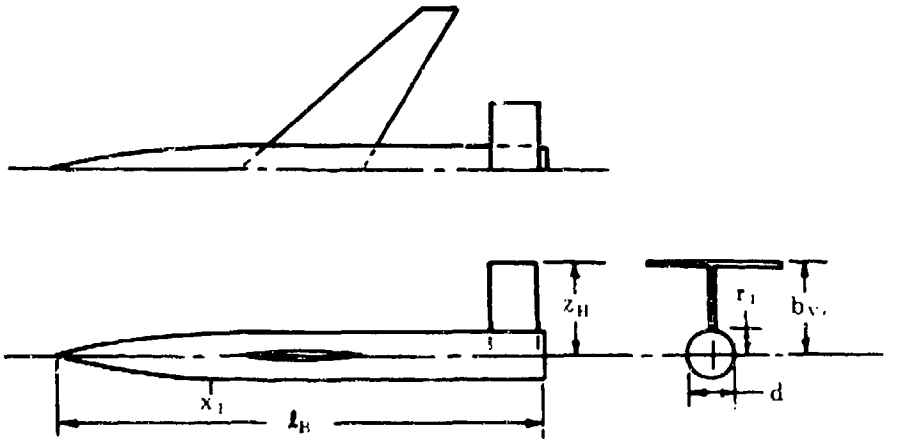
$(\Delta C_{Y_\beta})_p$ is the increment in C_{Y_β} gained by successive additions of the panels in the empennage obtained from Method 3, paragraph A, Section 5.3.1.1

For a wingless configuration, $(\Delta C_{Y_\beta})_p$ is based on the vehicle reference area and the contribution of the body to the total derivative can be obtained from Section 4.2.1.1 as $(C_{Y_\beta})_B = -(C_{L_\alpha})_B$, based on the vehicle reference area.

Sample Problems

1. Method 1

Given: A configuration of reference 1 consisting of wing, body, horizontal tail, and vertical tail.



Wing Characteristics

$A_W = 4.00$ $S_W = 36.0$ sq in. $\Lambda_{c/4_W} = 45°$ $\Gamma = 0$ $z_W = 0$

Horizontal Tail Characteristics

$A_H = 2.78$ $S_H = 9.0$ sq in. $z_H = -3.30$ in.

Vertical Tail Characteristics

$A_V = 1.835$ $S_V = 5.94$ sq in. $\Lambda_{c/2_V} = 0$ $b_V = 3.30$ in. $\lambda_V = 1.00$

NACA 65A006 airfoil

Body Characteristics

$\ell_B = 18.25$ in. $x_1 = 5.83$ in. $V_B^{2/3} = 10.4$ sq in. $d = 1.667$ in.

Additional Characteristics

$M = 0.60$ $r_1 = 0.8335$ in. $x/c_v = 0.25$

Compute:

Step 1. Determine the wing-body contribution to C_{Y_β} using the method of Section 5.2.1.1.

$K_i = 1.0$ (midwing)

$f = \frac{\ell_B}{d} = 10.95$

$(k_2 - k_1) = 0.95$ (figure 4.2.1.1-20a)

$x_1/\ell_B = 0.319$

$x_0/\ell_B = 0.545$ (figure 4.2.1.1-20b)

$x_0 = (0.545)(18.25) = 9.95$ in.

$S_0 = \pi\left(\frac{d}{2}\right)^2 = 2.18$ sq in.

$$(C_{Y_\beta})_{WB} = K_i(C_{Y_\beta})_B\left(\frac{\text{Body Reference Area}}{S_w}\right) + (\Delta C_{Y_\beta})_\Gamma \qquad \text{(equation 5.2.1.1-a)}$$

$$= K_i\left(\frac{-2\,(k_2 - k_1)\,S_0}{V_B^{2/3}}\right)\left(\frac{V_B^{2/3}}{S_w}\right) + (\Delta C_{Y_\beta})_\Gamma$$

$$= 1.00\left(\frac{(-2)(0.95)(2.18)}{10.4}\right)\left(\frac{10.4}{36.0}\right) + 0$$

$= -0.115$ per rad (based on S_w)

Step 2. Determine the total empennage contribution to C_{Y_β} using Method 1, Paragraph A, Section 5.3.1.1.

$(c\ell_\alpha)_V = 6.57$ per rad (Section 4.1.1.2)

$\kappa = \frac{(c\ell_\alpha)_V}{2\pi} = 1.05$ (ratio of incompressible section lift-curve slope to 2π)

$b_V/2r_1 = 1.98$

$k = 0.76$ (figure 5.3.1.1-22d)

$\frac{(A)_{V(B)}}{A_V} = 1.50$ (figure 5.3.1.1-22a)

$(A)_{V(B)} = 1.50\,(A_V) = 2.75$

$S_H/S_V = 1.518$

$K_H = 1.06$ (figure 5.3.1.1-22c)

$z_H/b_V = -1.00$

$\frac{(A)_{V(HB)}}{(A)_{V(B)}} = 1.70$ (figure 5.3.1.1-22b)

$S_V/S_W = 0.165$

$z_W/d = 0$

$$A_{eff} = (A)_{V(B)} \left\{ 1 + K_H \frac{(A)_{V(HB)}}{(A)_{V(B)}} - 1 \right\} \qquad \text{(equation 5.3.1.1-a)}$$

$$= 2.75 \{1 + 1.06 [1.70 - 1]\} = 4.79$$

$$\frac{A_{eff}}{K} [\beta^2 + \tan^2 \Lambda_{c/2_V}]^{1/2} = 3.65$$

$\frac{(C_{L_\alpha})_V}{A_{eff}} = 1.02$ per rad (figure 4.1.3.2-49)

$(C_{L_\alpha})_V = 4.88$ per rad

$$\left(1 + \frac{\partial \sigma}{\partial \beta}\right) \frac{q_V}{q_\infty} = 0.724 + 3.06 \frac{S_V/S_W}{1 + \cos \Lambda_{c/4_W}} + 0.4 \frac{z_W}{d} + 0.009 A_W \qquad \text{(equation 5.4.1-a)}$$

$$= 0.724 + 3.06 \frac{(0.165)}{(1.707)} + 0 + 0.036$$

$$= 1.056$$

$$(\Delta C_{Y_\beta})_{V(WBH)} = -k (C_{L_\alpha})_V \left(1 + \frac{\partial \sigma}{\partial \beta}\right) \frac{q_V}{q_\infty} \frac{S_V}{S_W} \qquad \text{(equation 5.3.1.1-b)}$$

$$= -(0.76)(4.88)(1.056)(0.165)$$

$$= -0.645 \text{ per rad (based on } S_W)$$

Solution:

$$C_{Y_\beta} = (C_{Y_\beta})_{WB} + (\Delta C_{Y_\beta})_{V(WBH)} \qquad \text{(equation 5.6.1.1-a)}$$

$$= -0.115 - 0.645$$

$$= -0.760 \text{ per rad (based on } S_W)$$

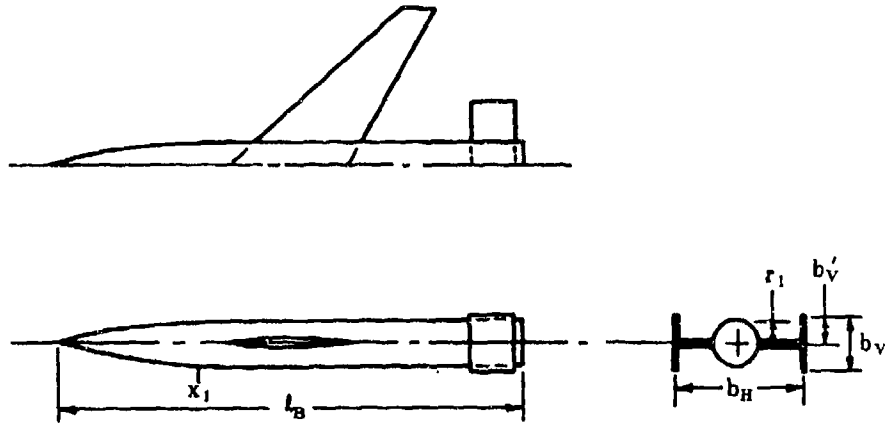
The experimental results (based on S_W) from reference 1, are $(C_{Y_\beta})_{WB} = -0.143$ per radian, $(\Delta C_{Y_\beta})_{V(WBH)} = -0.716$ per radian, and $C_{Y_\beta} = -0.859$ per radian.

2. Method 2

Given: A configuration of reference 1, consisting of wing, body, horizontal tail, and twin vertical tails mounted o the tips of the horizontal tail. The wing and body are identical to those of sample problem 1 and their characteristics are not repeated.

Vertical Tail Characteristics

$b_V = 2.00$ in.	$b_V' = 1.00$ in.	$S_V = 3.60$ sq in.	$A_V = 1.11$
NACA 65A006 airfoil		$\phi_{TE_V} = 7^\circ$	



Additional Characteristics

r_1 = 0.8335 in. b_H = 4.80 in. M = 0.60

Compute:

Step 1. Determine the wing-body contribution to C_{Y_β} using the Method of Section 5.3.1.1.

$(C_{Y_\beta})_{WB}$ = -0.115 per rad (sample problem 1)

Step 2. Determine the total empennage contribution to C_{Y_β} using Method 2, paragraph A, Section 5.3.1.1.

b_V'/b_V = 0.50

$\frac{A_{eff}}{A}$ = 1.0 (figure 5.3.1.1-24a)

A_{eff} = 1.11

$(C_{Y_\beta})_{V_{eff}}$ = 1.78 per rad (figure 5.3.1.1-24b)

$2r_1/b_V$ = 0.8335

$\frac{b_H}{\ell_B} = \frac{4.80}{18.25}$ = 0.263

$\frac{(C_{Y_\beta})_{V(WBH)}}{(C_{Y_\beta})_{V_{eff}}}$ = 0.595 (figure 5.3.1.1-24c)

$$(\Delta C_{Y_\beta})_{V(WBH)} = -\frac{(C_{Y_\beta})_{V(WBH)}}{(C_{Y_\beta})_{V_{eff}}} (C_{Y_\beta})_{V_{eff}} \frac{2S_V}{S_W} \qquad \text{(equation 5.3.1.1-c)}$$

$$= -(0.595)\,(1.78)\,\frac{2(3.60)}{36.0}$$

= -0.212 per rad (based on S_W)

Solution:

$$C_{Y_\beta} = (C_{Y_\beta})_{WB} + (\Delta C_{Y_\beta})_{V(WBH)} \qquad \text{(equation 5.3.1.1-a)}$$

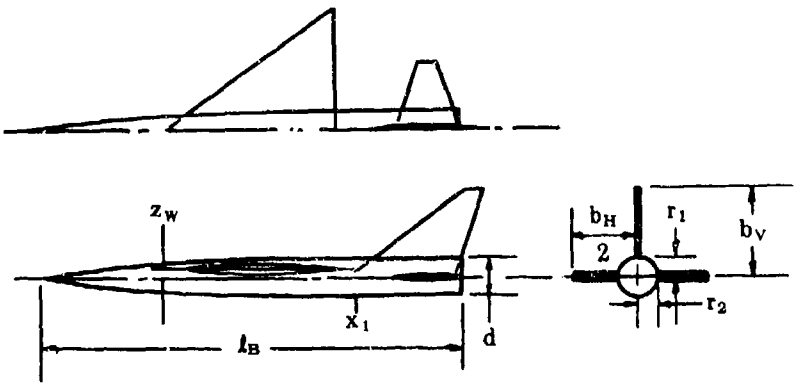
= -0.115 - 0.212

= -0.327 per rad (based on S_W).

The experimental results (based on S_W) from reference 1 are $(C_{Y_\beta})_{WB} = -0.143$ per radian, $(\Delta C_{Y_\beta})_{V(WBH)} = -0.258$ per radian, and $C_{Y_\beta} = -0.401$ per radian.

3. Method 3

Given: The configuration of reference 2, consisting of wing, body, horizontal tail, and upper vertical tail.



Wing Characteristics

$A_W = 3.0$ $S_W = 576$ sq in. $z_W = -2.08$ in. $\Gamma = 0$

Horizontal Tail Characteristics

$A_H = 4.0$ $b_H/2 = 11.21$ in. $z_H = 0$

Vertical Tail Characteristics

$A_V = 1.50$ $A_{V_e} = 1.43$ $S_V = 153.7$ sq in. $S_{V_e} = 109.7$ sq in.

$\Lambda_{\alpha/2_V} = 41.9^\circ$ $\lambda_V = 0.16$ $\lambda_{V_e} = 0.189$ $b_V = 15.23$ in.

NACA 0003.5-64 airfoil

Body Characteristics

$l_B = 72.0$ in. $x_1 = 54.0$ in. $V_B^{2/3} = 133.0$ sq in. $d = 6.0$ in.

Additional Characteristics

$M = 0.25$ $r_1 = 2.76$ in. $r_2 = 2.76$ in

Compute:

Step 1. Determine the wing-body contribution to C_{Y_β} using the method of Section 5.2.1.1.

$$\frac{z_W}{d/2} = \frac{-2.08}{3.0} = -0.694$$

$K_1 = 1.58$ (figure 5.2.1.1-7)

$$f = \frac{l_B}{d} = 12.0$$

$k_2 - k_1 = 0.955$ (figure 4.2.1.1-20a)

$x_1/l_B = 0.75$

$x_0/\ell_B = 0.765$ (figure 4.2.1.1-20b)

$x_0 = (0.765)(72.0) = 55.08$ in.

$S_0 = \pi\left(\frac{d}{2}\right)^2 = 28.28$ sq in.

$$(C_{Y_\beta})_{WB} = K_I (C_{Y_\beta})_B \left(\frac{\text{Body Reference Area}}{S_W}\right) + (\Delta C_{Y_\beta})_\Gamma \qquad \text{(equation 5.2.1.1-a)}$$

$$= K_I \left(\frac{-2(k_2 - k_1) S_0}{V_B^{2/3}}\right)\left(\frac{V_B^{2/3}}{S_W}\right) + (\Delta C_{Y_\beta})_\Gamma$$

$$= 1.58\left(\frac{(-2)(0.955)(28.28)}{133.0}\right)\left(\frac{133.0}{576.0}\right) + 0$$

$$= -0.1480 \text{ per rad (based on } S_W)$$

Step 2. Determine the total empennage contribution to C_{Y_β} using Method 3, paragraph A, Section 5.3.1.1 to determine the contributions of individual panels.

$(c\ell_\alpha)_V = 6.18$ per rad (Section 4.1.1.2)

$$\kappa = \frac{(c\ell_\alpha)_V}{2\pi} = 0.984 \text{ (ratio of incompressible section lift-curve slope to } 2\pi)$$

$2A_{V_e} = 2.86$

$$\frac{2A_{V_e}}{\kappa}\left[\beta^2 + \tan^2 \Lambda_{c/2_V}\right]^{1/2} = 3.84$$

$$\frac{(C_{L_\alpha})_V}{2A_{V_e}} = 0.995 \text{ per rad (figure 4.1.3.2-49)}$$

$(C_{L_\alpha})_V = (0.995)(2A_{V_e}) = 2.85$ per rad (based on S_{V_e})

Determine the increment in C_{Y_β} due to adding the horizontal tail to the wing-body configuration. In this case the empennage consists of the body and the horizontal tail. The apparent-mass ratio to be found is that due to adding the horizontal tail to the body, $K_{H(B)}$.

$z_H/r_1 = 0$

$K_{H(B)} = 0$ (figure 5.3.1.1-25oo)

$$(\Delta C_{Y_\beta})_{H(WB)} = K_{H(B)} (C_{Y_\beta})_B \frac{S_{B_{Ref}}}{S_W} \qquad \text{(equation 5.3.1.1-e)}$$

$$= 0$$

Determine the increment in C_{Y_β} due to adding the upper vertical stabilizer to the wing-body-horizontal tail configuration. In this case the empennage consists of body, horizontal tail, and upper vertical stabilizer. The apparent-mass ratio to be found is that due to adding the upper vertical stabilizer to the combination of body and horizontal tail, $K_{V(BH)}$.

$$r_1/r_2 = 1.000;\ \frac{r_2}{b_H/2} = 0.246;\ (r_1/b)_{V_{\substack{\text{existing}\\\text{panel}}}} = 1.000;\ (r_1/b)_{V_{\substack{\text{added}\\\text{panel}}}} = 0.181$$

By using the above parameters and Table 5.3.1.1-A, $K_{V(BH)}$ can be obtained from figures 5.3.1.1-25b, -25c, and -25d interpolated for a value of $\frac{r_2}{b_H/2} = 0.246$.

$K_{V(BH)} = 1.225$

$$(\Delta C_{Y_\beta})_{V(WBH)} = -K_{V(BH)} (C_{L_\alpha})_V \frac{S_{V_e}}{S_W} \qquad \text{(equation 5.3.1.1-d)}$$

$$= -(1.225)(2.85) \frac{109.7}{576}$$

$$= -0.665 \text{ per rad (based on } S_W)$$

Solution:

$$C_{Y_\beta} = (C_{Y_\beta})_{WB} + \Sigma_p (\Delta C_{Y_\beta})_p \qquad \text{(equation 5.6.1.1-b)}$$

$$= (C_{Y_\beta})_{WB} + (\Delta C_{Y_\beta})_{H(WB)} + (\Delta C_{Y_\beta})_{V(WBH)}$$

$$= -0.1480 + 0 - 0.665$$

$$= -0.813 \text{ per rad (based on } S_W)$$

The experimental results (based on S_W) from reference 2 are $(C_{Y_\beta})_{WB} = -0.149$ per radian, $(\Delta C_{Y_\beta})_{V(WBH)} = -0.556$ per radian, and $C_{Y_\beta} = -0.705$ per radian.

B. TRANSONIC

A brief discussion of the flow phenomena associated with forces generated on a vertical panel at transonic speeds is given in paragraph B of Section 5.3.1.1. The effect of wing-body wake and sidewash, and the mutual interference effects between component combinations at transonic sp[illegible] are extremely sensitive to changes in local contour.

At the present time these effects cannot be predicted with accuracy and the vehicle sideslip derivative C_{Y_β} is usually obtained by wind-tunnel testing or estimated from comparison with similar configurations.

DATCOM METHOD

No method is available in the literature for estimating the vehicle sideslip derivative C_{Y_β} at transonic speeds and none is presented in the Datcom. Some typical transonic data for this derivative are presented as figure 5.6.1.1-14.

C. SUPERSONIC

The procedure for estimating the supersonic sideslip derivative C_{Y_β} of a wing-body-tail configuration is essentially the same as that at subsonic speeds. The problem of estimating the contribution of the empennage is complicated by the presence of shock waves. This effect is discussed in paragraph C of Section 5.3.1.1.

DATCOM METHOD

The side force due to sideslip for the complete configuration at supersonic speeds is given by equation 5.6.1.1-b

$$C_{Y_\beta} = (C_{Y_\beta})_{WB} + \Sigma_p (\Delta C_{Y_\beta})_p$$

where the subscript p refers to panels present in the empennage

$(C_{Y_\beta})_{WB}$ is obtained from Section 5.2.1.1

$(\Delta C_{Y_\beta})_p$ are the increments in C_{Y_β} gained by successive additions of the panels in the empennage obtained from paragraph C, Section 5.3.1.1

The order of configuration build-up will generally proceed as outlined for subsonic speeds (Method 3, paragraph A). The one exception to that build-up procedure is the case at supersonic speeds where the vertical panels are stag-

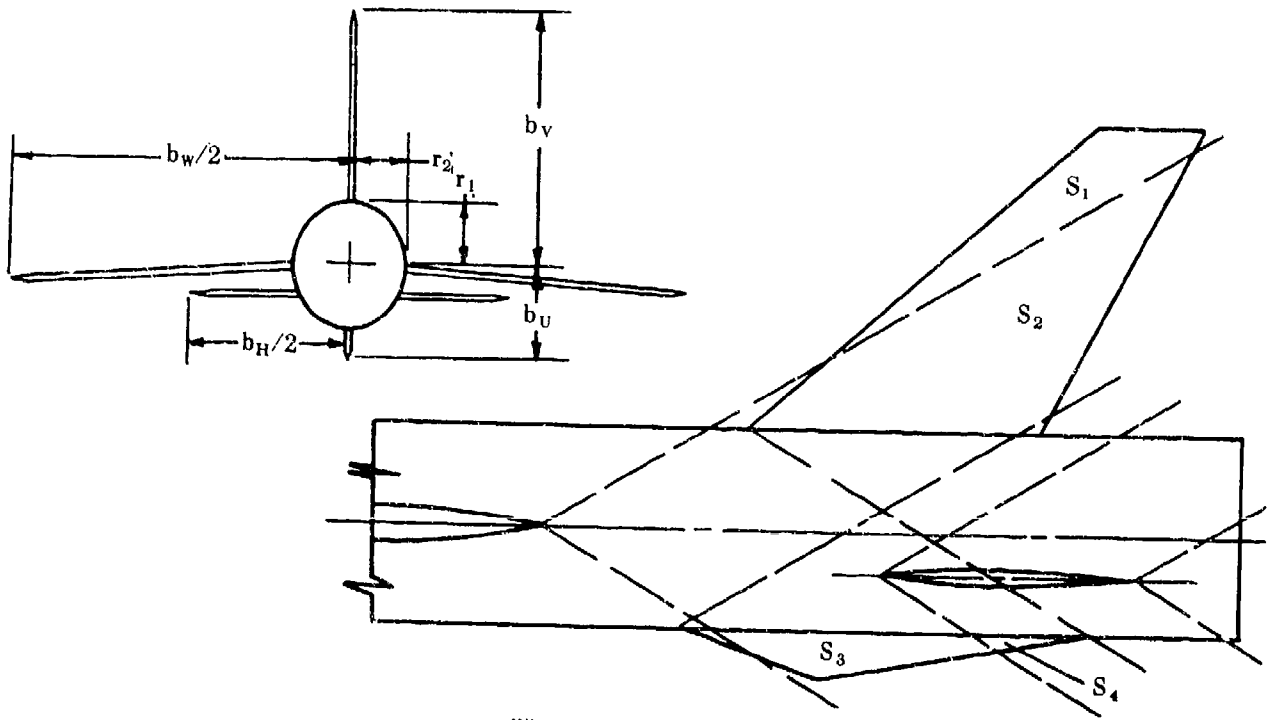
gered along the body so that their leading edges intersect the body at different locations. In this case, the panel whose leading edge intersects the body farthest aft is added first.

This method is limited to configurations in which the horizontal tail is mounted on the body or configurations with no horizontal tail.

For a wingless configuration the remarks following the Datcom methods of paragraph A above are also applicable at supersonic speeds.

Sample Problem

Given: The configuration of reference 3 consisting of wing, body, horizontal tail upper vertical tail, and lower vertical tail.



Wing Characteristics

$A_W = 3.18$	$S_W = 114.5$ sq in.	$b_W = 19.08$ in.	$z_W = 0$	$\Gamma = -3.5°$

Horizontal Tail Characteristics

$A_H = 3.06$	$b_H = 9.12$ in.	$z_H = 0.84$ in.

Vertical Tail Characteristics

$A_{V_e} = 1.48$	$S_{V_e} = 19.20$ sq in.	$\Lambda_{LE_V} = 49.2°$	$b_V = 7.08$ in.	$\lambda_{V_e} = 0.392$

Ventral Tail Characteristics

$A_{U_e} = 0.2025$	$S_{U_e} = 3.24$ sq in.	$\Lambda_{LE_U} = 70.2°$	$b_U = 2.56$ in.	$\lambda_U = 0$

Additional Characteristics

$M = 2.01$	$\mu = \sin^{-1} 1/M = 29.8°$	$r_1 = 1.75$ in.	$r_2 = 1.496$ in.
$r_1/r_2 = 1.170$	$S_1 = 4.63$ sq in.	$S_2 = 14.56$ sq in.	$S_3 = 2.74$ sq in.
$S_4 = 0.50$ sq in.	$\frac{S_{act}}{S_{ext}} = 0.875$		

Compute:

Step 1. Determine the wing-body contribution to C_{Y_β}.

The Datcom does not present methods at supersonic speeds that will predict the side-force characteristics of the wing-body configuration of this sample problem. In such cases it is suggested that test results of a similar configuration be used, if available, and corrected for the difference in relative size of the fuselage and wing for the two configurations. If the vertical location of the wing on the fuselage is not similar, a correction for wing-fuselage interference must also be made.*

An experimental result for $(C_{Y_\beta})_{WB}$ is not available for this configuration. Use is made of the experimental result for $(C_{Y_\beta})_{WBH}$. However, the increment due to adding the horizontal tail to the wing-body configuration will be computed for the sake of completeness.

$(C_{Y_\beta})_{\substack{WBH \\ test}} = -0.315$ per rad (based on S_W)

Step 2. Determine the total empennage contribution to C_{Y_β} using the method of paragraph C, Section 5.3.1.1 to determine the contributions of individual panels.

Upper Vertical Panel

$2A_{V_e} \tan \Lambda_{LE_V} = 3.42$

$\dfrac{\tan \Lambda_{LE_V}}{\beta} = \dfrac{1.1585}{1.744} = 0.664$

$\beta(C_{N_\alpha})_V = 4.10$ per rad

(figures 4.1.3.2-56c,-56d, -56e interpolated for $\lambda_{V_e} = 0.392$)

$(C_{N_\alpha})_V = 2.35$ per rad (based on S_{V_e})

Lower Vertical Panel

$2A_{U_e} \tan \Lambda_{LE_U} = 1.125$

$\dfrac{\beta}{\tan \Lambda_{LE_U}} = 0.628$

$\tan \Lambda_{LE_U} (C_{N_\alpha})_U = 1.73$ per rad (figure 4.1.3.2-56d)

$(C_{N_\alpha})_U = 0.622$ per rad (based on S_{U_e})

Determine the increment in C_{Y_β} due to adding the horizontal tail to the wing-body configuration. In this case the empennage consists of the body and the horizontal tail. The apparent-mass ratio to be found is that due to adding the horizontal tail to the body, $K_{H(B)}$.

$\left(\dfrac{z_H}{r_1}\right) = \dfrac{0.84}{1.75} = 0.480; \left(\dfrac{r_2}{b_H/2}\right) = \dfrac{1.496}{4.56} = 0.328$

From figure 5.3.1.1-25oo, values of $K_{H(B)}$ are obtained for $\left(\dfrac{z_H}{r_1}\right) = 1.0, 0, -1.0$ at $\left(\dfrac{r_2}{b_H/2}\right) = 0.328$

Since K charts are not presented for the case of a horizontal surface added to an elliptical body the body is considered circular and an interpolation is performed to obtain

$K_{H(B)}$ at $\left(\dfrac{z_H}{r_1}\right) = 0.480$**

$K_{H(B)} = 0.130$

The side-force-curve slope of the body is given by slender-body theory. $(C_{Y_\beta})_B = -2$ per rad (based on S_B)

$(\Delta C_{Y_\beta})_{H(WB)} = K_{H(B)} (C_{Y_\beta})_B \dfrac{S_{B_{Ref}}}{S_W} \dfrac{S_{act}}{S_{ext}}$ (equation 5.3.1.1-g)

$= (0.130)(-2)\left(\dfrac{\pi r_1 r_2}{114.5}\right)(0.875)$

*See reference 5 for discussion of design corrections.

**See Method 3, paragraph A, Section 5.3.1.1 for interpolation procedure.

$$= (0.130)(-2)\left[\frac{(\pi)(1.75)(1.496)}{114.5}\right](0.875)$$

$$= -0.0163 \text{ per rad (based on } S_W)$$

Determine the increment in C_{Y_β} due to adding the upper vertical stabilizer to the wing-body-horizontal stabilizer combination. The empennage in this case consists of the body, horizontal tail, and upper vertical stabilizer. The apparent-mass ratio to be found is that due to adding the upper vertical stabilizer to the body and horizontal tail, $K_{V(HB)}$.

In the configuration sketch part of the upper vertical panel S_1 senses only the wing-body combination, while S_2 senses only the body. Therefore, the effective apparent-mass ratio is given by

$$K'_{V(HB)} = K_{V(WB)} \frac{S_1}{S_{V_e}} + K_{V(B)} \frac{S_2}{S_{V_e}}$$

Determine $K_{V(WB)}$:

$$\left(\frac{r_1}{r_2}\right) = 1.170; \left(\frac{r_2}{b_W/2}\right) = 0.157; \left(\frac{r_1}{b}\right)_{\substack{V \\ \text{added} \\ \text{panel}}} = 0.247; \left(\frac{r_1}{b}\right)_{\substack{U \\ \text{existing} \\ \text{panel}}} = 1.000$$

By using the above parameters and table 5.3.1.1-A it is seen that $K_{V(WB)}$ can be obtained from figures 5.3.1.1-25b, -25c, -25e, and 5.3.1.1-25x, -25y, -25z, and 5.3.1.1-25dd, -25ee, -25ff, interpolated for

$\frac{r_2}{b_W/2} = 0.157$ and $r_1/r_2 = 1.170$.

$$K_{V(WB)} = 1.49$$

Determine $K_{V(B)}$:

$$\left(\frac{r_1}{r_2}\right) = 1.170; \left(\frac{r_1}{b}\right)_{\substack{V \\ \text{added} \\ \text{panel}}} = 0.247; \left(\frac{r_1}{b}\right)_{\substack{U \\ \text{existing} \\ \text{panel}}} = 1.000$$

By using the above parameters and table 5.3.1.1-A it is seen that $K_{V(B)}$ can be obtained from figures 5.3.1.1-25a, -25w, and -25cc, interpolated for $r_1/r_2 = 1.170$

$$K_{V(B)} = 1.27$$

$$K'_{V(HB)} = (1.49)\left(\frac{4.63}{19.20}\right) + (1.27)\left(\frac{14.57}{19.20}\right) = 1.32$$

$$(\Delta C_{Y_\beta})_{V(WBH)} = -K'_{V(HB)} (C_{N_\alpha})_V \frac{S_{V_e}}{S_W} \qquad \text{(equation 5.3.1.1-f)}$$

$$= -(1.32)(2.35)\frac{19.20}{114.5}$$

$$= -0.520 \text{ per rad (based on } S_W)$$

Determine the increment in C_{Y_β} due to adding the lower vertical stabilizer to the wing-body-horizontal stabilizer-upper vertical stabilizer combination. The empennage in this case consists of body, horizontal tail, upper vertical stabilizer, and lower vertical stabilizer. The apparent-mass ratio to be found is that due to adding the lower vertical stabilizer to the combination of body, horizontal tail, and upper vertical stabilizer, $K_{U(BHV)}$.

In the configuration sketch part of the lower vertical stabilizer S_3 senses only the body, while S_4 senses both the body and horizontal tail. Therefore, the effective apparent-mass ratio is given by

$$K'_{U(BHV)} = K_{U(B)} \frac{S_3}{S_{U_e}} + K_{U(BH)} \frac{S_4}{S_{U_e}}$$

Determine $K_{U(B)}$:

$$\left(\frac{r_1}{r_2}\right) = 1.170; \left(\frac{r_1}{b}\right)_{\substack{U \\ \text{added} \\ \text{panel}}} = 0.685; \left(\frac{r_1}{b}\right)_{\substack{V \\ \text{existing} \\ \text{panel}}} = 1.000$$

By using the above parameters and table 5.3.1.1-A it is seen that $K_{U(B)}$ can be obtained from figures 5.3.1.1-25a, -25w, and -25cc, interpolated for $r_1/r_2 = 1.170$.

$$K_{U(B)} = 3.0$$

Determine $K_{U(BH)}$:

$$\left(\frac{r_1}{r_2}\right) = 1.170; \left(\frac{r_1}{b}\right)_{\substack{U \\ \text{added} \\ \text{panel}}} = 0.685; \left(\frac{r_1}{b}\right)_{\substack{V \\ \text{existing} \\ \text{panel}}} = 1.000; \left(\frac{r_2}{b_H/2}\right) = 0.328; \left(\frac{z_H}{r_1}\right) = 0.480$$

Since the horizontal tail is located below the body centerline and the body is elliptical, we have a horizontal tail-body combination not covered by the K charts of Section 5.3.1.1. To handle this case, either the body has to be considered circular and an interpolation made for horizontal tail height, or the horizontal tail has to be assumed to be located at the mid-position and an interpolation made between r_1/r_2 ratios. A comparison between figures 5.3.1.1-25d, -25z, and 25ff shows that a small variation in cross section has a significant effect on the apparent-mass ratio in the region of $(r_1/b)_U = 0.685$. Therefore, an interpolation for body shape will be made rather than for horizontal tail height.

From figures 5.3.1.1-25c, -25d, -25e and 5.3.1.1-25y, -25z, -25aa and 5.3.1.1-25ee, -25ff, -25gg obtain $K_{U(BH)}$ interpolated for $\frac{r_2}{b_H/2} = 0.328$. An interpolation between those values of $K_{U(BH)}$ gives, for $(r_1/r_2) = 1.170$

$$K_{U(BH)} = 3.04$$

$$K'_{U(BHV)} = (3.0)\left(\frac{2.74}{3.24}\right) + (3.04)\left(\frac{0.50}{3.24}\right)$$

$$= 3.01$$

$$(\Delta C_{Y_\beta})_{U(WBHV)} = -K'_{U(BHV)} (C_{N_\alpha})_U \frac{S_{U_e}}{S_W} \qquad \text{(equation 5.3.1.1-f)}$$

$$= -(3.01)(0.622) \frac{3.24}{114.5}$$

$$= -0.053 \text{ per rad (based on } S_W)$$

Solution:

$$C_{Y_\beta} = (C_{Y_\beta})_{WB} + \Sigma_p (\Delta C_{Y_\beta})_p \qquad \text{(equation 5.6.1.1-b)}$$

$$= (C_{Y_\beta})_{WB} + (\Delta C_{Y_\beta})_{H(WB)} + (\Delta C_{Y_\beta})_{V(WBH)} + (\Delta C_{Y_\beta})_{U(WBHV)}$$

For this sample problem use is made of the test result for $(C_{Y_\beta})_{WBH}$, so

$$C_{Y_\beta} = (C_{Y_\beta})_{WBH} + (\Delta C_{Y_\beta})_{V(WBH)} + (\Delta C_{Y_\beta})_{U(WBHV)}$$

$$= (-0.315) + (-0.520) + (-0.053)$$

$$= -0.888 \text{ per rad (based on } S_W)$$

The experimental result from reference 3 is $C_{Y_\beta} = -0.888$ per radian (based on S_W).

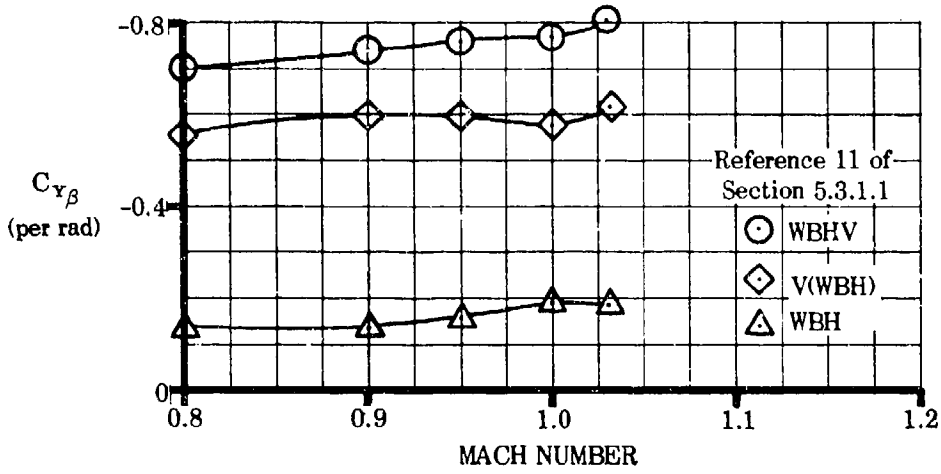

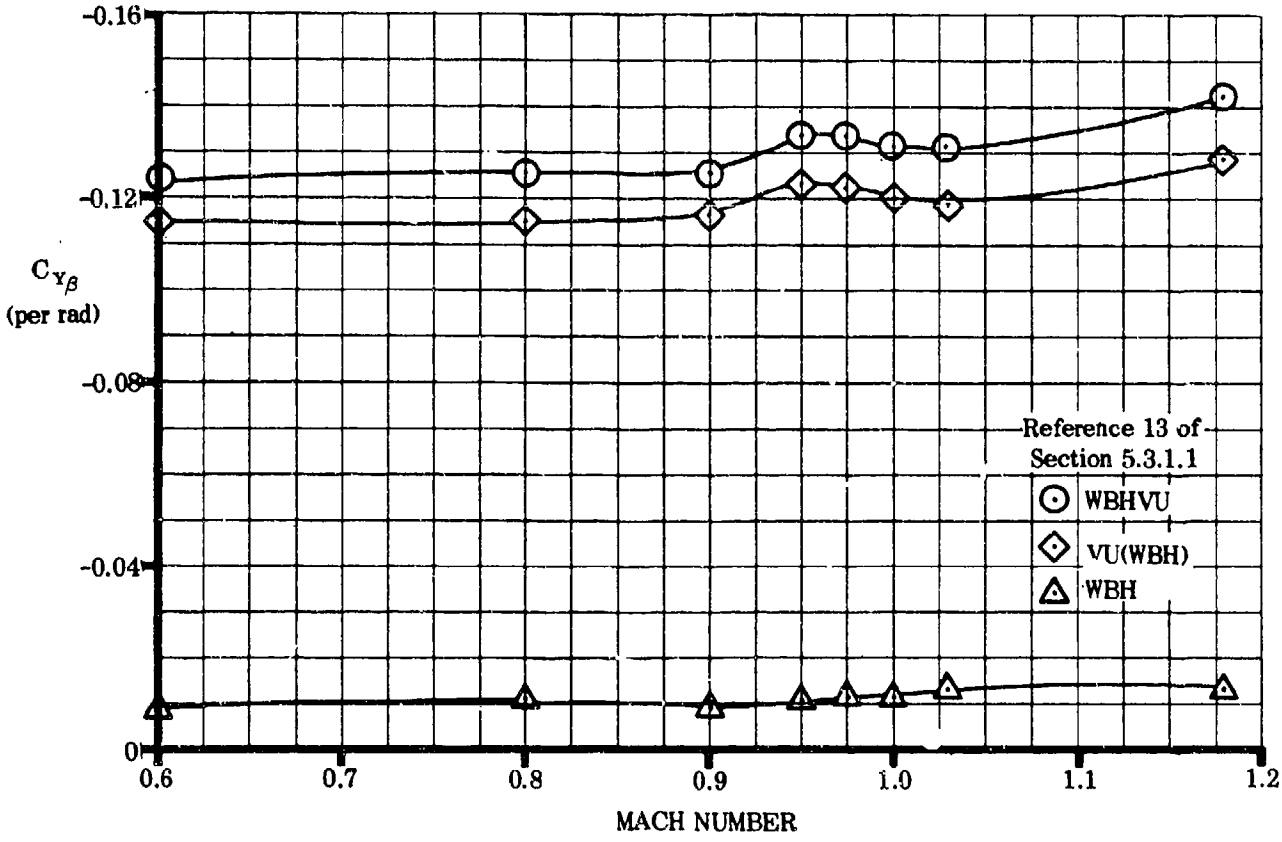

FIGURE 5.6.1.1-14 TYPICAL TRANSONIC DATA

5.6.1.2 WING-BODY-TAIL SIDE-FORCE COEFFICIENT C_Y AT ANGLE OF ATTACK

The wing-body-tail side force developed at combined angles is nonlinear with respect to both sideslip and angle of attack for the reasons cited in the introductory remarks of Sections 5.2.1.2 and 5.3.1.2, and as in those Sections, to obtain C_{Y_β}, it is recommended that C_Y be calculated at several angles of attack for a small sideslip angle ($\beta \leq 4^\circ$). Then at each angle of attack the side force is assumed linear with sideslip for small values of β so that

$$C_{Y_\beta} \approx \frac{C_Y}{\beta}.$$

A. SUBSONIC

No method is presently available for determining the wing-body-tail side force at large angles of attack and subsonic speeds. The method presented herein is restricted to first-order approximations at relatively low angles of attack.

DATCOM METHOD

It is recommended that the method of paragraph A of Section 5.6.1.1 be used, with consideration given to the angle-of attack restriction presented in figure 5.1.1.1-4.

B. TRANSONIC

The comments appearing in paragraph B of Section 5.6.1.1 are equally appropriate here.

DATCOM METHOD

No method is available for estimating this coefficient and none is presented in the Datcom.

C. SUPERSONIC

The analysis of wing-body-tail configurations at combined angles is taken from reference 1 and is accomplished through a combination of the methods of Sections 5.2.1.2 and 5.3.1.2. Therefore, the discussions in paragraph C of those Sections apply to this Section as well. Note in Section 5.3.1.2 that the method is limited to configurations with circular bodies, and to the analysis of horizontal tail effects only when that surface is body-mounted.

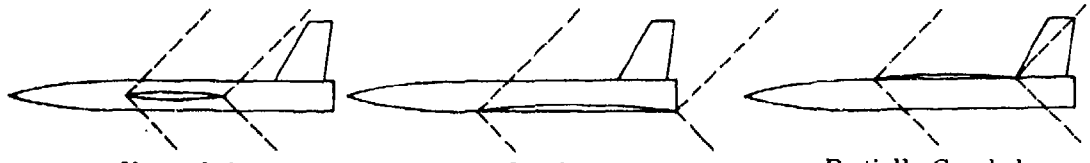
In addition to the phenomena previously discussed, three types of interference exist between the wing and tail surfaces. If the vertical tail panels are in the wing-flow field, mutual interaction occurs in the same way as that between horizontal and vertical tail panels. This effect is taken into account through the apparent-mass factor concept. Secondly, there is interference due to the wing-flow field which alters the local dynamic pressure and Mach number acting on the vertical tail surfaces. This is a nonlinear effect of angle of attack and is taken into account by a tail effectiveness parameter η_W based on two-dimensional shock-expansion theory. Wing-vertical tail interference also results from the effect of the wing-flow field on the body vortices. The positions and strengths of the body vortices are both influenced by the wing. The wing-flow field cuts off the body feeding vortex sheet along the length of the exposed wing root chord and the body vortex path is curved as it passes through the wing-flow field. The effect of the wing is taken into account herein by an approximation to the method of reference 2. It is assumed that both vortex strengths and positions are those about a body alone, foreshortened by the length of the exposed wing root chord. This assumption satisfactorily accounts for the effect of the wing-flow field on vortex strength but neglects the effect of the wing-flow field in altering the path of the vortices; however, the error introduced at small angles of sideslip is negligible.

Two methods are discussed in reference 2 for approximating the effect of the wing-flow field on the body vortex positions. One method is based on two-dimensional shock-expansion theory which precludes accurate prediction of lateral vortex positions and also restricts the results to configurations with slender wing panels. A second method applicable to slender configurations is suggested in which the calculation of the vortex paths with the wing panels

present can be made by using slender-body theory and proceeding step by step. However, the practical calculation of the paths with any degree of accuracy requires the use of automatic computing methods.

Sections 5.2.1.2 and 5.3.1.2 have considered separately wing-body and tail-body configurations. Wing-body-tail configurations may be classified as either uncoupled, coupled, or partially coupled, depending on the physical relationship between the wing-flow field and the tail. The three classes of configurations are illustrated in sketch (a). For the uncoupled configurations a body section separates the wing from the empennage so that the wing-flow field does not directly impinge on the tail surfaces. For the coupled configuration the tail surfaces are totally enveloped in the wing-flow field. Partially coupled configurations have partial coupling between the wing-flow field and the tail. The primary difference between the three classes of configurations in so far as the present theory is concerned is that the shock-expansion effects of the wing on the tail are neglected when dealing with uncoupled configurations.

The wing-flow field at angle of attack and supersonic speeds is defined by the method outlined in Section 5.3.1.2 for determining the horizontal tail-flow field at angle of attack and supersonic speeds.



SKETCH (a)

DATCOM METHOD

The method for determining the wing-body-tail side-force coefficient at combined angles is given by

$$C_{Y_{WBHVU}} = C_{Y_{WB}} + C_{Y_{HVU(WB)}} \qquad 5.6.1.2\text{-a}$$

where

$C_{Y_{WB}}$ is the wing-body contribution obtained from equation 5.2.1.2-a

$C_{Y_{HVU(WB)}}$ is the empennage contribution obtained from equation 5.6.1.2-b

The contribution of the empennage is given by

$$C_{Y_{HVU(WB)}} = C_{Y_{H(B)}} + C_{Y_{V(\eta)}} + C_{Y_{U(\eta)}} \qquad 5.6.1.2\text{-b}$$

where

$C_{Y_{H(B)}}$ is the horizontal tail contribution obtained from equation 5.3.1.2-b

$C_{Y_{V(\eta)}}$ is the vertical tail contribution obtained from equation 5.6.1.2-c

$C_{Y_{U(\eta)}}$ is the ventral fin contribution obtained from equation 5.6.1.2-d

The order in which the tail panels should be added to the wing-body configuration for analysis purposes parallels that prescribed in Section 5.3.1.2 for a tail-body configuration.

The contribution of the vertical tail is given by

$$C_{Y_{V(\eta)}} = C_{Y_{V(K,\phi)}} + C_{Y_{V(\Gamma_B)}} \qquad 5.6.1.2\text{-c}$$

for uncoupled configurations, and by

$$C_{Y_{V(\eta)}} = [C_{Y_{V(K,\phi)}} + C_{Y_{V(\Gamma_B)}}]\ \eta_{W_V} \qquad 5.6.1.2\text{-c}$$

for coupled or partially coupled configurations;

where

$C_{Y_{V(K,\phi)}}$ accounts for α and β cross-coupling and any mutual interaction between the vertical tail and other surfaces in the empennage and is given by equation 5.3.1.2-d. In addition, any impingement of the wing-flow field on the vertical tail must be considered in determining the effective apparent-mass factor K'_V. The method for defining the wing flow field is the same as for the horizontal tail, and is given step-by-step in paragraph C, Section 5.3.1.2. Note that the upper trailing edge is marked by a shock wave rather than a Mach line.

$C_{Y_{V(\Gamma_B)}}$ accounts for the effect of body vortices on the vertical stabilizer, and includes influence of the wing on the vortex strength. The wing effect is approximated by foreshortening the body length by the exposed wing root chord c_{r_e} when finding vortex strength and position from figures 4.3.1.3-13b, 4.3.1.3-14, and 4.3.1.3-15. That is, the figures are entered with $\frac{\alpha'(x - x_s - c_{r_e})}{r}$, rather than $\frac{\alpha(x - x_s)}{r}$.* The results are then applied to equations 5.3.1.2-f and 5.3.1.2-e to obtain $C_{Y_{V(\Gamma_B)}}$.**

η_{W_V} is the tail effectiveness parameter of the upper vertical stabilizer obtained from figure 5.6.1.2-9 as a function of angle of attack and Mach number. These charts take into account the changes in dynamic pressure and Mach number at the tail by direct application of two-dimensional shock-expansion theory. Any effects of wing-body interference or wing section in distorting the shock-expansion field are neglected.

For a specified initial Mach number there is a maximum value of the angle of attack for which there exists an oblique shock solution. Or, conversely, for a specified angle of attack there is a minimum initial Mach number for which there is an oblique shock solution. The relation between Mach number and angle of attack below which no solutions for η_W may be obtained is indicated in sketch (a) of Section 5.3.1.2.

The procedure for using these charts is

Step 1: Draw on transparent paper the relative positions of the wing exposed root chord and the vertical surfaces. Choose the scale so that the exposed chord length coincides with that shown in figure 5.6.1.2-9 .

Step 2: Overlay the drawing on the figure to locate the tail in the proper influence zone.

Step 3: The vertical tail is divided into several areas. The average value of η_{W_V} in each area is multiplied by the ratio of its area to S_{V_e}.

Step 4: Sum the weighted values of η_{W_V} to obtain the total tail effectiveness parameter η_{W_V}.

Step 5: Interpolation for angle of attack and/or Mach number may be necessary. If so, a three-point interpolation for α should be made using weighted values of η_{W_V}. Two points are sufficient for Mach number interpolation.

The contribution of the ventral fin is given by

$$C_{Y_{U(\eta)}} = C_{Y_U} \qquad 5.6.1.2\text{-d}$$

for uncoupled configurations, and by

$$C_{Y_{U(\eta)}} = C_{Y_U}\,\eta_{W_U} \qquad 5.6.1.2\text{-d}'$$

for coupled or partially coupled configurations;

* If x_s indicates vortex separation aft of the exposed wing root-chord leading edge, then only that portion of c_{r_e} aft of the indicated separation point is subtracted.

** The vortex positions given by equation 5.3.1.2-f are the positions at a given longitudinal station about the body alone foreshortened by c_{r_e} and do not include the effects of the wing-flow field in altering the paths of the vortices.

where

C_{Y_U} accounts for α and β cross-coupling and any mutual interaction between the vertical tail and other surfaces in the empennage, and is given by equation 5.3.1.2-g. In addition, any impingement of the wing flow field on the ventral tail must be considered in determing the effective apparent-mass factor K'_U.

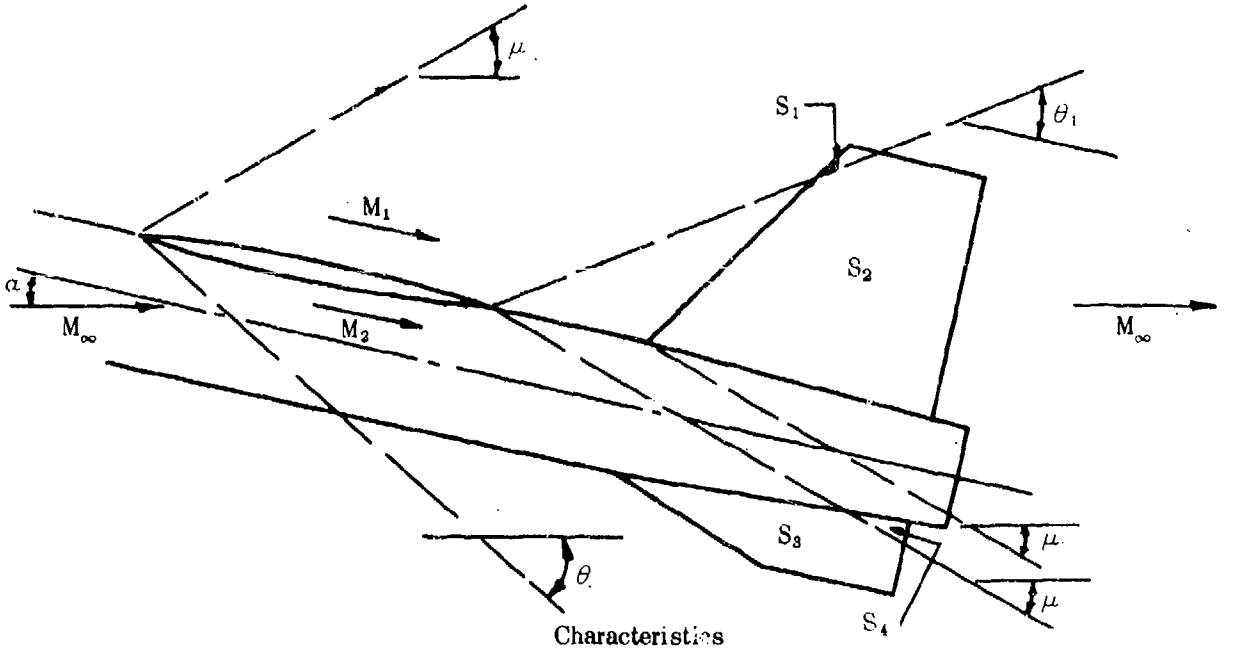
η_{W_U} is the tail effectiveness parameter of the ventral fin and is obtained from figure 5.6.1.2-9 by following the steps describing the determination of η_{W_V}.

As noted in paragraph C of Section 5.3.1.2, the body vortices do not affect the ventral fin.

Values for the incremental coefficient resulting from the addition of vertical tails to wing-body configurations, calculated using the Datcom method, are compared with experimental results in figure 5.6.1.2-8. The correlation between experiment and estimate is relatively good at $\beta = 5.1°$ and poor at $\beta = 10°$. The poor correlation at $\beta = 10°$ can be attributed to the assumption that the body vortex positions are those about a body foreshortened by the length of the exposed wing root chord. This assumption neglects the effects of the wing-flow field on the body vortex positions and poor correlation can be expected at higher sideslip angles where viscous lateral cross-flow effects become important.

Sample Problem

Given: Configuration of sample problem, paragraph C, Sections 5.2.1.2 (with slight boattail) and 5.3.1.2. There is no horizontal tail on this configuration. Some of the characteristics are repeated. Find the side-force coefficient developed by the wing-body-tail combination at $\alpha = 12°$, $\beta = 4°$, and $M = 2.01$.



Characteristics

$\frac{r_1}{b_V} = 0.200$ $\frac{r_1}{b_U} = 0.492$. $\Lambda_{LE_V} = 32.5°$ $\Lambda_{LE_U} = 70°$ $S_W = 144.0$ sq in.

$b_W = 24.0$ in. $c_{r_e} = 8.90$ in.

$S_{V_e} = 31.6$ sq in. $S_{U_e} = 8.54$ sq in. $S_1 = 0.40$ sq in. $S_2 = 31.2$ sq in. $S_3 = S_{U_e} = 8.54$ sq in.

x = 32.8 in. (x measured from nose to 50-percent-chord point of MAC of exposed vertical panel)

$C_{Y_{WB}} = -0.400$ (sample problem, paragraph C, Section 5.2.1.2)

$C_{Y_{H(B)}} = 0$ (no horizontal tail on this configuration)

At positive angle of attack, vertical-tail exposed root-chord leading edge is aft of ventral-fin exposed root-chord leading edge.

Ventral fin is not influenced by presence of upper vertical tail at this angle of attack and Mach number.

Configuration is partially coupled at this angle of attack and Mach number.

Compute:

Determine the vertical tail contribution $C_{Y_{V(\eta)}}$

K'_V = 1.13 (method of paragraph C, Section 5.3.1.1 with S_1 = 0.40 sq in. and S_2 = 31.2 sq in.)

K_{ϕ_V} = 0.687 figure 5.3.1.2-12 at $(r_1/b)_V$ = 0.200)

$(C_{N_\alpha})_V$ = 2.12 per rad (based on S_{V_e}) (sample problem, paragraph C, Section 5.3.1.2)

$$C_{Y_{V(\kappa,\phi)}} = [K'_V - K_{\phi_V} \alpha \tan \Lambda_{LE_V}] (-C_{N_\alpha})_V \beta \frac{S_{V_e}}{S_W} \qquad \text{(equation 5.3.1.2-d)}$$

$$= [1.13 - (0.687)(0.209) \tan 32.5^\circ] (-2.12) (0.070) \left(\frac{31.6}{144.0}\right)$$

$$= -0.0339 \text{ (based on } S_W)$$

For the purpose of finding vortex characteristics:

$\frac{x_s}{r}$ = 10.6 (figure 4.3.1.3-13a at α' = 12.65°)

Vortex separation is forward of exposed wing root-chord leading edge.

$$\frac{\alpha'(x - x_s - c_{r_e})}{r} = 0.221\left(\frac{32.8}{1.50} - 10.6 - \frac{8.90}{1.50}\right) = 1.180$$

$\frac{y_0}{r}$ = 0.63 (figure 4.3.1.3-14)

$\frac{z_0}{r}$ = 1.25 (figure 4.3.1.3-13b)

$\frac{\Gamma_B}{2\pi\alpha' V r}$ = 0.62 (figure 4.3.1.3-15)

} at $\frac{\alpha'(x - x_s - c_{r_e})}{r}$

ϕ = 18.4° (sample problem, paragraph C, Section 5.3.1.2)

then the positions of the body vortices at the vertical tail (neglecting the effect of the wing-flow field in altering the paths of the vortices) are:

$$\frac{z_{v_1}}{b_V} = \frac{r}{b_V}\left[\frac{z_0}{r}\cos\phi + \frac{y_0}{r}\sin\phi\right] \qquad \text{(equation 5.3.1.2-f)}$$

$$= \frac{1.50}{7.48}\left[1.25\cos 18.4^\circ + 0.63 \sin 18.4^\circ\right] = 0.278$$

$$\frac{y_{v_1}}{b_V} = \frac{r}{b_V}\left[\frac{z_0}{r}\sin\phi - \frac{y_0}{r}\cos\phi\right] \qquad \text{(equation 5.3.1.2-f)}$$

$$= \frac{1.50}{7.48}\left[1.25 \sin 18.4^\circ - 0.63 \cos 18.4^\circ\right] = -0.0408$$

$$\frac{z_{v_2}}{b_V} = \frac{r}{b_V}\left[\frac{z_0}{r}\cos\phi - \frac{y_0}{r}\sin\phi\right] \qquad \text{(equation 5.3.1.2-f)}$$

$$= \frac{1.50}{7.48}\left[1.25\cos 18.4^\circ - 0.63\sin 18.4^\circ\right] = 0.198$$

$$\frac{y_{v_2}}{b_V} = \frac{r}{b_V}\left[\frac{z_0}{r}\sin\phi + \frac{y_0}{r}\cos\phi\right] \qquad \text{(equation 5.3.1.2-f)}$$

$$= \frac{1.50}{7.48}\left[1.25\sin 18.4^\circ + 0.63\cos 18.4^\circ\right] = 0.199$$

$$\left.\begin{aligned} i_{v_1} &= -0.9 \\ i_{v_2} &= -0.6 \end{aligned}\right\} \qquad \text{(figure 5.3.1.2-13a)}$$

$$\Delta i_v = i_{v_1} - i_{v_2} = (-0.9) - (-0.6) = -0.3$$

$$C_{Y_{V(\Gamma_B)}} = \Delta i_v\left[\frac{\Gamma_B}{2\pi\alpha' Vr}\right]\left[\frac{(-C_{N_\alpha})_V\,\alpha' S_{V_e}}{\left(\frac{b_V}{r} - 1\right) S_W}\right] \qquad \text{(equation 5.3.1.2-e)}$$

$$= (-0.3)(0.62)\left[\frac{(-2.12)(0.221)(31.6)}{\left(\frac{7.48}{1.5} - 1\right)(144.0)}\right]$$

$$= 0.00478 \text{ (based on } S_W)$$

Determine tail effectiveness parameter η_{W_V}

By interpolation using figures 5.6.1.2-9g, -9h, and -9i, obtain $\eta_{W_V} = 0.98$ (see steps 1 through 5, page 5.6.1.2-3)

$$C_{Y_{V(\eta)}} = \left[C_{Y_{V(K,\phi)}} + C_{Y_{V(\Gamma_B)}}\right]\eta_{W_V} \qquad \text{(equation 5.6.1.2-c')}$$

$$= [(-0.0339) + (0.00478)](0.98)$$

$$= -0.0285 \text{ (based on } S_W)$$

Determine the ventral fin contribution $C_{Y_{U(\eta)}}$

$K'_U = 3.15$ (method of paragraph C, Section 5.3.1.1 with $S_s \approx S_{U_e} = 8.54$ sq in.)

$K_{\phi_U} = 0.535$ (figure 5.3.1.2-12 at $(r_1/b)_U = 0.492$)

$C_{N_{\alpha_U}} = 1.09$ per rad (based on S_{U_e}) (sample problem, paragraph C, Section 5.3.1.2)

$$C_{Y_U} = C_{Y_{U(K,\phi)}} = \left[K'_U + K_{\phi_U}\,\alpha\tan\Lambda_{LE_U}\right](-C_{N_\alpha})_U\,\beta\,\frac{S_{U_e}}{S_W} \qquad \text{(equation 5.3.1.2-g)}$$

$$= \left[3.15 + (0.535)(0.209)\tan 70^\circ\right](-1.09)(0.070)\left(\frac{8.54}{144.0}\right)$$

$$= -0.0156 \text{ (based on } S_W)$$

Determine the tail effectiveness parameter η_{W_U}

By interpolation using figures 5.6.1.2-9g, -9h, and -9i, obtain $\eta_{W_U} = 1.20$ (see steps 1 through 5, page 5.6.1.2-3)

$C_{Y_{U(\eta)}} = C_{Y_U}\ \eta_{W_U}$ (equation 5.6.1.2-d')

$= (-0.0156)\ (1.20)$

$= -0.0187$ (based on S_W)

Determine total empennage contribution

$C_{Y_{HVU(WB)}} = C_{Y_{H(B)}} + C_{Y_{V(\eta)}} + C_{Y_{U(\eta)}}$ (equation 5.6.1.2-b)

$= 0 + (-0.0285) + (-0.0187)$

$= -0.0472$ (based on S_W)

Solution:

$C_{Y_{WBHVU}} = C_{Y_{WB}} + C_{Y_{HVU(WB)}}$ (equation 5.6.1.2-a)

$= (-0.0400) + (-0.0472)$

$= -0.0872$ (based on S_W)

This compares with an experimental value (based on S_W) of $C_{Y_{WBHVU}} = -0.096$ from reference 3.

5.6.2 WING-BODY-TAIL SIDESLIP DERIVATIVE C_{l_β}

5.6.2.1 WING-BODY-TAIL SIDESLIP DERIVATIVE C_{l_β} IN THE LINEAR ANGLE-OF-ATTACK RANGE

The information contained in this section is for estimating the rolling moment due to sideslip C_{l_β} of wing-body-tail configurations at low angles of attack. In general, it consists of a synthesis of material presented in other sections. Discussions of the various aerodynamic aspects of vehicle components and component combinations in sideslip are presented in other sections and are not repeated here.

The effect of a horizontal tail is more important in estimating C_{l_β} than C_{Y_β} and C_{n_β}, since the tail itself contributes to C_{l_β} in addition to affecting the vertical-panel contribution. The effect of the horizontal tail on the vertical-panel contribution and a discussion regarding the effects of the induced pressure field on the horizontal tail that is generated by the vertical panel are discussed in the introduction to Section 5.3.2.1 and are not repeated here.

For most configurations at subsonic speeds the horizontal-tail contribution is usually very small, and reasonable results can be obtained when it is neglected. However, for configurations employing a large horizontal tail with either significant twist and/or dihedral, the contribution may be worthy of consideration. For such a configuration the contribution of the horizontal tail may be estimated by using the method of Section 5.1.2.1; i.e., by treating the horizontal tail as an isolated wing. (Caution should be exercised to make certain the horizontal-tail contribution to C_{l_β} is converted to the same reference area and length $S_W b_W$ as the wing-body contribution, before adding them together.) However, since the horizontal-tail contribution is very small for most configurations in the subsonic speed regime, the method presented here neglects its contribution.

At transonic and supersonic speeds the horizontal-tail contribution should not be neglected. At transonic speeds the pressure field of the entire horizontal surface is affected by the presence of the vertical panel; while at supersonic speeds the effects are restricted to regions on the horizontal surface within boundaries defined by the shock-wave pattern of the vertical tail. Because of the complexity of the problem, no method is presented at transonic speeds. The method presented at supersonic speeds does not include the contribution of a horizontal tail; however, the effect of the horizontal tail on the vertical-tail contribution is accounted for as in Section 5.3.2.1.

The methods presented are similar to those of Section 5.6.1.1, in that the derivative of the configuration is given as the sum of the contributions of the wing-body combination and the empennage combination. The method of estimating the empennage contribution to C_{l_β} is similar to that for estimating the empennage contribution to C_{n_β} in Section 5.6.3.1. That is, the side-force contributions of the panels of the empennage are multiplied by an appropriate moment arm to obtain their individual contributions to the derivative C_{l_β}.

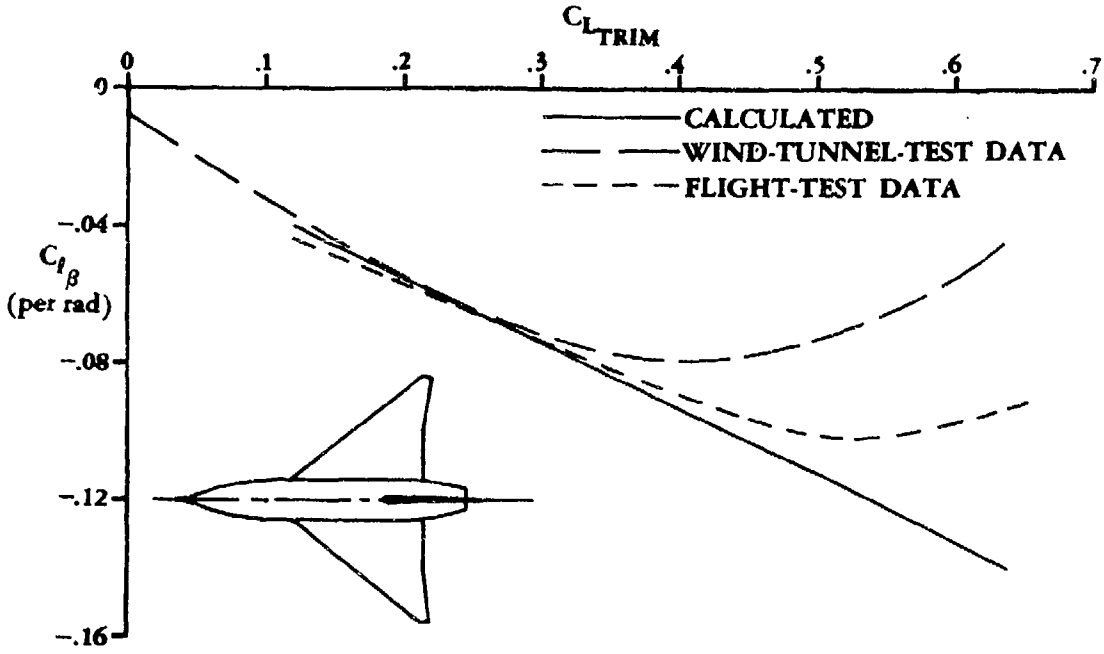
A. SUBSONIC

The method of estimating the subsonic values of the empennage contribution to the derivative C_{l_β} is based on the values of C_{Y_β} estimated by the methods of Paragraph A of Section 5.3.1.1. If the apparent-mass-concept method (Method 3, Paragraph A, Section 5.3.1.1) is used, the build-up

procedure outlined in Method 3 of Paragraph A of Section 5.6.1.1 must be applied in determining the individual side-force derivatives, with one exception. That is, the horizontal-tail increment is not to be expressed explicitly as a contributing term in the total empennage contribution; however, the effect of the presence of the horizontal tail must be considered in computing the contributions of the vertical panels.

For most configurations, the presence of flaps at a given lift coefficient causes C_{l_β} to become a larger negative value (see References 1 through 7). The exceptions to this are a few cases at low lift coefficients where C_{l_β} becomes a lower negative value (References 8, 9, and 10). However, the incremental changes in C_{l_β} vary dramatically with variations in lift coefficient for different configurations. This variation in the incremental change in C_{l_β} with flaps extended prevents the formulation of a hand procedure to estimate the flap effects on C_{l_β}.

Comparison of the subsonic method presented here with available flight-test data (References 11 through 15) supplements the substantiation of the method based on wind-tunnel data that is presented in Sections 5.2.2.1 and 5.3.2.1. A typical comparison of flight-test data (Reference 11) with the predicted variation of C_{l_β} as a function of $C_{L_{trim}}$ is shown in Sketch (a).



SKETCH (a)

As implied in the introduction to this section, the Datcom method at subsonic speeds is applicable to a configuration with a horizontal tail in the empennage.

DATCOM METHOD

The rolling moment (about the longitudinal stability axis) due to sideslip of a wing-body-tail configuration, referred to an arbitrary moment center and based on wing area and wing span, is given by

$$C_{l_\beta} = \left(C_{l_\beta}\right)_{WB} + \sum_p \left\{ \left(\Delta C_{Y_\beta}\right)_p \left[\frac{z_p \cos\alpha - \ell_p \sin\alpha}{b_W} \right] \right\} \qquad 5.6.2.1\text{-a}$$

where

p is the subscript referring to the vertical panels present in the empennage (either an upper vertical stabilizer V or a lower vertical stabilizer U).

$\left(C_{l_\beta}\right)_{WB}$ is the contribution of the wing-body configuration to the total rolling moment due to sideslip, obtained from Paragraph A, Section 5.2.2.1.

$\left(\Delta C_{Y_\beta}\right)_p$ is the side force due to sideslip of the added vertical panel determined as follows:

For configurations with the horizontal panel mounted on the body or for configurations with no horizontal panel, use Method 1 or Method 3, Paragraph A, Section 5.3.1.1. If Method 1 of Paragraph A of Section 5.3.1.1 is used, the total empennage increment is given by a single term. If Method 3 of Paragraph A of Section 5.3.1.1 is used, the build-up procedure outlined in Method 3 of Paragraph A of Section 5.6.1.1 must be applied to determine the individual increment of each added vertical panel*.

For configurations with a horizontal panel mounted on the vertical panel, use Method 1, Paragraph A, Section 5.3.1.1. The total empennage increment is given by a single term.

For configurations with twin vertical panels mounted on the tips of a horizontal panel, use Method 2, Paragraph A, Section 5.3.1.1. The total empennage increment is given by a single term.

z_p is the distance measured normal to the longitudinal body axis between the moment reference center and the MAC of the vertical panel, positive for the panel above the body.

ℓ_p is the distance parallel to the longitudinal body axis between the vehicle moment center and the quarter-chord point of the MAC of the vertical panel, positive for the panel aft of the vehicle moment center.**

b_W is the span of the wing.

All geometry used in determining the moment arms for the above method is based on the vertical panel extended to the body center line.

*See remarks of Paragraph A above, regarding horizontal-panel effects when using Method 3 of Paragraph A of Section 5.3.1.1.

**The aerodynamic center of the vertical panel could be used, but the inaccuracies of the basic method do not warrant this degree of refinement.

For a wingless configuration, b_W is replaced by the vehicle reference length, $\left(\Delta C_{Y_\beta}\right)_p$ is based on the vehicle reference area, and the contribution of the body alone to the total derivative may be ignored.

Sample Problems

1. Given: A configuration of Reference 16 consisting of a wing, body, horizontal tail, and vertical tail. This is the same configuration as that of Sample Problem 1, Paragraph A, Section 5.6.1.1. Some of the characteristics are repeated.

Wing Characteristics:

$A_W = 4.0$ $S_W = 36.0$ sq in. $b_W = 12.0$ in. $\lambda_W = 0.30$

$\Lambda_{c/2_W} = 40.9°$ $\Gamma = 0$ $z_W = 0$ (midwing)

Additional Characteristics:

$M = 0.60$ $\ell_V = 6.035$ in. $z_V = 1.65$ in. $\ell_f = 14.3$ in.

C_L	α (deg) (test)
0	0
0.1	1.55
0.2	3.20
0.3	4.65

Compute:

$$\frac{\ell_f}{b_W} = 1.192$$

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2_W}} = -0.0035 \text{ per deg} \quad \text{(Figure 5.1.2.1-27)}$$

$$\cos \Lambda_{c/2_W} = 0.755$$

$$M \cos \Lambda_{c/2_W} = 0.453$$

$$\frac{A_W}{\cos \Lambda_{c/2_W}} = 5.30$$

$K_{M_\Lambda} = 1.035$ (Figure 5.1.2.1-28a)

$K_f = 0.91$ (Figure 5.2.2.1-26)

$\left(\frac{C_{l_\beta}}{C_L}\right)_\Lambda = -0.001$ (Figure 5.1.2.1-28b)

$$\left(C_{l_\beta}\right)_{WB} = C_L \left[\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2_W}} K_{M_\Lambda} K_f + \left(\frac{C_{l_\beta}}{C_L}\right)_\Lambda\right] \text{ per deg} \quad \text{(Equation 5.2.2.1-c)}$$

$$= C_L \left[(-0.0035)(1.035)(0.91) + (-0.001)\right]$$

$$= -0.0043\, C_L \text{ per deg}$$

$\left(\Delta C_{Y_\beta}\right)_{V(WBH)} = -0.645$ per rad (Sample Problem 1, Paragraph A, Section 5.6.1.1)

$= -0.01125$ per deg (based on S_W)

Solution:

$$C_{l_\beta} = \left(C_{l_\beta}\right)_{WB} + \sum_p \left\{\left(\Delta C_{Y_\beta}\right)_p \left[\frac{z_p \cos\alpha - \ell_p \sin\alpha}{b_W}\right]\right\} \quad \text{(Equation 5.6.2.1-a)}$$

$$= \left(C_{l_\beta}\right)_{WB} + \left(\Delta C_{Y_\beta}\right)_{V(WBH)} \left[\frac{z_V \cos\alpha - \ell_V \sin\alpha}{b_W}\right]$$

$$= -0.0043\, C_L + (-0.01125) \left(\frac{1.65\cos\alpha - 6.035\sin\alpha}{12.0}\right) \text{ per deg (based on } S_W b_W)$$

① C_L	② α (deg)	③ $(C_{l_\beta})_{WB}$ (per deg) -0.0043 ①	④ $z_V \cos\alpha$ (in.)	⑤ $\ell_V \sin\alpha$ (in.)	⑥ $\frac{z_V\cos\alpha - \ell_V\sin\alpha}{b_W}$ [④ − ⑤]/12.0	⑦ $(C_{l_\beta})_{V(WBH)}$ (per deg) -0.01125 ⑥	⑧ C_{l_β} (per deg) ③ + ⑦

SKETCH (c)

B. TRANSONIC

A brief discussion of the flow phenomena associated with the forces generated on vertical panels at transonic speeds is given in Paragraph B of Section 5.3.1.1. At the present time there are no methods available to predict the effect of wing-body wake and sidewash or the mutual interference effects between vehicle components on the sideslip characteristics at transonic speeds. In addition, the effects of the impingement of the pressure field generated by the vertical panel on the horizontal-tail surface are difficult to evaluate.

DATCOM METHOD

No explicit method is available in the literature for estimating the vehicle sideslip derivative C_{l_β} at transonic speeds and none is presented in the Datcom. Some typical transonic data for this derivative are presented as Figure 5.6.2.1-15.

C. SUPERSONIC

The procedure for estimating the supersonic sideslip derivative C_{l_β} is essentially the same as that at subsonic speeds. That is, the rolling-moment contributions of vertical panels are based on the sideslip derivative C_{Y_β}. The problem of estimating the forces generated on vertical panels is complicated by the presence of shock waves. This effect is discussed in Paragraph C of Section 5.3.1.1.

As stated in the introduction to this section, no method is available for determining the horizontal-tail contribution to the derivative C_{l_β}. However, the effect of the horizontal tail on the vertical-tail contribution is accounted for by proper use of the apparent-mass factor (K) charts in determining the vertical-panel side force.

DATCOM METHOD

The rolling moment (about the longitudinal stability axis) due to sideslip of a wing-body-vertical-tail configuration, referred to an arbitrary moment center and based on wing area and wing span, is given by Equation 5.6.2.1-a:

$$C_{l_\beta} = \left(C_{l_\beta}\right)_{WB} + \sum_p \left\{ \left(\Delta C_{Y_\beta}\right)_p \left[\frac{z_p \cos\alpha - \ell_p \sin\alpha}{b_W} \right] \right\}$$

where C_{l_β}, $\left(C_{l_\beta}\right)_{WB}$, z_p, and b_W are defined in Paragraph A above, and

$\left(\Delta C_{Y_\beta}\right)_p$ is the side force due to sideslip of an added vertical panel from Paragraph C of Section 5.3.1.1. The build-up procedure outlined in Paragraph C of Section 5.6.1.1 (neglecting the contribution of a horizontal tail) must be applied in determining the individual increment of each added panel. The effect of the presence of a horizontal tail must be considered in computing the contributions of the vertical panels.

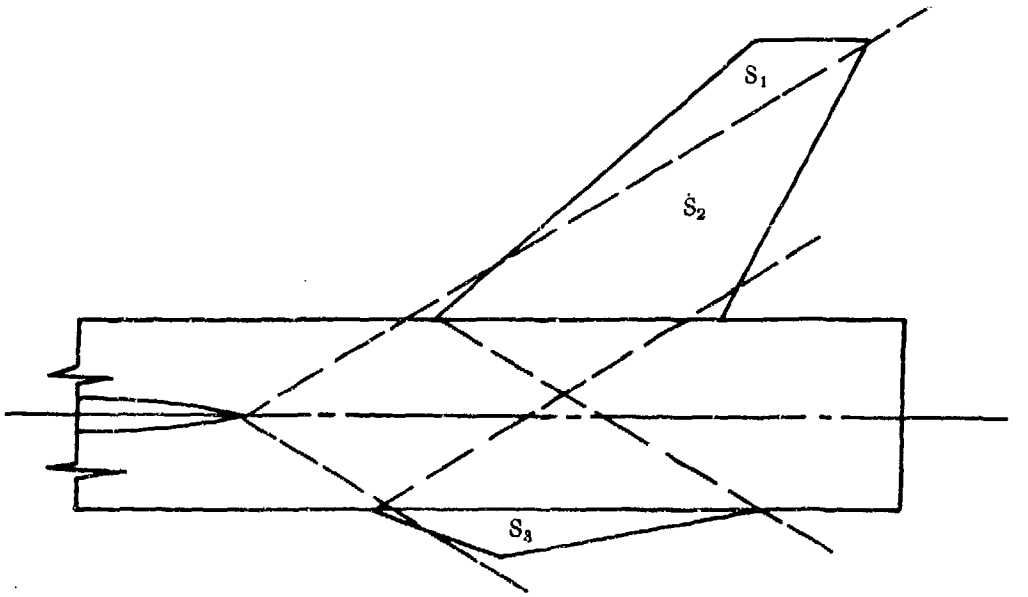
ℓ_p is the distance parallel to the longitudinal body axis between the moment reference center and the 50-percent chord of the MAC of the added vertical panel, positive for panel aft of the vehicle moment center.*

All geometry used in determining the moment arms of the vertical panels is based on the exposed panel.

For a wingless configuration the remarks following the Datcom methods of Paragraph A above are also applicable at supersonic speeds.

Sample Problem

Given: The configuration of Reference 18 consisting of a wing, body, upper vertical tail, and lower vertical tail. This is the same configuration as that of the sample problem of Paragraph C, Section 5.6.1.1 with the horizontal tail removed. Some characteristics are repeated.



Wing Characteristics:

A_W = 3.1[illegible] S_W = 114.5 sq in. z_W = 0 Γ = −3.5°

λ_W = 0.468 Λ_{LE_W} 48.08° No twist b_W = 19.08 in.

Vertical-Tail Characteristics:

A_{V_e} = 1.48 S_{V_e} = 19.20 sq in. Λ_{LE_V} = 49:2° b_V = 7.08 in.

*See footnote at bottom of Page 5.6.2.1-3.

$\lambda_{V_e} = 0.392$

Ventral-Tail Characteristics:

$A_{U_e} = 0.2025$ $S_{U_e} = 3.24$ sq in. $\Lambda_{LE_U} = 70.2°$ $b_U = 2.56$ in.

$\lambda_{U_e} = 0$

Additional Characteristics:

$M = 2.01$ $\mu = \sin^{-1}(1/M) = 29.8°$ $r_1 = 1.75$ in.

$r_2 = 1.496$ in. $r_1/r_2 = 1.170$ $S_1 = 4.63$ sq in.

$S_2 = 14.56$ sq in. $S_3 = S_{U_e} = 3.24$ sq in. $d/b_W = 0.157$

$\ell_V = 10.65$ in. $z_V = 4.05$ in. $\ell_U = 8.40$ in. $z_U = -2.05$ in.

$C_N = 0.10, \alpha = 2.20°$ (test)

Compute:

Step 1. Determine the wing-body contribution $\left(C_{l_\beta}\right)_{WB}$

$\sqrt{M^2 - 1} = 1.744$

$\Lambda_{LE_W} = 0.84$ rad; $1 + \Lambda_{LE_W} = 1.84$; $1 + \dfrac{\Lambda_{LE_W}}{2} = 1.42$

$1 + \lambda_W \left(1 + \Lambda_{LE_W}\right) = 1.860$

$\dfrac{\tan \Lambda_{LE_W}}{\sqrt{M^2 - 1}} = 0.639$

$\dfrac{M^2 \cos^2 \Lambda_{LE_W}}{A} = \dfrac{(4.04)(0.445)}{3.18} = 0.565$

$\left(\dfrac{\tan \Lambda_{LE_W}}{4}\right)^{4/3} = (0.2785)^{4/3} = 0.182$

Dihedral effect

$A_W \sqrt{M^2 - 1} = 5.55; \sqrt{M^2 - 1} \cot \Lambda_{LE_W} = 1.57$

$C_{l_p} = -0.28$ per rad (Figure 7.3.2.2-6)

$$\left(\frac{1 + 2\lambda}{1 + 3\lambda}\right)_W = 0.805$$

$$\frac{C_{l_\beta}}{\Gamma} = \frac{2}{(57.3)^2} \left(\frac{1 + 2\lambda}{1 + 3\lambda}\right)_W C_{l_p} = -0.000137 \text{ (per deg)}^2 \quad \text{(Equation 5.1.2.1-d)}$$

$$\frac{\Delta C_{l_\beta}}{\Gamma} = -0.0005 \sqrt{A_W} \left(\frac{d}{b_W}\right)^2 = -0.000022 \text{ (per deg)}^2 \quad \text{(Equation 5.2.2.1-b)}$$

$$\Gamma \left(\frac{C_{l_\beta}}{\Gamma} + \frac{\Delta C_{l_\beta}}{\Gamma}\right) = -0.000159\,\Gamma$$

$\left(C_{N_\alpha}\right)_W = 0.041$ per deg (based on S_W) (Section 4.1.3.2)

$$\left(C_{l_\beta}\right)_{WB} = -0.061\, C_N \left(C_{N_\alpha}\right)_W [1 + \lambda (1 + \Lambda_{LE})]_W \left(1 + \frac{\Lambda_{LE}}{2}\right)_W \left(\frac{\tan \Lambda_{LE_W}}{\sqrt{M^2 - 1}}\right)$$

$$\left[\frac{M^2 \cos^2 \Lambda_{LE_W}}{A_W} + \left(\frac{\tan \Lambda_{LE_W}}{4}\right)^{4/3}\right] + \Gamma \left(\frac{C_{l_\beta}}{\Gamma} + \frac{\Delta C_{l_\beta}}{\Gamma}\right)$$

(Equation 5.2.2.1-d)

$$= (-0.061)\, C_N\, (0.041)\, (1.860)\, (1.420)\, (0.639)\, [0.565 + 0.182]$$

$$+ (-3.5)\, (-0.000159)$$

$$= -0.00315\, C_N + 0.000556 \text{ per deg (based on } S_W b_W)$$

Step 2. Determine the empennage contribution

$\left(\Delta C_{Y_\beta}\right)_{V(WB)} = -0.520$ per rad (based on S_W) (Sample problem of Paragraph C, Section 5.6.1.1)

$= 0.0091$ per deg

The vertical tail in the sample problem of Paragraph C, Section 5.6.1.1 does not "see" the horizontal tail; therefore the increment in C_{Y_β} of the vertical tail in the presence of a wing and body is identical to $\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$ calculated in Section 5.6.1.1.

Calculate the increment in C_{Y_β} due to adding the lower vertical panel to the wing-body-upper-vertical-panel combination. In the configuration sketch the ventral panel senses only the body. The effective apparent mass ratio is

$$K'_{U(BV)} = K_{U(B)} = 3.0 \quad \text{(Section 5.3.1.1 with } (r_1/r_2) = 1.170, (r_1/b)_{U_{\text{added panel}}} = 0.685, \text{ and } (r_1/b)_{V_{\text{existing panel}}} = 1.000\text{)}$$

$\left(C_{N_\alpha}\right)_U = 0.622$ per rad (based on S_{U_e}) (Sample problem, Paragraph C, Section 5.6.1.1)

$$\left(\Delta C_{Y_\beta}\right)_{U(WBV)} = -K'_{U(BV)} \left(C_{N_\alpha}\right)_U \frac{S_{U_e}}{S_W} \quad \text{(Equation 5.3.1.1-f)}$$

$$= (-3.0)\,(0.622)\left(\frac{3.24}{114.5}\right)$$

$$= -0.0527 \text{ per rad (based on } S_W\text{)}$$

$$= -0.00092 \text{ per deg}$$

Solution:

$$C_{l_\beta} = \left(C_{l_\beta}\right)_{WB} + \sum_p \left\{ \left(\Delta C_{Y_\beta}\right)_p \left[\frac{z_p \cos\alpha - \ell_p \sin\alpha}{b_W} \right] \right\} \quad \text{(Equation 5.6.2.1-a)}$$

$$= \left(C_{l_\beta}\right)_{WB} + \left(\Delta C_{Y_\beta}\right)_{V(WB)} \left[\frac{z_V \cos\alpha - \ell_V \sin\alpha}{b_W} \right]$$

$$+ \left(\Delta C_{Y_\beta}\right)_{U(WBV)} \left[\frac{z_U \cos\alpha - \ell_U \sin\alpha}{b_W} \right]$$

$$= (-0.00315\ C_N + 0.000556) + (-0.0091)\left[\frac{4.05\cos\alpha - 10.65\sin\alpha}{19.08}\right]$$

$$+ (-0.00092)\left[\frac{(-2.05)\cos\alpha - 8.40\sin\alpha}{19.08}\right]$$

$$= [-0.00315\ (0.1) + 0.000556] + [(-0.00193)\cos 2.2^\circ + 0.00508\sin 2.2^\circ]$$

$$+ [0.00010\cos 2.2^\circ + 0.000405\sin 2.2^\circ]$$

$$= 0.00024 + (-0.00173) + (0.000116)$$

$$= -0.001374 \text{ per deg (based on } S_W b_W)$$

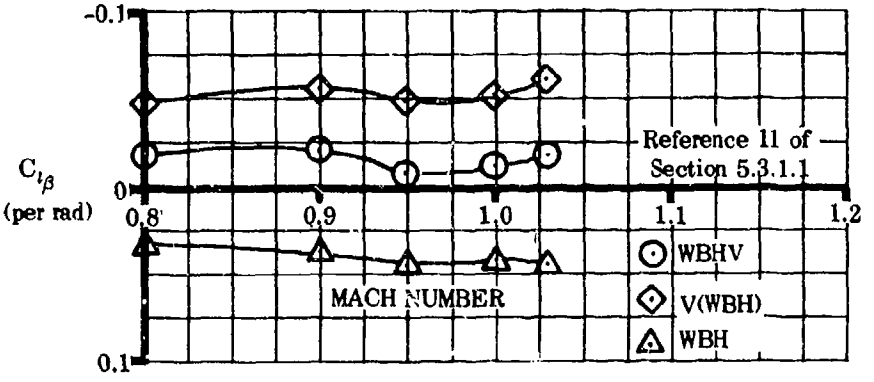

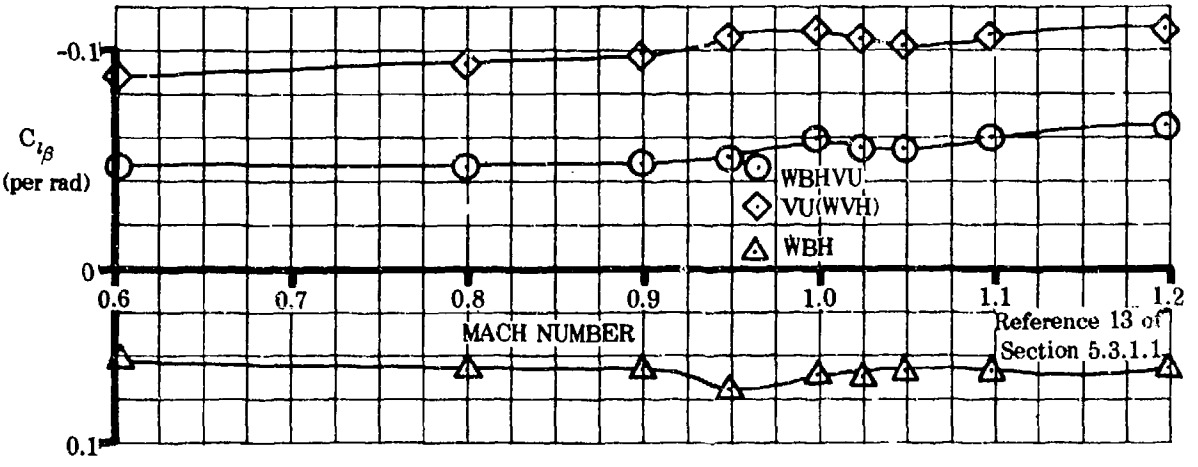

FIGURE 5.6.2.1-15 TYPICAL TRANSONIC DATA

5.6.3 WING-BODY-TAIL SIDESLIP DERIVATIVE C_{n_β}

5.6.3.1 WING-BODY-TAIL SIDESLIP DERIVATIVE C_{n_β} IN THE LINEAR ANGLE-OF-ATTACK RANGE

The information contained in this Section is for estimating the yawing moment due to sideslip C_{n_β} of wing-body-tail combinations at low angles of attack. In general, it consists of a synthesis of material presented in other Sections. Discussion of the various aerodynamic aspects of vehicle components in sideslip is given in other Sections of the Datcom and is not repeated here.

The methods presented are based on the procedure of totaling the wing-body contribution and the total empennage increment as was done in Section 5.6.1.1 for the determination of side force due to sideslip for a complete configuration. The yawing moment of the complete empennage is determined by applying the appropriate moment arm to each of the incremental values of side force which make up the total, as determined in Section 5.6.1.1.

A. SUBSONIC

The methods of estimating the subsonic values of the empennage contribution to the derivative C_{n_β} are based on the values of C_{Y_β} estimated by the methods of paragraph A of Section 5.3.1.1. If the apparent-mass-concept method (Method 3, paragraph A, Section 5.3.1.1) is used, the build-up procedure outlined in Method 3 of paragraph A of Section 5.6.1.1 must be applied in determining the individual panel side-force derivatives.

Two methods of determining the moment arm through which the empennage panel side force acts at subsonic speeds are presented in Section 5.3.3.1. The moment arm can be taken as (a) the distance parallel to the longitudinal axis between the vehicle moment center and the quarter-chord point of the mean aerodynamic chord of the added panel or (b) the distance parallel to the longitudinal axis between the vehicle moment center and the aerodynamic center of the added panel. For most cases the simplified approximation (a) is used. However, for short coupled configurations where the tail length distance is relatively short and the size of the added panel large the refined approximation (b) is recommended.

DATCOM METHODS

Method 1

Simplified Method

The yawing moment due to sideslip of a wing-body-tail configuration, referred to an arbitrary moment center and based on the wing area and wing span, is given by

$$C_{n_\beta} = (C_{n_\beta})_{WB} + \Sigma_p \left[-(\Delta C_{Y_\beta})_p \frac{\ell_p}{b_w} \right] \qquad 5.6.3.1\text{-a}$$

where the subscript $_p$ refers to panels present in the empennage

$(C_{n_\beta})_{WB}$ is the contribution of the wing-body combination to the total yawing moment due to sideslip, obtained from Section 5.2.3.1

$(\Delta C_{Y_\beta})_p$ is the side force due to sideslip of the added panel determined as follows

For configurations with the horizontal panel mounted on the body, or for configurations with no horizontal panel use Method 1 or Method 3, paragraph A, Section 5.3.1.1. If Method 1 of paragraph A of Section 5.3.1.1 is used, the total empennage increment is given by a single term. If Method 3 of paragraph A of Section 5.3.1.1 is used, the build-up procedure outlined in Method 3 of paragraph A of Section 5.6.1.1 must be applied to determine the individual increment of each added panel.

For configurations with a horizontal panel mounted on the vertical panel, use Method 1, paragraph A, Section 5.3.1.1. The total empennage increment is given by a single term.

For configurations with twin vertical panels mounted on the tips of a horizontal panel use Method 2, paragraph A, Section 5.3.1.1. The total empennage increment is given by a single term.

ℓ_p is the distance parallel to the longitudinal axis between the vehicle moment center and the quarter-chord point of the MAC of the added panel, positive for the panel aft of the vehicle moment center

b_W is the span of the wing

Method 2

Refined Method

In this case the sideslip derivative C_{n_β}, referred to an arbitrary moment center and based on wing area and wing span, is given by

$$C_{n_\beta} = (C_{n_\beta})_{WB} + \Sigma_p \left[-(\Delta C_{Y_\beta})_p \left(\frac{\ell_p + (x_{a.c.})_p}{b_W} \right) \right] \qquad 5.6.3.1\text{-b}$$

where $(C_{n_\beta})_{WB}$, $(\Delta C_{Y_\beta})_p$, ℓ_p, and b_W are defined in Method 1 above, and

$(x_{a.c.})_p$ is the distance parallel to the longitudinal axis between the quarter-chord point of the MAC of the added panel and the aerodynamic center of the added panel obtained from paragraph A of Section 4.1.4.2, positive for the a.c. behind the quarter-chord point of the MAC. (In determining the vertical panel a.c. use the aspect ratio of the panel mounted on an infinite reflection plane).

All geometry used in determining the moment arms for the above methods is based on the panel extended to the body centerline.

For a wingless configuration, b_W is replaced by the vehicle reference length, $(\Delta C_{Y_\beta})_p$ is based on the vehicle reference area, and the contribution of the body to the total derivative can be obtained from Section 4.2.2.1 as $(C_{n_\beta})_B \approx -(C_{m_\alpha})_B$, based on the vehicle reference area.

Sample Problems

1. Method 1

Given: A wing-body-horizontal tail-vertical tail configuration of reference 1. This is the same configuration as that of sample problem 1, paragraph A, Section 5.6.1.1. Some of the characteristics are repeated.

Wing Characteristics

S_W = 36.0 sq in. b_W = 12.0 in.

Body Characteristics

ℓ_B = 18.25 in. x_m = 10.42 in. S_{B_S} = 25.6 sq in. h_1/h_2 = 0.950

h/w = 1.000

Additional Characteristics

M = 0.60 R_ℓ = 7.43×10^6 (based on ℓ_B) ℓ_V = 6.035 in.

α = 0

Compute:

$\frac{x_m}{\ell_B} = 0.572$

$\left(\frac{h_1}{h_2}\right)^{1/2} = 0.975$

$\frac{\ell_B^2}{S_{B_S}} = 13.00$

Using the above computed parameters and the Reynolds number obtain K_N from figure 5.2.3.1-5

$K_N = 0.0014$

$$(C_{n_\beta})_{WB} = -K_N \frac{S_{B_S}}{S_W} \frac{\ell_B}{b_W} \text{ per deg} \qquad \text{(equation 5.2.3.1-a)}$$

$$= -(0.0014)\left(\frac{25.6}{36.3}\right)\left(\frac{18.25}{12.0}\right)$$

$$= -0.00151 \text{ per deg (based on } S_W b_W)$$

$$= -0.0865 \text{ per rad (based on } S_W b_W)$$

$(\Delta C_{Y_\beta})_{V(WBH)} = -0.645$ per rad (based on S_W) (sample problem 1, paragraph A, Section 5.6.1.1)

Solution:

$$C_{n_\beta} = (C_{n_\beta})_{WB} + \Sigma_p \left[-(\Delta C_{Y_\beta})_p \frac{\ell_p}{b_W} \right] \qquad \text{(equation 5.6.3.1-a)}$$

$$= (C_{n_\beta})_{WB} + \left[-(\Delta C_{Y_\beta})_{V(WBH)} \frac{\ell_V}{b_W} \right]$$

$$= -0.0865 + \left[-(-0.645)\left(\frac{6.035}{12.0}\right) \right]$$

$$= -0.0865 + 0.324$$

$$= 0.2375 \text{ per rad (based on } S_W b_W)$$

The experimental results (based on $S_W b_W$) from reference 1 are $(C_{n_\beta})_{WB} = -0.063$ per radian, $(\Delta C_{n_\beta})_{V(WBH)} = 0.350$ per radian, and $C_{n_\beta} = 0.286$ per radian.

2. Method 1

Given: The wing-body-horizontal tail-vertical tail configuration of reference 2. This is the same configuration as that of sample problem 3, paragraph A, Section 5.6.1.1. Some characteristics are repeated.

Wing Characteristics

$S_W = 576$ sq in. $\quad b_W = 41.56$ in.

Body Characteristics

$\ell_B = 72.0$ in. $\quad x_m = 39.60$ in. $\quad S_{B_S} = 349.9$ sq in. $\quad h_1/h_2 = 0.730$

$h/w = 1.000$

Additional Characteristics

$M = 0.25$ $\quad R_\ell = 9.73 \times 10^6$ (based on ℓ_B) $\quad \ell_V = 24.89$ in.

$\ell_H = 26.2$ in. $\quad \alpha = 0$

Compute:

$$\frac{x_m}{\ell_B} = 0.550$$

$$\left(\frac{h_1}{h_2}\right)^{1/2} = 0.854$$

$$\frac{\ell_B^2}{S_{B_S}} = 14.80$$

Using the parameters computed above and the Reynolds number obtain K_N from figure 5.2.3.1-5

$K_N = 0.0013$

$(C_{n_\beta})_{WB} = -K_N \frac{S_{B_S}}{S_W} \frac{\ell_B}{b_W}$ per deg (equation 5.2.3.1-a)

$= -(0.0013)\left(\frac{349.9}{576.0}\right)\left(\frac{72.0}{41.56}\right)$

$= -0.001365$ per deg (based on $S_W b_W$)

$= -0.0782$ per rad (based on $S_W b_W$)

From sample problem 3, paragraph A, Section 5.6.1.1

$(\Delta C_{Y_\beta})_{H(WB)} = 0$

$(\Delta C_{Y_\beta})_{V(WBH)} = -0.665$ per rad (based on S_W)

Solution:

$C_{n_\beta} = (C_{n_\beta})_{WB} + \Sigma_p \left[-(\Delta C_{Y_\beta})_p \frac{\ell_p}{b_W}\right]$ (equation 5.6.3.1-a)

$= (C_{n_\beta})_{WB} + \left[-(\Delta C_{Y_\beta})_{H(WB)} \frac{\ell_H}{b_W}\right] + \left[-(\Delta C_{Y_\beta})_{V(WBH)} \frac{\ell_V}{b_W}\right]$

$= -0.0782 + 0 + \left[-(-0.665)\left(\frac{24.89}{41.56}\right)\right]$

$= -0.0782 + 0.398$

$= 0.3198$ per rad (based on $S_W b_W$)

The experimental results (based on $S_W b_W$) from reference 2 are $(C_{n_\beta})_{WB} = -0.057$ per radian, $(\Delta C_{n_\beta})_{V(WBH)} = 0.409$ per radian, and $C_{n_\beta} = 0.352$ per radian.

B. TRANSONIC

A brief discussion of the flow phenomena associated with forces generated on vertical panels at transonic speeds is given in paragraph B of Section 5.3.1.1. At the present time there are no methods available to predict the effect of wing-body wake and sidewash or the mutual interference effects between vehicle components on the sideslip characteristics at transonic speeds.

DATCOM METHOD

No explicit method is available for estimating the vehicle sideslip derivative C_{n_β} at transonic speeds and none is presented in the Datcom. Some typical transonic data for this derivative are presented as figure 5.6.3.1-8.

C. SUPERSONIC

The procedure for estimating the supersonic sideslip derivative C_{n_β} of a wing-body-tail configuration is essentially the same as that at subsonic speeds. The problem of estimating the forces generated on vertical panels is complicated by the presence of shock waves. This effect is discussed in paragraph C of Section 5.3.1.1.

The moment arm through which an added vertical panel acts can be taken as (a) the distance parallel to the longitudinal axis between the vehicle moment center and the 50-percent-chord point of the mean aerodynamic chord of the added vertical panel or (b) the distance parallel to the longitudinal axis between the vehicle moment center and

the aerodynamic center of the added vertical panel. For short-coupled configurations with a large vertical panel the latter approach is recommended. At supersonic speeds the centroid of area of the region of interference approximates the center of pressure in the case of the increment gained by adding a horizontal surface.

This method is limited to configurations in which the horizontal tail is mounted on the body or configurations with no horizontal tail.

DATCOM METHODS

Method 1

Simplified Method

The yawing moment due to sideslip of a wing-body-tail configuration, referred to an arbitrary moment center and based on wing area and wing span, is given by equation 5.6.3.1-a

$$C_{n_\beta} = (C_{n_\beta})_{WB} + \Sigma_p \left[-(\Delta C_{Y_\beta})_p \frac{\ell_p}{b_W} \right]$$

where $(C_{n_\beta})_{WB}$ is defined in paragraph A above, and

$(\Delta C_{Y_\beta})_p$ is the side force due to sideslip of an added panel obtained from paragraph C, Section 5.3.1.1. The build-up procedure outlined in paragraph C of Section 5.6.1.1 must be applied in determining the individual increment of each added panel.

ℓ_p is the distance parallel to the longitudinal axis between the vehicle moment center and the 50-percent-chord point of the MAC of an added vertical panel, positive for the vertical panel aft of of the vehicle moment center. In the case of the increment gained by adding a horizontal panel, ℓ_p is the distance parallel to the longitudinal axis between the vehicle moment center and the centroid of the area of the region of interference, positive for the horizontal panel aft of the vehicle moment center.

Method 2

Refined Method

In this case the sideslip derivative C_{n_β}, referred to an arbitrary moment center and based on wing area and wing span, is given by equation 5.6.3.1-b

$$C_{n_\beta} = (C_{n_\beta})_{WB} + \Sigma_p \left[-(\Delta C_{Y_\beta})_p \left(\frac{\ell_p + (x_{a.c.})_p}{b_W} \right) \right]$$

where $(C_{n_\beta})_{WB}$, $(\Delta C_{Y_\beta})_p$, and ℓ_p are defined in Method 1 above, and

$(x_{a.c.})_p$ is the distance parallel to the longitudinal axis between the 50-percent-chord point of the MAC of an added vertical panel and the aerodynamic center of the added panel obtained from paragraph C of Section 4.1.4.2, positive for the a.c. behind the 50-percent-chord point. (In determining the vertical panel a.c. use the aspect ratio of the isolated panel mounted on an infinite reflection plane.)

In the case of the increment gained by adding a horizontal panel, the moment arm is treated as in Method 1 above.

All geometry used in determining the moment arms of the vertical panels in the above methods is based on the exposed panel.

For a wingless configuration the remarks following the Datcom methods of paragraph A above are also applicable at supersonic speeds.

Sample Problem

Method 1

Given: The wing-body-horizontal tail-upper vertical tail-lower vertical tail configuration of reference 3. This is the same configuration as that of the sample problem of paragraph C, Section 5.6.1.1. Some characteristics are repeated..

Wing Characteristics

S_W = 114.5 sq in. b_W = 19.08 in.

Body Characteristics

ℓ_B = 32.88 in. x_m = 18.00 in. S_{B_S} = 92.24 sq in. h_1/h_2 = 1.1175

h/w = 1.340

Additional Characteristics

M = 2.01 R_ℓ = 3.38 · 10^6 (based on ℓ_B) α = 0

ℓ_V = 10.65 in. ℓ_U = 8.40 in. ℓ_H = 11.45 in. (c.g. to centroid of region of interference)

Compute:

$$\frac{x_m}{\ell_B} = 0.548$$

$$\left(\frac{h_1}{h_2}\right)^{1/4} = 1.058$$

$$\frac{\ell_B^2}{S_{B_S}} = 11.72$$

Using the parameters computed above and the Reynolds number obtain K_N from figure 5.2.3.1-5

K_N = 0.0017

$$(C_{n_\beta})_{WB} = -K_N \frac{S_{B_S}}{S_W} \frac{\ell_B}{b_W} \text{ per deg} \qquad \text{(equation 5.2.3.1-a)}$$

$$= -(0.0017)\left(\frac{92.24}{114.5}\right)\left(\frac{32.88}{19.08}\right)$$

$$= -0.00236 \text{ per deg (based on } S_W b_W)$$

$$= -0.135 \text{ per rad (based on } S_W b_W)$$

$(\Delta C_{Y_\beta})_{H(WB)}$ = −0.0163 per rad (based on S_W)
$(\Delta C_{Y_\beta})_{V(WBH)}$ = −0.520 per rad (based on S_W)
$(\Delta C_{Y_\beta})_{U(WBHV)}$ = −0.053 per rad (based on S_W)

(sample problem, paragraph C, Section 5.6.1.1.)

Solution:

$$C_{n_\beta} = (C_{n_\beta})_{WB} + \Sigma_p \left[-(\Delta C_{Y_\beta})_p \frac{\ell_p}{b_W} \right] \qquad \text{(equation 5.6.3.1-a)}$$

$$= (C_{n_\beta})_{WB} + \left[-(\Delta C_{Y_\beta})_{H(WB)} \frac{\ell_H}{b_W} \right] + \left[-(\Delta C_{Y_\beta})_{V(WBH)} \frac{\ell_V}{b_W} \right] + \left[-(\Delta C_{Y_\beta})_{U(WBHV)} \frac{\ell_U}{b_W} \right]$$

$$= -0.135 + \left[-(0.0163)\left(\frac{11.45}{19.08}\right)\right] + \left[-(-0.520)\left(\frac{10.65}{19.08}\right) + \left[-(0.053)\left(\frac{8.40}{19.08}\right)\right]\right.$$

$$= -0.135 + 0.0098 + 0.290 + 0.0233$$

$$= 0.1881 \text{ per rad (based on } S_w b_w)$$

The experimental results from reference 3 (based on $S_w b_w$) are $(C_{n_\beta})_{WBH} = -0.169$ per radian, $(\Delta C_{n_\beta})_{V(WBH)} = 0.338$ per radian, $(\Delta C_{n_\beta})_{U(WBHV)} = 0.0286$ per radian, and $C_{n_\beta} = 0.1975$ per radian.

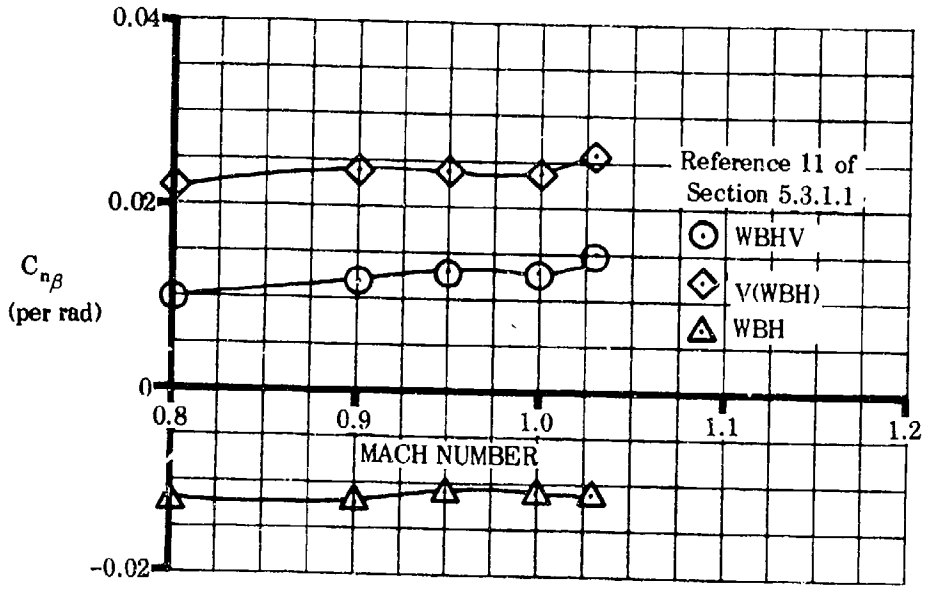

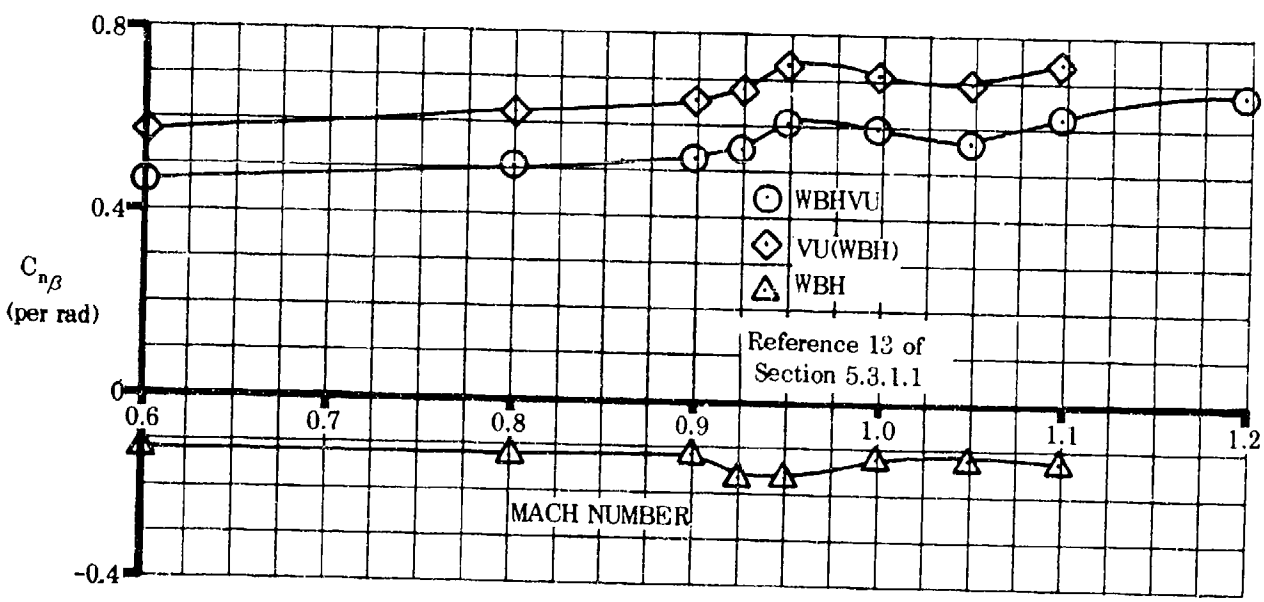

FIGURE 5.6.3.1-8 TYPICAL TRANSONIC DATA

5.6.3.2 WING-BODY-TAIL YAWING-MOMENT COEFFICIENT C_n AT ANGLE OF ATTACK

The wing-body-tail yawing moment developed at combined angles is nonlinear with respect to both sideslip and angle of attack for the reasons cited in the introductory remarks of Sections 5.2.1.2 and 5.3.1.2. To obtain the derivative C_{n_β} it is recommended that C_n be calculated at several angles of attack for a small sideslip angle ($\beta \leq 4°$). Then at each angle of attack the yawing moment is assumed linear with sideslip for small values of β so that

$$C_{n_\beta} \approx \frac{C_n}{\beta}$$

A. SUBSONIC

No method is presently available for determining the wing-body-tail yawing moment at large angles of attack and subsonic speeds. The method presented herein is restricted to first-order approximations at relatively low angles of attack.

DATCOM METHOD

It is recommended that the method of Section 5.6.3.1 be used in the linear-lift angle-of-attack range.

B. TRANSONIC

The comments appearing in Paragraph B of Section 5.6.1.1 are equally appropriate here.

DATCOM METHOD

No method is available for estimating this coefficient and none is presented in the Datcom.

C. SUPERSONIC

The discussion of Paragraph C in Section 5.6.1.2 applies here also and will not be repeated.

DATCOM METHOD

The method for estimating the wing-body-tail yawing moment at combined angles is basically that of Section 5.6.1.2. The yawing-moment coefficient is obtained simply by applying the proper moment arms to the various side-force coefficients calculated in that section. The restrictions noted in Section 5.6.1.2 also apply here.

The wing-body yawing-moment coefficient is given by

$$(C_n)_{WBHVU} = (C_n)_{WB} + (C_n)_{HVU(WB)} \qquad 5.6.3.2\text{-a}$$

where

$(C_n)_{WB}$ is the wing-body contribution obtained from Equation 5.2.3.2-a

$(C_n)_{HVU(WB)}$ is the empennage contribution obtained from Equation 5.6.3.2-b.

The contribution of the empennage is given by

$$(C_n)_{HVU(WB)} = -\frac{\ell_H \cos\alpha + z_H \sin\alpha}{b_W}(C_Y)_{H(B)} - \frac{\ell_V \cos\alpha + z_V \sin\alpha}{b_W}(C_Y)_{V(\eta)} - \frac{\ell_U \cos\alpha + z_U \sin\alpha}{b_W}(C_Y)_{U(\eta)} \qquad 5.6.3.2\text{-b}$$

where

$(C_Y)_{H(B)}$ is from Equation 5.3.1.2-b.

$(C_Y)_{V(\eta)}$ is from Equation 5.6.1.2-c.

$(C_Y)_{U(\eta)}$ is from Equation 5.6.1.2-d.

ℓ_H, z_H, ℓ_V, z_V, ℓ_U, z_U are defined under Equation 5.3.3.2-a.

Values for the incremental coefficient resulting from the addition of vertical tails to wing-body configurations, calculated using the Datcom method, are compared with experimental results in Figure 5.6.3.2-4. The assessment of the correlation parallels that of the incremental side-force coefficient, and the comments appearing in Section 5.6.1.2 are equally applicable here.

Sample Problem

Given: Configuration of Sample Problem, Paragraph C, Sections 5.2.3.2 (with slight boattail) and 5.6.1.2. There is no horizontail tail on this configuration. Some of the characteristics are repeated. Find the yawing-moment coefficient developed by the wing-body-tail configuration at $\alpha = 12°$, $\beta = 4°$, and $M = 2.01$.

Characteristics:

$\ell_V = 12.0$ in. $z_V = 4.15$ in. $\ell_U = 12.0$ in. $z_U = -2.15$ in. $b_W = 24.0$ in.

$(C_n)_{WB}$ = −0.00695 (Sample Problem, Paragraph C, Section 5.2.3.2)

$(C_Y)_{H(B)}$ = 0 (no horizontal tail on this configuration)

$(C_Y)_{V(\eta)}$ = −0.0285
$(C_Y)_{U(\eta)}$ = −0.0187
} (Sample Problem, Paragraph C, Section 5.6.1.2)

Compute:

$$(C_n)_{HVU(WB)} = -\frac{\ell_H \cos\alpha + z_H \sin\alpha}{b_W}(C_Y)_{H(B)} - \frac{\ell_V \cos\alpha + z_V \sin\alpha}{b_W}(C_Y)_{V(\eta)}$$

$$- \frac{\ell_U \cos\alpha + z_U \sin\alpha}{b_W}(C_Y)_{U(\eta)} \qquad \text{(Equation 5.6.3.2-b)}$$

$$= 0 - \frac{(12.0)\cos 12^\circ + (4.15)\sin 12^\circ}{24.0}(-0.0285)$$

$$- \frac{(12.0)\cos 12^\circ + (-2.15)\sin 12^\circ}{24.0}(-0.0187)$$

$$= 0.0238 \text{ (based on } S_W b_W)$$

Solution:

$$(C_n)_{WBHVU} = (C_n)_{WB} + (C_n)_{HVU(WB)} \qquad \text{(Equation 5.6.3.2-a)}$$

$$= -0.00695 + 0.0238$$

$$= 0.01685 \text{ (based on } S_W b_W)$$

This compares with an experimental value (based on $S_W b_W$) of $(C_n)_{WBHVU}$ = 0.0175 from Reference 2.

6.1 SYMMETRICALLY DEFLECTED FLAPS AND CONTROL DEVICES ON WING-BODY AND TAIL-BODY COMBINATIONS

6.1.1 SECTION LIFT WITH HIGH-LIFT AND CONTROL DEVICES

Conventional aerodynamic high-lift and control devices, and jet flaps are similar in that each functions by changing the lift generated by the portion of wing ahead of and/or behind it. Although their stability-and-control and performance applications are quite different, no distinction is made in this section between the aerodynamic characteristics of these devices. The fundamental aerodynamic characteristics of each are discussed in the appropriate sections.

The methods of this section provide the section lift characteristics of the following:

High-Lift Devices

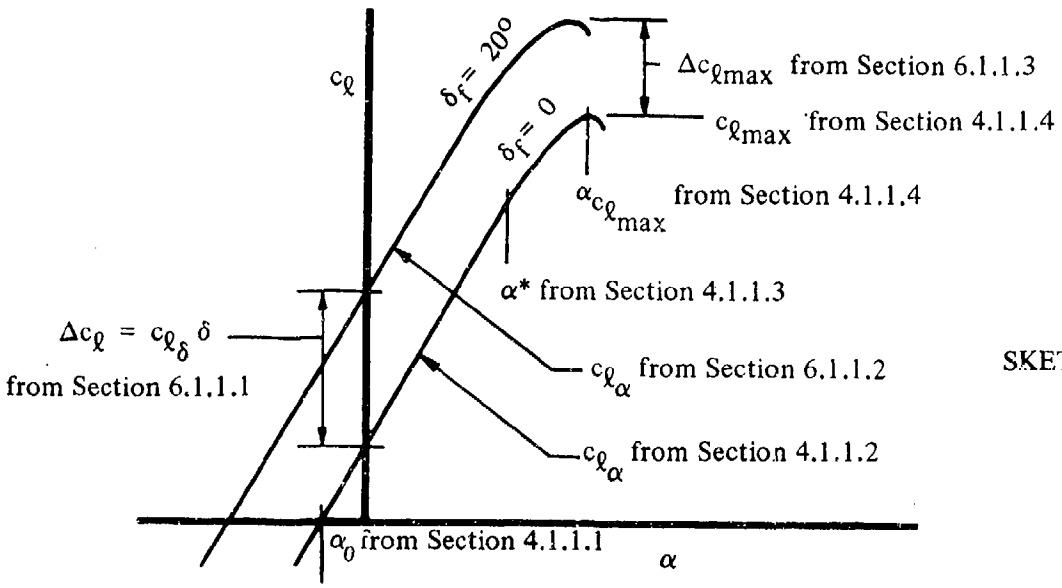
Split flaps	Fowler flaps
Plain flaps	Jet flaps
Single-slotted flaps	Leading-edge flaps
Double-slotted flaps	Slats

Control Devices

Trailing-edge flap types

Spoilers (plug and flap types)

In general, sufficient information is presented in the Datcom to permit the complete lift characteristics of a given device to be calculated. The complete lift characteristics can then be constructed as in the following sketch.



SKETCH (a)

6.1.1.1 SECTION LIFT EFFECTIVENESS OF HIGH-LIFT AND CONTROL DEVICES

Lift effectiveness is defined and used in the literature in several ways. For linear systems, the rate of change of lift with control or flap deflection at constant angle of attack is frequently used. This parameter is defined as

$$c_{\ell_\delta} = \left(\frac{\partial c_\ell}{\partial \delta}\right)_\alpha \qquad 6.1.1.1\text{-a}$$

In cases where nonlinear effects must be accounted for, it is customary to use lift increments for flap deflections at constant angle of attack. Another convention frequently used is the rate of change of zero-lift angle of attack with flap deflection.

$$\left(\frac{\partial \alpha}{\partial \delta}\right)_{c_\ell=0} = \alpha_\delta = -\frac{\left(c_{\ell_\delta}\right)_\alpha}{\left(c_{\ell_\alpha}\right)_\delta} \qquad 6.1.1.1\text{-b}$$

Again, for nonlinear characteristics, increments in angle of attack at zero lift are used. Several of these definitions of lift effectiveness are used in this section, depending upon the particular device being discussed.

In the linear-lift range, α_δ can be obtained from c_{ℓ_δ}, and vice versa, by means of Equations 6.1.1.1-a and 6.1.1.1-b.

The methods presented in this section are limited to subsonic flow.

A. TRAILING-EDGE FLAPS

Trailing-edge flaps operating in the linear-lift range change the lift of the basic airfoil by changing the effective airfoil angle of attack. The means by which each type of flap accomplishes this end is discussed in the following paragraphs. Various types of flaps in common usage are illustrated in Section 6.1.1.3.

Plain Trailing-Edge Flaps

For plain, sealed trailing-edge flaps the theoretical derivative c_{ℓ_δ} is a function of flap-chord-to-wing-chord ratio and airfoil thickness ratio. Increasing airfoil thickness increases the theoretical lift increment for a given flap deflection.

The boundary layer for plain flapped airfoils is shed at the trailing edge of the flap. Lift increments are therefore sensitive to the conditions of the boundary layer – the thicker the boundary layer the lower the value of c_{ℓ_δ} derived from the flap. Since boundary layers are thicker on thick airfoils than on thin airfoils, actual c_{ℓ_δ} values tend to be lower for the thick airfoils.

In general, for a given increase in airfoil thickness ratio the reduction in c_{ℓ_δ} due to viscous effects is greater than the increase in c_{ℓ_δ} as predicted from inviscid-flow theory In the charts of this section, viscous effects are accounted for by using the experimental lift-curve slope as a parameter, since c_{ℓ_α} is influenced by viscous effects in the same manner as c_{ℓ_δ}.

Because of the sensitivity of plain flaps to the boundary layer, the flow separates over the flap surface at relatively small deflection angles. The linear range of c_{ℓ_δ} for plain flaps is therefore limited to the range from 0 to 10° or 15° of flap deflection. An empirical correction factor is applied in this section to account for the nonlinear effects at high flap deflection.

Slotted Trailing-Edge Flaps

For efficiently designed slotted trailing-edge flaps the airfoil boundary layer is shed at the slot lip and a new boundary layer forms over the flap surface. The lift derived from efficiently designed slotted flaps is therefore not affected by the boundary layer of the basic airfoil. Experimental data for slotted flaps support this observation.

Fowler Flaps

Many flap designs have been developed in which the instantaneous center of rotation moves rearward as the flap deflects. An example of such a flap is the Fowler flap.

Aerodynamically, Fowler flaps function in the same way as single-slotted flaps. Additional lift benefits are derived from such flaps because of the increase in planform area due to flap translation.

The effect of translation can be approximated by calculating the increase in airfoil chord as a function of flap deflection.

Split Flaps

The deflection of split trailing-edge flaps causes a wide wake to appear behind the airfoil. This wake prevents the realization of the full increase in circulation due to flap deflection. The rate of increase of lift with flap deflection is therefore lower than that for the corresponding plain flap. The rate also decreases continuously with increasing flap deflection, because the wake widens as the flap deflection is increased.

B. JET FLAPS

The term jet flap has been used to describe a propulsive jet emitted from the wing trailing edge as a plane jet at an angle of inclination to the mainstream. In three dimensions, the jet is distributed in the spanwise direction on a wing. Such an integrated jet-flap system is depicted schematically in Sketch (a), along with a definition of the section jet momentum coefficient C_μ.

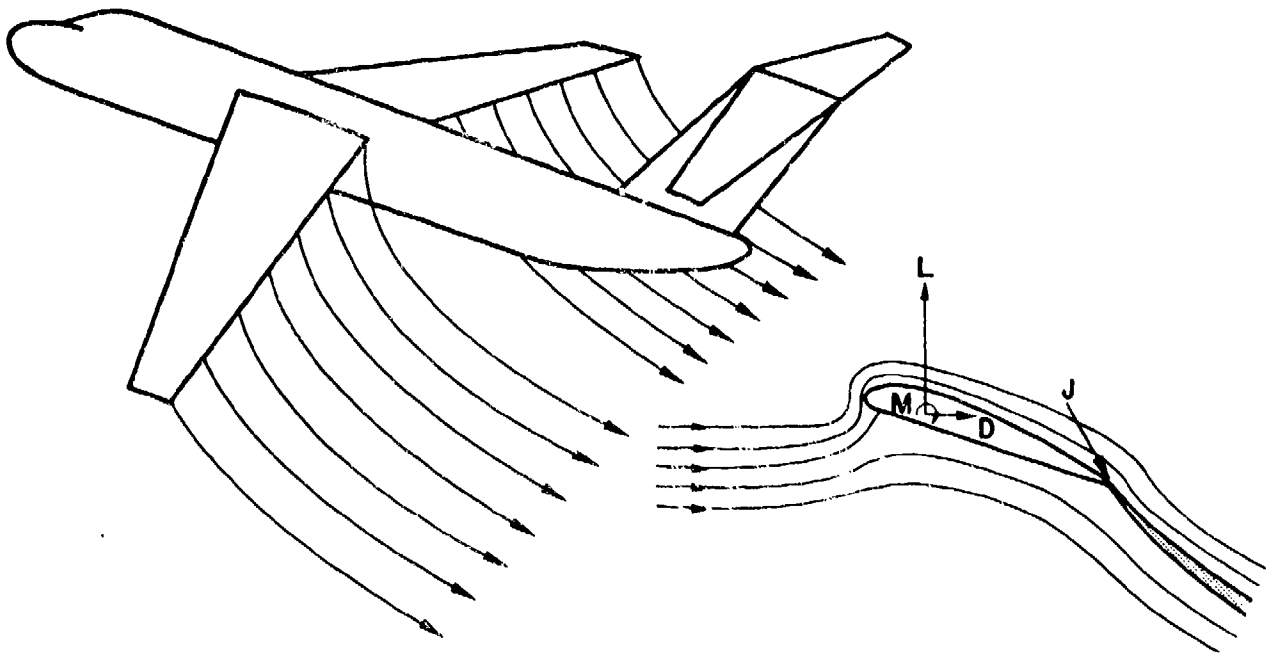
In order that the Datcom user may better understand the jet-flap concept, a brief discussion covering the salient aspects of the jet-flap principle is presented. This general discussion is taken essentially from References 1 and 2.

The primary objective of a jet-flap system is to increase significantly the lift component beyond that which a conventional mechanical flap system can possibly attain. The lift of a jet flap can be attributed to three different sources as follows:

1. Direct-lift component of the jet reaction. This is directly proportional to the jet momentum emitted at the trailing edge.

2. Circulation generated around the airfoil. Since the amount of circulation greatly exceeds that of a corresponding pure airfoil, it is sometimes termed supercirculation. Physically, this additional increase in lift may be explained as follows: The air on the upper surface of the airfoil is drawn down by the deflected jet, creating a suction, while the air flow below is blocked by the jet, producing pressure. Both effects tend to increase lift on the airfoil. Scientists investigating jet lift prefer to call this circulation effect the magnification of the direct jet lift.

3. Automatic boundary-layer control. The jet tends to prevent the flow above the airfoil from separating by reducing the adverse pressure gradient which the boundary layer must negotiate. Some reduction of the adverse pressure gradient can be attributed to the jet entrainment.



$$C_\mu = \frac{m_j V_j}{1/2\,\rho\, V^2\, c} = \frac{J}{qc} \quad \text{and} \quad C'_\mu = \frac{m_j V_j}{1/2\,\rho\, V^2\, c'} = \frac{J}{qc'}$$

where

C_μ is the section nondimensional trailing-edge jet momentum coefficient.

m_j is the mass-flow rate of the gas efflux (per section).

V_j is the velocity of the gas efflux leaving the trailing edge of the airfoil.

J is the jet momentum; i.e., the product of m_j and V_j.

ρ is the density of the free stream.

V is the velocity of the free stream.

c is the airfoil chord.

c is the extended airfoil chord (see Figures 6.1.1.1-44 through -46 and Figure 6.1.1.1-48).

q is the free-stream dynamic pressure.

SKETCH (a)

The above effect that dominates the lift contribution depends on the magnitude of the jet momentum. The boundary-layer control effect is most significant when the jet momentum is small ($C_\mu < 1$), while the supercirculation effect predominates when the momentum is moderate or large.

With respect to the supercirculation, the downward extending jet acts generally in a manner similar to that of a mechanical flap. Although the jet sheet extends downstream to infinity, only its initial portion, before it has been curved around so as to become almost straight, could significantly affect

the flow. Therefore, its effect is analogous to some specific mechanical flap of finite extension. As the jet momentum is increased, the jet would penetrate farther into the mainstream, corresponding to a larger mechanical flap. The name "jet flap" was derived from such analogy.

The basic jet-flap scheme, often referred to as an internal-flow system, essentially requires the gas to be ducted through the wing either to the trailing edge or to a slot at the knee of a flap which is used for varying the jet angle. Several alternatives to the basic jet-flap scheme have been devised for directing the gas efflux to the trailing edge. Some of these concepts are shown in Sketch (b). For the external-flow system shown in Sketch (b), the gas from the engine is ducted or directed outside the wing. With an underslung podded engine, the round jet may be guided to impinge on a mechanical flap system and form a flattened jet sheet. Alternatively, with the engine mounted on the top, the exit nozzle may be elongated spanwise to generate a plane jet sheet. Another approach shown in Sketch (b) is the augmentor-wing concept. With this scheme the jet efflux can also be used to drive an ejector system that will, in turn, augment the thrust by the entrainment of the free-stream flow.

The fact that all these concepts exhibit a flat jet sheet at the trailing edge, which characteristically has the same effect of inducing supercirculation, provides the basis for a common theoretical analysis.

The analysis of jet-flap problems inherently requires that the wing and jet be treated as an integrated system. Thus far, theoretical treatments of jet-flap aerodynamic problems have been based on linearized small-disturbance concepts. In the context of linearized theory, the basic difference between the jet wing and a conventional wing is that, in addition to the wing planform, the jet sheet itself should be regarded as a discontinuity sheet in longitudinal velocity. Roughly speaking, the jet-flapped wing may be treated as if the wing planform were extended to infinity. Unfortunately, the shape of the jet sheet, unlike that of the wing, is not known. Thus a dynamic boundary condition must be introduced for the jet, in contrast to the kinematic boundary condition for the wing. Therefore, the development of an analytical solution for aerodynamic characteristics of a jet-flapped wing encounters two difficulties. One is due to the mixed boundary conditions; the other is due to the fact that the boundary conditions are prescribed over a region of semi-infinite extent. An elegant solution for the two-dimensional jet-flap problem has been obtained by Spence in References 3 and 4. His approach is based on the assumptions that the flows inside and outside the jet are irrotational and at constant, although not necessarily equal, densities. Since entrainment into the jet is neglected, it can be regarded as if bounded by streamlines. These simplifications enable a relation between the pressure differences across the jet and its curvature to be found. The limiting case of a thin, high-speed jet is considered by assuming that the jet has zero thickness but finite momentum. Airfoil thickness is neglected, the airfoil and jet are assumed near zero angle of attack, and the airfoil and jet boundary conditions are transferred to the semi-infinite line through the trailing edge and parallel to the undisturbed flow. The result of these approximations is the representation of the flow by a mixed-boundary-value problem on this semi-infinite line. Spence has obtained three basic solutions: angle of attack, flap deflection, and jet deflection. Close agreement has been obtained between Spence's theory and the experimental results of Dimmock (Reference 5) over the range of jet momentum and jet deflection angles of practical interest.

Several experimental and theoretical studies have been conducted to investigate the effects of ground proximity on jet-flapped wings. Insofar as theoretical methods are concerned, however, only a simple mathematical representation of the two-dimensional jet-flap airfoil has been formulated (Reference 6).

SKETCH (b)

C. LEADING-EDGE FLAPS AND SLATS

Leading-Edge Flaps

Leading-edge flaps change the lift of an airfoil by changing the effective angle of attack in the same way that trailing-edge flaps do. Unlike trailing-edge flaps, however, a positive leading-edge-flap deflection (nose down) causes a loss in lift instead of an increase in lift. In general, the change in lift per degree of flap deflection is smaller for leading-edge flaps than for trailing-edge flaps.

Leading-edge-flap effectiveness is not affected by the airfoil boundary layer.

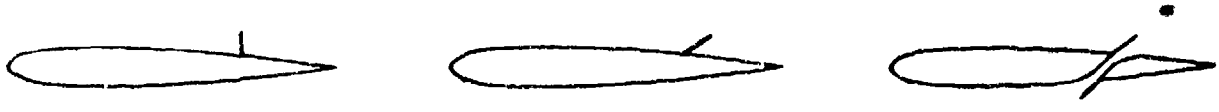
Leading-Edge Slats

The lift parameter c_{ℓ_δ} for leading-edge slats is affected by two factors. First, the deflection or rotation of the slat causes a loss in lift similar to that of leading-edge flaps. Secondly, slat extension or translation increases the planform area.

D. SPOILERS

Spoilers are generally used for two reasons -- for roll control when deflected asymmetrically and for high drag generation when deflected symmetrically. Only the section-lift aspects of spoilers are discussed herein.

Many types of spoilers have been developed, depending upon control-power limitations, structural limitations, and aerodynamic requirements. Some of the more commonly used types are illustrated in Sketch (c).

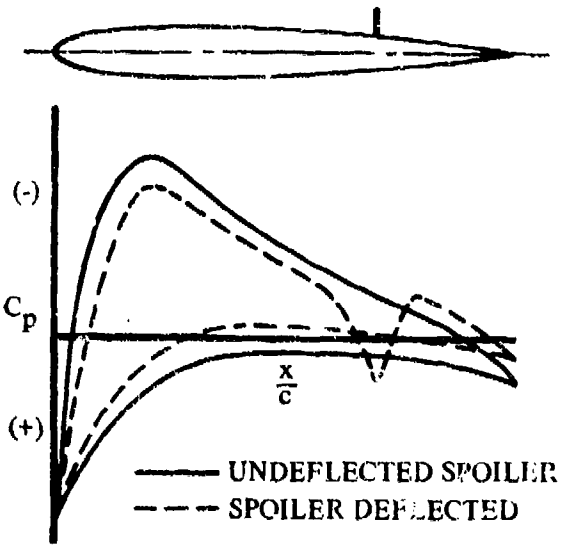


PLUG SPOILER | FLAP SPOILER | SLOTTED SPOILER

SKETCH (c) TYPICAL SPOILER ARRANGEMENTS

Unlike flaps, spoilers operate by causing a loss in airfoil lift – rather than an increase – by separating the flow downstream. The effective angle of attack is decreased and the lift correspondingly reduced. There are two viewpoints that can be used in explaining the operation of spoilers. One is to consider the pressure field over the airfoil and the other is to consider the effect of the spoiler on the wake pattern. These viewpoints are discussed in the following paragraphs.

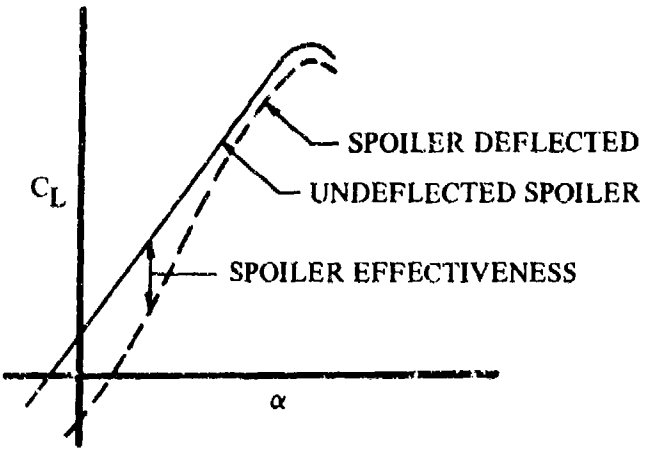
For flap- and plug-type spoilers the pressure loading forward of the spoiler (difference in upper- and lower-surface pressures) is reduced, and the local lift is reduced accordingly. Aft of the spoiler the pressure loading is increased because of high suction pressures behind the spoiler on the upper surface. The increase in lift aft of the spoiler, however, does not offset the decrease in lift forward of the spoiler, and a total loss in lift results. These phenomena are illustrated in Sketch (d).



SKETCH (d) TYPICAL AIRFOIL PRESSURE DISTRIBUTION FOR PLUG-TYPE SPOILER

For large spoiler deflections a wide wake exists behind the spoiler, the width of which depends upon spoiler height, location, and airfoil angle of attack. The lift generated from the airfoil is related to the width and direction of the wake with respect to the free stream.

At subsonic and transonic speeds the wake characteristics vary nonlinearly with angle of attack and spoiler deflection. Therefore, the corresponding lift characteristics are also nonlinear, as shown in Sketch (e). The loss in effectiveness at high angles of attack should be noted. This loss, which is particularly pronounced for thin wings, can be greatly alleviated by the use of leading-edge flaps (Reference 7) or by incorporating a slot behind the spoiler, as discussed below (Reference 8).



SKETCH (e) TYPICAL LIFT CURVES FOR PLUG-TYPE SPOILER

For small deflections of plug- and flap-type spoilers, the flow reattaches behind the spoiler and the spoiler becomes ineffective. This generally occurs for spoiler deflections less than one percent of the airfoil chord. This problem is discussed in detail in Reference 9.

One commonly used variation of the flap-type spoiler is the slotted spoiler with a deflector on the lower surface (see Sketch (c)). This system has several advantages. First, the air that is ducted from the underside of the airfoil relieves the upper-surface suction pressures behind the spoiler and increases the spoiler effectiveness. Secondly, the problem of flow reattachment does not occur for small spoiler deflections. Thirdly, the opposing aerodynamic loads on the spoiler and deflector can be used to achieve low actuation power requirements.

The information presented in this section is limited to the region near zero lift, where the spoiler lift characteristics are essentially linear with angle of attack.

DATCOM METHODS

A. TRAILING-EDGE FLAPS

Plain Flaps

The section lift increment due to the deflection of plain trailing-edge flaps with sealed gaps, based on the method of Reference 10, is given by

$$\Delta c_{\ell} = \delta_f \left[\frac{c_{\ell_\delta}}{\left(c_{\ell_\delta}\right)_{theory}} \right] \left(c_{\ell_\delta}\right)_{theory} K' \qquad 6.1.1.1\text{-c}$$

where

$\left(c_{\ell_\delta}\right)_{theory}$ is the theoretical flap-lift effectiveness from Figure 6.1.1.1-39a for a given airfoil thickness ratio and flap-chord-to-airfoil-chord ratio.

$\dfrac{c_{\ell_\delta}}{\left(c_{\ell_\delta}\right)_{theory}}$ is an empirical correction factor obtained from Figure 6.1.1.1-39b

The parameter $c_{\ell_\alpha}/\left(c_{\ell_\alpha}\right)_{theory}$ used in reading this chart is obtained from Section 4.1.1.2 (Figure 4.1.1.2-8a).

δ_f is the flap deflection.

K' is an empirical correction factor from Figure 6.1.1.1-40. This factor has been derived from a large body of test data (References 11 through 28). It corrects Δc_{ℓ} for nonlinear effects at high flap deflections.

This method does not include the effects of unsealed gaps, beveled trailing edges, or compressibility.

In general, the effectiveness of the control is reduced when the gap is unsealed. This effect is more pronounced for airfoils with beveled trailing edges than for airfoils with true-contour trailing edges.

The method may be applied to true-contour airfoils or airfoils with slightly modified trailing-edge contours. The method should not be applied to airfoils with beveled trailing edges. Not enough experimental data are available to allow a quantitative prediction of the effect of bevel. However, the data do show a decrease in control effectiveness with increasing bevel.

Compressibility will have serious effects on the lift effectiveness of plain trailing-edge controls. Experimental data (References 17, 18, and 57 through 59) show decreases in lift effectiveness up to one half the low-speed values at high subsonic speeds. Although there are not enough data to allow a quantitative prediction of compressibility effects, they do demonstrate significant effects of airfoil thickness, control size, and trailing-edge angle on the control effectiveness as the Mach number is increased. The onset of an abrupt loss in control effectiveness is delayed to higher Mach numbers by a reduction in airfoil thickness (References 58 and 59), an increase in control size (Reference 17), or a reduction in trailing-edge angle (References 56 and 57).

A comparison of low-speed test data with Δc_ℓ of plain-flapped airfoils calculated by this method is presented as Table 6.1.1.1-A.

Single-Slotted Flaps

Two methods are presented for estimating the section lift increment due to the deflection of single-slotted flaps. Both methods are applicable in the high-flap-deflection range and limited to the low-speed regime. Method 1 is preferable when test data are available for the section lift-curve slope of the unflapped airfoil. When no section lift-curve-slope test data are available, Method 2 should be used.

Method 1

The section life increment due to the deflection of single-slotted flaps is given by

$$\Delta c_\ell = -c_{\ell_\alpha} \alpha_\delta \delta_f \qquad \text{6.1.1.1-d}$$

where

c_{ℓ_α} is the section lift-curve slope of the unflapped airfoil, including the effects of compressibility, obtained from test data or Section 4.1.1.2.

α_δ is the section lift-effectiveness parameter of single-slotted flaps obtained from the empirical correlation of Figure 6.1.1.1-41. This parameter, based on the data of References 29 through 50, is presented as a function of flap deflection for several values of the ratio of flap chord to airfoil chord c_f/c.

δ_f is the flap deflection.

A comparison of test data with Δc_ℓ due to single-slotted flaps calculated by this method is presented as Table 6.1.1.1-B.

Method 2

This method (Reference 70) uses the theoretical lift effectiveness of a simple trailing-edge flap as obtained from thin-airfoil theory, modified by an empirical lift-effectiveness parameter. The section-lift increment due to the deflection of single-slotted flaps is given by

$$\Delta c_\ell = c_{\ell_\delta} \delta_f \eta_1 \frac{c'}{c} \qquad \text{6.1.1.1-e}$$

where

c_{ℓ_δ} is the theoretical lift effectiveness from thin-airfoil theory of a simple trailing-edge flap, obtained from Figure 6.1.1.1-42 as a function of flap-chord ratio c_1/c (see Figure 6.1.1.1-44 for a geometric representation of c_1/c).

δ_f is the flap deflection in degrees.

η_1 is the empirical lift-efficiency factor for single-slotted flaps, obtained from Figure 6.1.1.1-43a as a function of the effective turning angle Φ,

where

$$\Phi = \delta_f + \phi_{TE_{upper}} \qquad 6.1.1.1\text{-f}$$

where

$$\phi_{TE_{upper}} = \tan^{-1}\left(\frac{Y_{90} - Y_{100}}{0.10}\right) \qquad 6.1.1.1\text{-g}$$

Y_{90} is the upper-surface ordinate of the flap at 90% chord in the retracted position, in fractions of the chord.

Y_{100} is the upper-surface ordinate of the flap at 100% chord in the retracted position, in fractions of the chord.

$\frac{c'}{c}$ is the ratio of the extended-wing chord to the basic wing chord. (See Figure 6.1.1.1-44 for a schematic definition.)

A comparison of test data with Δc_2 due to single-slotted flaps calculated by this method is presented as Table 6.1.1.1-C. These data are the same data that appear in Table 6.1.1.1-B.

It is virtually impossible to present quantitative information on the effects of the various geometric and aerodynamic variables involved because of the lack of systematic experimental data. Although a large body of test data is available, the data consist of a large number of unrelated combinations of airfoils and slotted flaps. The configurations listed in Table 6.1.1.1-B include wide variations in chordwise position of slot lip, slot-entry shape, slot-lip shape, flap-nose shape, and position of the flap with respect to the slot lip.

Because of the number of variables involved and the design parameters not considered in the Datcom methods, the comparison between theory and experiment cannot be analyzed by examining the isolated effect of any one variable.

Fowler Flaps

Section lift increments for Fowler flaps are obtained by using the methods presented for single-slotted flaps. Fowler flaps are included in the empirical correlation of slotted-flap lift effectiveness in Figure 6.1.1.1-41 of Method 1. It should be noted, however, that this design chart

applies only when the Fowler flap is near its fully extended position and the slot is properly developed. Method 2 predicts an increase in lift increment that is directly proportional to the ratio of the extended chord to the retracted chord.

Not enough test data for airfoils are available to fully substantiate these methods. However, the accuracy of the methods when applied to Fowler flaps near their fully extended position and with a properly developed slot should be comparable to that shown for the single-slotted flap methods in Tables 6.1.1.1-B and 6.1.1.1-C.

Double-Slotted Flaps

Two methods, taken from Reference 70, are presented for estimating the section lift increment due to the deflection of a double-slotted flap. Both methods are applicable in the high-flap-deflection range and limited to the low-speed regime. Method 1 is applicable to the conventional vane-plus-aft-flap configuration as shown in Figure 6.1.1.1-45 where $c_1/c_2 \leq 0.60$. Method 2 is applicable to a double-slotted configuration where the two flap-chord segments are approximately equal (see Figure 6.1.1.1-46). This configuration is referred to as a double-deflected flap in several references.

Method 1

The section lift increment due to the deflection of double-slotted flaps of the conventional vane-plus-aft-flap combination is given by

$$\Delta c_\ell = \eta_1 \, c_{\ell_{\delta_{f_1}}} \, \delta_{f_1} \left(\frac{c + c_1}{c} \right) + \eta_2 \, c_{\ell_{\delta_{f_2}}} \left(\delta_{f_1} + \delta_{f_2} \right) \left(\frac{c'}{c} \right) \qquad 6.1.1.1\text{-h}$$

where

η_1, η_2 are the empirical lift-efficiency factors for the vane and aft-flap segments obtained from Figure 6.1.1.1-43a, based on c_1/c and c_2/c, respectively, and the effective turning angle Φ,

where

$$\Phi = \delta_{f_1} + \phi_{TE_{upper}} \qquad \text{(vane segment)}$$

$$\Phi = \delta_{f_1} + \delta_{f_2} + \phi_{TE_{upper}} \qquad \text{(flap segment)}$$

and $\phi_{TE_{upper}}$ is defined in Equation 6.1.1.1-g.

$c_{\ell_{\delta_{f_1}}}, c_{\ell_{\delta_{f_2}}}$ are the theoretical lifting-efficiency factors for the vane and aft-flap segments obtained from Figure 6.1.1.1-42 and based on c_1/c and c_2/c, respectively.

All remaining parameters are illustrated and defined in Figure 6.1.1.1-45.

A comparison of test data with Δc_ℓ due to double-slotted flaps calculated by this method is presented in Table 6.1.1.1-D.

Method 2

The section lift increment due to the deflection of double-slotted flaps with approximately equal flap-chord segments is given by

$$\Delta c_{\ell} = \eta_1 \, c_{\ell_{\delta_{f_1}}} \, \delta_{f_1} \left(\frac{c_a'}{c} \right) + \eta_2 \eta_t \, c_{\ell_{\delta_{f_2}}} \, \delta_{f_2} \left(1 + \frac{c' - c_a'}{c} \right) \qquad 6.1.1.1\text{-i}$$

where

η_1, η_2 are the empirical lift-efficiency factors for the forward- and aft-flap segments obtained from Figure 6.1.1.1-43a, based on c_1'/c and c_2/c, respectively, and the effective turning angle Φ,

where

$$\Phi = \delta_{f_1} + \phi_{TE_{upper}} \qquad \text{(forward segment)}$$

$$\Phi = \delta_{f_2} + \phi_{TE_{upper}} \qquad \text{(aft segment)}$$

and $\phi_{TE_{upper}}$ is defined in Equation 6.1.1.1-g.

$c_{\ell_{\delta_{f_1}}}, c_{\ell_{\delta_{f_2}}}$ are the theoretical lifting-efficiency factors for the forward- and aft-flap segments obtained from Figure 6.1.1.1-42, based on c_1'/c and c_2/c, respectively.

η_t is the turning-efficiency factor of the aft flap obtained from Figure 6.1.1.1-43b, based on the forward- and aft-flap-deflection angles.

All remaining parameters are illustrated and defined in Figure 6.1.1.1-46.

No substantiation table is presented for this method because of the lack of test data for this type of configuration. However, for those cases that have been evaluated, the accuracy of the method is analogous to that of Method 1 above.

The double-slotted flap may be defined as a single-slotted flap with a turning vane in the slot. Consequently, the important design parameters for double-slotted flaps are more complicated than those for single-slotted flaps, particularly in relation to determining the efficiency of flow through the slot. As in the case for single-slotted flaps, a lack of systematic test data precludes quantitative examination of the effects of the various geometric and aerodynamic variables involved.

Because of the design parameters not considered in the Datcom method, the comparison between theory and experiment cannot be analyzed by examining the isolated effect of any one variable.

Split Flaps

The section lift increment due to the deflection of split flaps is given by

$$\Delta c_{\ell} = -c_{\ell_\alpha} \alpha_\delta \delta_f \qquad 6.1.1.1\text{-j}$$

where

c_{ℓ_α} is the section lift-curve slope of the unflapped airfoil, including the effects of compressibility, obtained from Section 4.1.1.2.

α_δ is the section lift-effectiveness parameter of split flaps obtained from the empirical curves of Figure 6.1.1.1-47. This parameter, based on the curves presented in Reference 53, is presented as a function of flap deflection for several values of the ratio of flap chord to airfoil chord c_f/c.

δ_f is the flap deflection, measured tangent to airfoil lower-surface contour at trailing edge.

A comparison of test data with Δc_{ℓ} due to split flaps calculated by this method is presented as Table 6.1.1.1-E.

B. JET FLAPS

Methods that are adaptable to a handbook application are not available for all jet-flap schemes. The method presented below is applicable to the pure jet-flap concept and the internally-blown-flap (IBF) and externally-blown-flap (EBF) concepts with a plain trailing-edge flap. For an IBF or EBF concept with a single-slotted or multislotted flap configuration, this method should be used only as a first approximation. No handbook method is currently available to analyze the section lift increment due to an augmentor-wing concept.

The method presented herein is a combination of methods presented in References 2 and 70 (based on Spence's theoretical results). The pertinent geometrical parameters are defined and illustrated in Figure 6.1.1.1-48. No substantiation of the method is presented herein; however, the method has been acknowledged as being substantiated in the literature (References 1 and 4).

This method is capable of estimating the lift increments in the linear-lift range (preferably at zero angle of attack) for three types of configurations:

1. Pure jet flap
2. IBF or EBF
3. Combination jet-flap and plain-flap deflection (see Figure 6.1.1.1-48)

It is of particular interest to note that the factor $[1 + k_t(t/c')]$ in Equation 6.1.1.1-k below corrects the pressure lift contribution for thickness effects, under the constraint of no trailing-edge separation. No values for the lifting-efficiency factor are available as a function of flap setting and jet momentum coefficient. For this reason, the user must exercise caution not to apply the method to conditions where trailing-edge separation exists and/or low values of jet momentum coefficient prevail.

It should be noted that the flap-chord value c_f/c' used in Figure 6.1.1.1-49 is not the true mechanical flap length for flaps with Fowler-type motion. For Fowler-type flaps, the flap chord is the length from the flap trailing edge to the intersection of the flap-chord and wing-chord lines.

The section lift increment due to flap deflection and jet efflux of a jet-flap combination, based on the retracted airfoil chord c, is given by

$$\Delta c_\ell = \left\{ \left[1 + k_t \left(\frac{t}{c'} \right) \right] \delta_f \left(c_{\ell_{\delta_f}} - C'_\mu \right) + C'_\mu \, \delta_f \right.$$

$$\left. + \left[1 + k_t \left(\frac{t}{c'} \right) \right] \delta_j \left(c_{\ell_{\delta_j}} - C'_\mu \right) + C'_\mu \, \delta_j \right\} \frac{c'}{c} \qquad \text{6.1.1.1-k}$$

where

k_t is the airfoil-theory thickness factor; i.e.,

$k_t = 1.0$ for elliptic airfoils

$= 0.637$ for parabolic airfoils

For airfoil sections other than elliptic or parabolic, a value of 0.80 for k_t is suggested (Reference 70).

$\frac{t}{c'}$ is the airfoil thickness ratio, based on the extended chord; see Figure 6.1.1.1-48.

$c_{\ell_{\delta_f}}$ is the rate of change of section lift coefficient with respect to flap deflection obtained from Figure 6.1.1.1-49 as a function of the trailing-edge jet momentum C_μ' and the ratio of the flap chord to the extended wing chord c_f/c'. (The term c'_{ℓ_α} appearing in Figure 6.1.1.1-49 is the jet-flap lift-curve slope uncorrected for thickness effects.)

As noted above, the flap-chord value c_f is the length from the flap trailing edge to the intersection of the flap-chord and wing-chord lines.

C_μ' is the section nondimensional trailing-edge jet-momentum coefficient based on the extended airfoil chord (defined in Sketch (a) of this section).

δ_f is the flap deflection in radians, see Figure 6.1.1.1-48.

$c_{\ell_{\delta_j}}$ is the rate of change of section lift coefficient with respect to the jet deflection obtained from Figure 6.1.1.1-49 as a function of the trailing-edge jet momentum C_μ'.

δ_j is the trailing-edge jet momentum angle in radians, with respect to the trailing-edge camber line, see Figure 6.1.1.1-48.

$\frac{c'}{c}$ is the ratio of the extended wing chord to the retracted wing chord.

C. LEADING-EDGE FLAPS AND SLATS

The available experimental section characteristics for leading-edge devices (References 15, 69, and 76) are insufficient to allow substantiation of the methods presented. However, the methods should provide results that are suitable for first approximations for flapped airfoils with geometric parameters within the boundaries of thin-airfoil theory. Consequently, the methods are considered applicable for airfoil-flap configurations with $t/c \leq 0.10$ and with small flap deflections, in the linear-lift range (preferably at zero angle of attack).

It should be noted that the c_{ℓ_δ} values for all leading-edge devices are of opposite sign from the values for trailing-edge flaps.

Leading-Edge Flaps

The method presented below is taken from Reference 70 and is based on thin-airfoil theory. The section lift increment due to leading-edge flap deflection is given by

$$\Delta c_\ell = c_{\ell_\delta} \delta_f \qquad 6.1.1.1\text{-}l$$

where

c_{ℓ_δ} is the leading-edge flap-effectiveness parameter obtained from Figure 6.1.1.1-50 as a function of the nose-flap-chord to wing-chord ratio c_f/c.

δ_f is the nose-flap deflection in degrees, as shown in Figure 6.1.1.1-51.

Krueger Flaps

The method presented below is a modification of the method presented immediately above (Reference 70), to account for the chord extension associated with Krueger leading-edge devices.

No substantiation of this method is presented because of the lack of test data. The section lift increment due to a Krueger leading-edge flap deflection is given by

$$\Delta c_\ell = c_{\ell_\delta} \delta_f \frac{c'}{c} \qquad 6.1.1.1\text{-}m$$

where

c_{ℓ_δ} is the leading-edge flap-effectiveness parameter obtained from Figure 6.1.1.1-50 as a function of the Krueger flap-chord to wing-chord ratio c_f/c'

δ_f is the Krueger flap deflection, in degrees, as shown in Figure 6.1.1.1-51.

$\frac{c'}{c}$ is the ratio of the extended wing chord to airfoil chord as shown in Figure 6.1.1.1-51.

Leading-Edge Slats

The method presented here is a modification of the method presented for leading-edge flaps (Reference 70); i.e., it is modified to account for the chord extension associated with leading-edge slats. The section lift increment due to a leading-edge slat deflection is given by

$$\Delta c_\ell = c_{\ell_\delta} \delta_f \frac{c'}{c} \qquad \text{6.1.1.1-m}$$

where

c_{ℓ_δ} is the leading-edge flap-effectiveness parameter obtained from Figure 6.1.1.1-50 as a function of the leading-edge-slat-chord to wing-chord ratio c_f/c'.

δ_f is the slat deflection, in degrees, as shown in Figure 6.1.1.1-51.

$\frac{c'}{c}$ is the ratio of the extended wing chord to airfoil chord as shown in Figure 6.1.1.1-51.

D. SPOILERS

The section lift increment due to either plug or flap spoilers is given by

$$\Delta c_\ell = -c_{\ell_\alpha} \Delta\alpha'_s \qquad \text{6.1.1.1-n}$$

where

c_{ℓ_α} is the lift-curve slope of the basic airfoil, including compressibility effects, from Section 4.1.1.2.

$\Delta\alpha'_s$ is the spoiler lift-effectiveness parameter expressed in terms of change in zero-lift angle of attack, from Figure 6.1.1.1-52. This design chart, taken from Reference 55, was developed from data obtained by testing a series of airfoils with various plug-spoiler configurations.

In Figure 6.1.1.1-52, the parameter x_s is the distance from the nose of the airfoil to the spoiler lip, and h_s is the height of the spoiler measured from and normal to the airfoil mean line at x_s.

Experimental section characteristics (Reference 77) for airfoils with plain or plug spoilers are too meager to allow substantiation of this method. However, if a reliable value of c_{ℓ_α} is used, the method should provide results that can be used with confidence within the limitations of the design chart for determining $\Delta\alpha'_s$.

The lift effectiveness of a slotted spoiler with a deflector on the lower surface is greater (causes larger lift loss) than that of plug and flap spoilers. No known method is available for predicting the section lift effectiveness of slotted spoilers.

Sample Problems

1. Plain Trailing-Edge Flap

Given: The flapped airfoil of Reference 13.

NACA 0009 airfoil $\quad c_f/c = 0.20 \quad \delta_f = 50^o \quad R_\ell = 2.76 \times 10^6$

$\tan\frac{1}{2}\phi_{TE} = 0.099$ (streamwise airfoil geometry)

Compute:

$(c_{\ell_\delta})_{theory} = 3.61$ per rad $= 0.063$ per deg (Figure 6.1.1.1-39a)

$\frac{c_{\ell_\alpha}}{(c_{\ell_\alpha})_{theory}} = 0.837$ (Figure 4.1.1.2-8a)

$\frac{c_{\ell_\delta}}{(c_{\ell_\delta})_{theory}} = 0.725$ (Figure 6.1.1.1-39b)

$K' = 0.543$ (Figure 6.1.1.1-40)

Solution:

$$\Delta c_\ell = \delta_f \left[\frac{c_{\ell_\delta}}{(c_{\ell_\delta})_{theory}}\right] (c_{\ell_\delta})_{theory} \; K' \qquad \text{(Equation 6.1.1.1-c)}$$

$= (50)(0.725)(0.063)(0.543)$

$= 1.24$

This compares with a test value of 1.15 from Reference 13.

2. Single-Slotted Trailing-Edge Flap (Method 1)

Given: The flapped airfoil of Reference 41 with the slot lip at 0.84 c.

NACA 65-210 airfoil $\quad c_f/c = 0.25 \quad \delta_f = 50^o$

Low Speed; $\beta = 1.0 \quad R_\ell = 6.0 \times 10^6$

$\tan\frac{1}{2}\phi'_{TE} = 0.084$ (streamwise airfoil geometry)

Compute:

c_{ℓ_α} (Section 4.1.1.2)

$$\frac{c_{\ell_\alpha}}{(c_{\ell_\alpha})_{theory}} = 0.879 \qquad \text{(Figure 4.1.1.2-8a)}$$

$$(c_{\ell_\alpha})_{theory} = 6.78 \text{ per rad} \qquad \text{(Figure 4.1.1.2-8b)}$$

$$c_{\ell_\alpha} = \frac{1.05}{\beta}\left[\frac{c_{\ell_\alpha}}{(c_{\ell_\alpha})_{theory}}\right](c_{\ell_\alpha})_{theory} \qquad \text{(Equation 4.1.1.2-a)}$$

$$= \frac{1.05}{1.0}(0.879)\,(6.78)/57.3 = 0.109 \text{ per deg}$$

α_δ = −0.300 (Figure 6.1.1.1-41)

Solution:

$$\Delta c_\ell = -c_{\ell_\alpha}\,\alpha_\delta\,\delta_f \qquad \text{(Equation 6.1.1.1-d)}$$

$$= -(0.109)\,(-0.300)\,(50)$$

$$= 1.64$$

This compares with a test value of 1.73 from Reference 41.

3. Single-Slotted Trailing-Edge Flap (Method 2)

Given: The flapped airfoil of Reference 41 with the slot lip at 0.84 c
(same sample problem as presented for Method 1)

NACA 65-210 airfoil $\quad \frac{c_f}{c} = 0.25 \quad \frac{c'}{c} = 1.078 \quad \alpha = 0$

$Y_{90} = 0.01327\,c \quad Y_{100} = 0 \quad \delta_f = 50°$

Low Speed; $\beta = 1.0$

Compute:

c_{ℓ_δ} = 0.0668 per deg (Figure 6.1.1.1-42)

$$\phi_{TE_{upper}} = \tan^{-1}\left(\frac{Y_{90} - Y_{100}}{0.10}\right) \qquad \text{(Equation 6.1.1.1-g)}$$

$$= \tan^{-1}\left(\frac{0.01327 - 0}{0.10}\right)$$

$$= 7.56^{o}$$

$$\Phi = \delta_f + \phi_{TE_{upper}} \qquad \text{(Equation 6.1.1.1-f)}$$

$$= 50 + 7.56 = 57.56^{o}$$

$$\eta_1 = 0.455 \qquad \text{(Figure 6.1.1.1-43a)}$$

$$\Delta c_\ell = c_{\ell_\delta}\, \delta_f\, \eta_1 \frac{c'}{c} \qquad \text{(Equation 6.1.1.1-e)}$$

$$= (0.0668)\,(50)\,(0.455)\,(1.078)$$

$$= 1.64$$

This compares with a test value of 1.73 from Reference 41.

4. Double-Slotted Trailing-Edge Flap (Method 1)

Given: The flapped airfoil of Reference 64.

NACA 64-208 airfoil	$c_1/c = 0.056$	$c_2/c = 0.25$	$c'/c = 1.127$
$M = 0.18$	$\delta_{f_1} = 25^{o}$	$\delta_{f_2} = 25^{o}$	$\alpha = 0$
$Y_{90} = 0.01067c$	$Y_{100} = 0$		

Compute:

$c_{\ell_{\delta_{f_1}}}$ = 0.0327 per deg (Figure 6.1.1.1-42)

$c_{\ell_{\delta_{f_2}}}$ = 0.0668 per deg (Figure 6.1.1.1-42)

$$\phi_{TE_{upper}} = \tan^{-1}\left(\frac{Y_{90} - Y_{100}}{0.10}\right) \qquad \text{(Equation 6.1.1.1-g)}$$

$$= \tan^{-1}\left(\frac{0.01067 - 0}{0.10}\right)$$

$$= 6.1^{o}$$

$$\Phi = \delta_{f_1} + \phi_{TE_{upper}} \quad \text{(vane segment)}$$

$$= 25 + 6.1 = 31.1^{o}$$

$$\Phi = \delta_{f_1} + \delta_{f_2} + \phi_{TE_{upper}} \quad \text{(flap segment)}$$

$$= 25 + 25 + 6.1 = 56.1^{o}$$

$$\left.\begin{aligned} \eta_1 &= 0.640 \\ \eta_2 &= 0.470 \end{aligned}\right\} \quad \text{(Figure 6.1.1.1-43a)}$$

$$\Delta c_{\ell} = \eta_1 \, c_{\ell_{\delta_{f_1}}} \, \delta_{f_1} \left(\frac{c + c_1}{c}\right) + \eta_2 \, c_{\ell_{\delta_{f_2}}} \left(\delta_{f_1} + \delta_{f_2}\right)\left(\frac{c'}{c}\right) \quad \text{(Equation 6.1.1.1-h)}$$

$$= (0.640)(0.0327)(25)(1.056) + (0.470)(0.0668)(50)(1.127)$$

$$= 0.552 + 1.770$$

$$= 2.32$$

This compares with a test value of 2.07 from Reference 64.

5. Double-Slotted Trailing-Edge Flap (Method 2)

Given: The flapped airfoil of Reference 78.

NACA 23012 airfoil $\quad c_1'/c = 0.40 \quad c_2/c = 0.2566$

$c_{\ell}'/c = 1.10 \quad c'/c = 1.14 \quad \delta_{f_1} = 30^{o} \quad \delta_{f_2} = 20^{o}$

Low Speed; $\beta = 1.0 \quad Y_{90} = 0.0168c \quad Y_{100} = 0.0013c$

Compute:

$c_{\ell_{\delta_{f_1}}} = 0.082$ per deg (Figure 6.1.1.1-42)

$c_{\ell_{\delta_{f_2}}} = 0.0672$ per deg (Figure 6.1.1.1-42)

$$\phi_{TE_{upper}} = \tan^{-1}\left(\frac{Y_{90} - Y_{100}}{0.10}\right) \qquad \text{(Equation 6.1.1.1-g)}$$

$$= \tan^{-1}\left(\frac{0.0168 - 0.0013}{0.10}\right)$$

$$= 8.8^{o}$$

$$\Phi = \delta_{f_1} + \phi_{TE_{upper}} \qquad \text{(forward segment)}$$

$$= 30 + 8.8 = 38.8^{o}$$

$$\Phi = \delta_{f_2} + \phi_{TE_{upper}} \qquad \text{(aft segment)}$$

$$= 20 + 8.8 = 28.8^{o}$$

$$\left.\begin{aligned} \eta_1 &= 0.69 \\ \eta_2 &= 0.71 \end{aligned}\right\} \qquad \text{(Figure 6.1.1.1-43a)}$$

$\eta_t = 0.84$ (extrapolated from Figure 6.1.1.1-43b)

$$\Delta c_{\ell} = \eta_1 \, c_{\ell_{\delta_{f_1}}} \, \delta_{f_1} \left(\frac{c_a'}{c}\right) + \eta_2 \, \eta_t \, c_{\ell_{\delta_{f_2}}} \, \eta_{f_2} \left(1 + \frac{c' - c_a'}{c}\right) \qquad \text{(Equation 6.1.1.1-i)}$$

$$= (0.69)\,(0.082)\,(30)\,(1.10) + (0.71)\,(0.84)\,(0.0672)\,(20)\,[1 + (1.14 - 1.10)]$$

$$= 1.867 + 0.834$$

$$= 2.70$$

This compares with a test value of 2.69 from Reference 78.

6. Split Trailing-Edge Flap

Given: The flapped airfoil of Reference 75

$\delta_f = 60^{o}$ NACA 23012 airfoil $c_f/c = 0.40$

$c_{\ell_\alpha} = 0.107$ per deg (test data)

Compute:

$\alpha_\delta = -0.30$ (Figure 6.1.1.1-47)

Solution:

$$\Delta c_{\ell} = -c_{\ell_{\alpha}} \alpha_{\delta} \delta_f \qquad \text{(Equation 6.1.1.1-j)}$$

$$= -(0.107)(-0.30)(60)$$

$$= 1.92$$

This compares with a test value of 1.71 from Reference 75.

7. Jet Flaps

Given: The pure jet-flap configuration of Reference 5.

Elliptic airfoil $\quad \frac{t}{c} = 0.125 \quad C_{\mu} = 4.0 \quad \frac{c'}{c} = 1.0$

$\frac{c_f}{c} = 0 \quad \delta_f = 0 \quad \alpha = 0 \quad \delta_j = 31.4^{\circ}$

Compute:

$k_t = 1.0$ (elliptic value)

$c_{\ell_{\delta_j}} = 9.60$ per rad (Figure 6.1.1.1-49)

$$\Delta c_{\ell} = \left\{ \left[1 + k_t \left(\frac{t}{c'} \right) \right] \delta_f \left(c_{\ell_{\delta_f}} - C'_{\mu} \right) + C'_{\mu} \delta_f \right.$$

$$\left. + \left[1 + k_t \left(\frac{t}{c'} \right) \right] \delta_j \left(c_{\ell_{\delta_j}} - C'_{\mu} \right) + C'_{\mu} \delta_j \right\} \frac{c'}{c} \qquad \text{(Equation 6.1.1.1-k)}$$

Since $\delta_f = 0$, the first two terms drop out.

$$\Delta c_{\ell} = [1 + (1.0)(0.125)] \frac{31.4}{57.3} (9.60 - 4.0) + 4.0 \left(\frac{31.4}{57.3} \right)$$

$$= 3.452 + 2.192$$

$$= 5.64 \text{ (based on } c)$$

This compares with a test value of 5.59 from Reference 5.

8. Leading-Edge Flaps

Given: The flapped airfoil of Reference 15.

NACA 0006 airfoil $\quad c_f/c = 0.15 \quad \delta_f = 20^o$

$M = 0.15$

Compute:

$c_{\ell_\delta} = -0.00286$ per deg (Figure 6.1.1.1-50)

$\Delta c_\ell = c_{\ell_\delta} \delta_f$ (Equation 6.1.1.1-ℓ)

$= (-0.00286)(20)$

$= -0.057$

This compares with a test value of −0.07 from Reference 15.

9. Leading-Edge Slats

Given: The flapped airfoil of Reference 69.

NACA 65A010 airfoil $\quad c_f/c = 0.17 \quad \delta_f = 25.6^o$

Low Speed $\quad R_\ell = 7.0 \times 10^6 \quad c'/c = 1.12$

Compute:

$c_{\ell_\delta} = -0.00350$ per deg (Figure 6.1.1.1-50)

$\Delta c_\ell = c_{\ell_\delta} \delta_f \frac{c'}{c}$ (Equation 6.1.1.1-m)

$= (-0.00350)(25.6)(1.12)$

$= -0.100$

This compares with a test value of −0.19 from Reference 69.

c' is the extended wing chord due to the deflection of the leading-edge device. In measuring c' the leading-edge device is rotated to the wing-chord line from its deflected position, about the point of intersection of the leading-edge-flap chord and the wing chord.

FIGURE 6.1.1.1-51 GEOMETRY OF LEADING-EDGE DEVICES

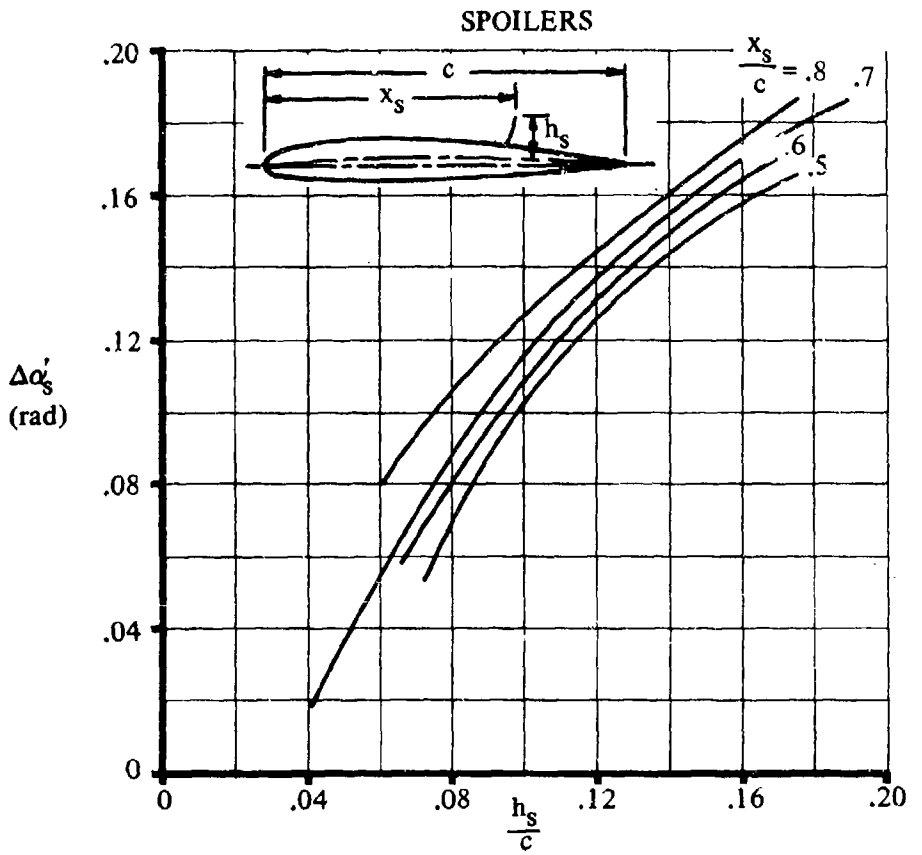

FIGURE 6.1.1.1-52 SPOILER LIFT EFFECTIVENESS – LOW SPEEDS

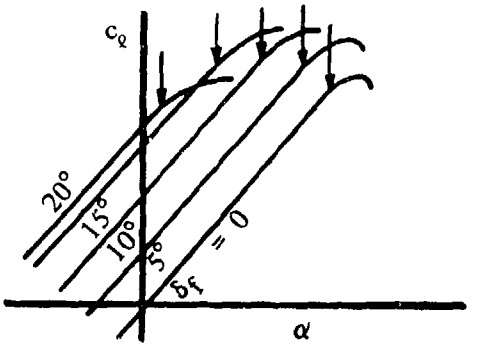
6.1.1.2 SECTION LIFT-CURVE SLOPE WITH HIGH-LIFT AND CONTROL DEVICES

Trailing-Edge Flaps

Thin-airfoil theory shows that the lift-curve slope of a cambered section is the same as that of the corresponding uncambered airfoil. Experimental data verify this theoretical prediction for the angle-of-attack and flap-deflection ranges for which the flow is attached over both the wing and flap surfaces.

Flow separation on the wing or flap causes the lift-curve slope to be lower than the theoretical value. Sketch (a) shows a typical set of lift curves for trailing-edge flaps at various deflections. The approximate points at which the curves become appreciably nonlinear for a given flap deflection are shown by the arrows.



SKETCH (a) TYPICAL LIFT CURVES FOR TRAILING-EDGE FLAPS

The sketch is typical of all types of trailing-edge flaps except split flaps, which have somewhat different lift characteristics. When a split flap is deflected, a reduced pressure exists in the wedge-shaped region between the flap and the wing. This reduced pressure creates a favorable pressure gradient near the wing trailing edge, which causes the boundary layer at the upper-surface trailing edge to be thinner for the flap-deflected condition than for the undeflected condition. Consequently, lift-curve slope for small split-flap deflections is greater than that of the unflapped airfoil. This effect is particularly pronounced on thick airfoils.

For flaps that translate as they deflect, the lift-curve slope is increased because of the increased effective area of the flapped section. Fowler flaps are the most commonly used flaps of this type.

Reference 1 contains a comprehensive summary of two-dimensional trailing-edge control-surface data, including data for the nonlinear angle-of-attack and flap-deflection ranges.

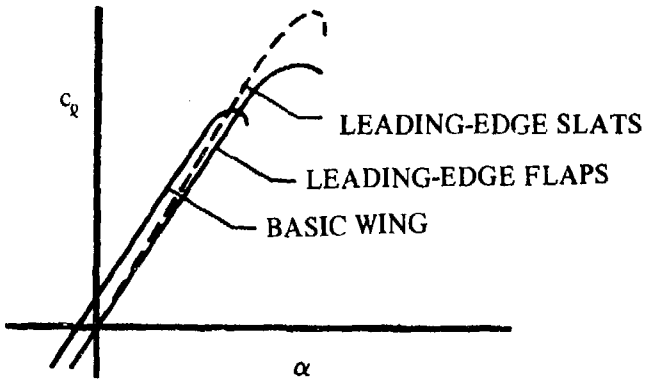
Jet Flaps

The lift-curve slope for a jet-flap airfoil is dependent upon the jet momentum trailing-edge coefficient C_μ. The method presented herein is Spence's adaptation of thin-airfoil theory as presented in References 2 and 3. In summary, Spence applies thin-airfoil theory to inviscid, incompressible flow past a thin, two-dimensional wing at a small incidence, with a jet of zero thickness and finite momentum emerging at a small angle of incidence from the trailing edge. The flow inside the jet is assumed to be irrotational and is bounded by vortex sheets that prevent mixing

with the mainstream. For flaps that extend as well as rotate, a correction is applied to account for the increased planform area. For more details regarding the fundamental concepts of jet flaps, the reader is referred to the discussion presented in Section 6.1.1.1.

Leading-Edge Flaps

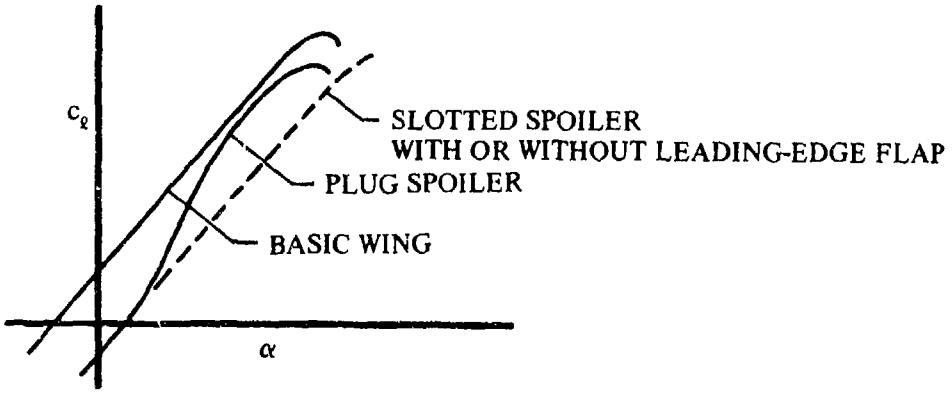
The lift-curve slope of an airfoil with a leading-edge flap is very nearly the same as that of the unflapped airfoil. For slats that extend forward as well as rotate, a correction must be made for the increased planform area. Typical lift curves are shown in Sketch (b).



SKETCH (b) TYPICAL LIFT CURVES FOR LEADING-EDGE FLAPS AND SLATS

Spoilers

The lift curves of airfoils with spoilers extended are extremely nonlinear, particularly at subsonic speeds. Sketch (c) shows a typical set of lift curves for an airfoil with and without plug and slotted spoilers. Leading-edge flaps in conjunction with plug spoilers tend to linearize the lift curve at high angles of attack. This effect is similar to that achieved by adding a slot and deflector behind a plug spoiler.



SKETCH (c) EFFECT OF SLOT AND LEADING-EDGE FLAP ON SPOILER LIFT CURVES

The Datcom methods presented below for trailing-edge flaps, jet flaps, leading-edge flaps and slats, and spoilers are limited to subsonic flow.

DATCOM METHODS

The approximate flap deflections at which flow separation and appreciable lift-curve-slope losses occur with increasing flap deflection are shown in Table 6.1.1.2-A for various types of flaps. Values for both good and poor designs are shown. Flap design is very critical to airfoil section and flap geometry. The effects of these variables on maximum lift are discussed in detail in Section 6.1.1.3.

1. Fixed-Hinge Trailing- and Leading-Edge Flaps

For these flaps the lift-curve slope is assumed to be the same as that of the unflapped section for unseparated flow conditions.

2. Translating Trailing-Edge Flaps and Leading-Edge Devices (Slats and Krueger Flaps)

For devices whose hinge line translates with deflection, the lift-curve slope is given by

$$\left(c_{\ell_\alpha}\right)_\delta = \frac{c'}{c}\left(c_{\ell_\alpha}\right)_{\delta=0} \qquad 6.1.1.2\text{-a}$$

where

$\left(c_{\ell_\alpha}\right)_{\delta=0}$ is the lift-curve slope of the unflapped airfoil, including compressibility effects, from Section 4.1.1.2

$\left(c_{\ell_\alpha}\right)_\delta$ is the lift-curve slope at leading- or trailing-edge deflection δ.

c is the chord of the unflapped airfoil.

c' is the effective chord of the flapped airfoil at any flap deflection. In measuring c' of a single-slotted trailing-edge flap or a leading-edge device, the flap or leading-edge device is rotated from its deflected position about the point of intersection of the flap or leading-edge-device chord with the wing chord, until the two coincide. In measuring c' of a double-slotted flap, the reader is referred to Figures 6.1.1.1-45 and 6.1.1.1-46.

3. Jet Flaps

The method presented here applies to the same configurations as indicated for the jet-flap method of Section 6.1.1.1; i.e., the pure jet flap and the internally-blown-flap (IBF) and externally-blown-flap (EBF) concepts with plain trailing-edge flaps. For an IBF or EBF concept with a single-slotted or multislotted flap configuration, this method should be used only as a first approximation.

No substantiation of the method is presented; however, the method has been acknowledged as being substantiated in the literature (References 4 and 5).

It should be noted that the term $[1 + k_t(t/c')]$ is used as a correction for airfoil thickness effects and applies to the pressure lift contribution calculated by thin-airfoil theory. This correction can be justified only if there is no trailing-edge separation.

For jet-flap configurations the total section lift-curve slope, based on the retracted airfoil chord, is given by

$$c_{\ell_\alpha} = \left\{\left[1 + k_t\left(\frac{t}{c'}\right)\right]\left(c'_{\ell_\alpha} - C'_\mu\right) + C'_\mu\right\}\frac{c'}{c} \qquad 6.1.1.2\text{-b}$$

where

k_t is the airfoil-theory thickness factor; i.e.,

k_t = 1.0 for elliptic airfoils

= 0.637 for parabolic airfoils

For airfoil sections other than elliptic or parabolic, a value of 0.80 for k_t is suggested (Reference 2).

$\frac{t}{c'}$ is the airfoil thickness ratio, based on the extended wing chord

c'_{ℓ_α} is the jet-flap lift-curve slope uncorrected for thickness effects obtained from Figure 6.1.1.1-49, based on the extended wing chord, as a function of C'_μ.

C'_μ is the section nondimensional trailing-edge jet momentum coefficient, based on the extended wing chord (defined in Sketch (a) of Section 6.1.1.1).

$\frac{c'}{c}$ is the ratio of the extended wing chord to airfoil chord, where c' is obtained as described in Section 6.1.1.1 for the appropriate flap geometry.

4. Spoilers

For the purposes of the Datcom the lift-curve slope of an airfoil with a spoiler, for the conditions $\alpha > 0$ and $c_\ell < 0$, is assumed to be the same as that of the basic airfoil.

Sample Problems

1. Translating Trailing-Edge Flap

Given: The flapped airfoil of Reference 7.

NACA 23012 airfoil Single-slotted flap $\delta_f = 30°$ $c'/c = 1.154$

$M = 0.105$; $\beta = 0.995$ $R_\ell = 3.5 \times 10^6$

$\tan 1/2\,\phi'_{TE} = 0.132$ (streamwise airfoil geometry)

Compute:

$$\left(c_{\ell_\alpha}\right)_{\delta=0} = 0.102 \text{ per deg} \quad \text{(Section 4.1.1.2)}$$

Solution:

$$\left(c_{\ell_\alpha}\right)_{\delta} = \frac{c'}{c}\left(c_{\ell_\alpha}\right)_{\delta=0} \quad \text{(Equation 6.1.1.2-a)}$$

$$= (1.154)\,(0.102)$$

$$= 0.118 \text{ per deg}$$

This compares with a test value of 0.120 per degree from Reference 7.

2. Jet Flap

Given: The pure jet-flap configuration of Reference 6.

Elliptic airfoil $\quad \frac{t}{c} = 0.125 \quad C_\mu = 4.0$

$$\frac{c_f}{c} = 0 \qquad \delta_f = 0 \qquad \delta_j = 31.4^\circ \qquad \frac{c'}{c} = 1.0$$

Compute:

$$k_t = 1.0 \text{ (elliptic airfoil)}$$

$$c'_{\ell_\alpha} = 13.63 \text{ per rad} \quad \text{(Figure 6.1.1.1-49)}$$

$$c_{\ell_\alpha} = \left\{\left[1 + k_t\left(\frac{t}{c'}\right)\right]\left(c'_{\ell_\alpha} - C'_\mu\right) + C'_\mu\right\}\frac{c'}{c} \quad \text{(Equation 6.1.1.2-b)}$$

$$= \left\{[1 + (1.0)(0.125)]\,(13.63 - 4.0) + 4.0\right\}\,1.0$$

$$= 14.83 \text{ per rad (based on c)}$$

This compares with a test value of 16.1 from Reference 6.

6.1.1.3 SECTION MAXIMUM LIFT WITH HIGH-LIFT AND CONTROL DEVICES

The maximum-lift increments obtainable by the use of leading- and trailing-edge flaps are strongly influenced by the flow characteristics of unflapped sections near the stall. The lift of unflapped sections near and at the stall is discussed in detail in Sections 4.1.1.3 and 4.1.1.4.

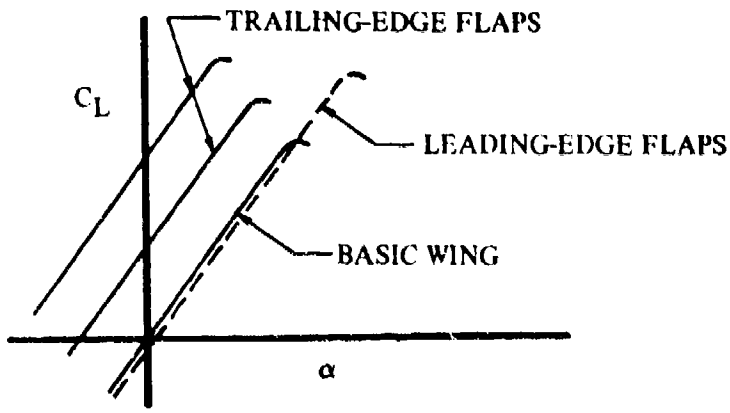
A discussion of the aerodynamic aspects of airfoil flaps is given in Reference 1, some of the more salient points of which are summarized in the following paragraphs.

Trailing-edge flaps increase the maximum lift of a section by means of the camber effect. Theoretically, the incremental load distribution due to flap deflection reaches a peak in the region of the flap hinge line, has a smaller peak at the leading edge, and falls to zero at the trailing edge. Thus the pressure gradient of the upper surface forward of the flap is relieved, although the gradient over the flap itself is greatly increased. The flow over the flap therefore separates at moderate angles, i.e., 10° to 15° for plain flaps. However, the separation is contained behind the flap hinge line and does not progress forward over the wing until the flap deflections become large. Lift continues to increase with flap deflection after separation takes place over the flap, but the rate of increase is considerably less than that for the small flap-deflection range where the flow is completely attached. Maximum lift is obtained just before the separation progresses forward of the flap or the flow separates from the leading edge.

Leading-edge flaps increase the maximum lift of airfoils by lowering the high peak suction pressures near the nose and thereby delaying leading-edge separation. Nose-flap deflection has only a second-order effect on the flow near the trailing edge. Maximum lift for a given flap deflection is achieved when the angle of attack is increased to the point where the pressure distribution around the nose approximates the pressure distribution of the unflapped section just before the stall. Leading-edge stall ensues as in the case of the unflapped section. This problem is treated theoretically in Reference 2.

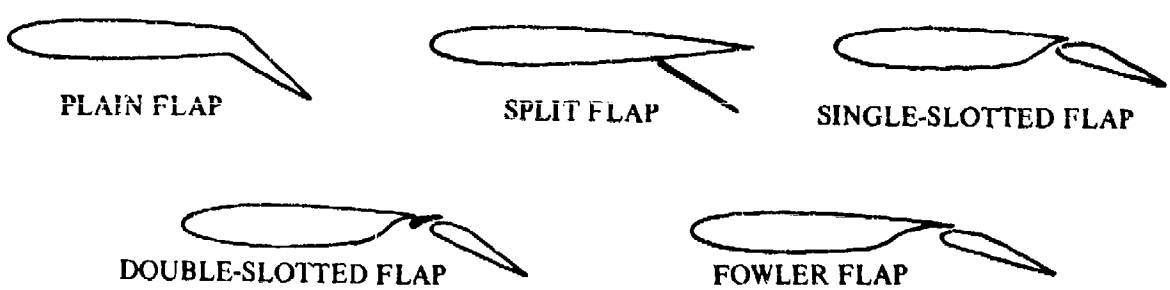
Thin airfoils stall as a result of leading-edge separation, and thick airfoils as a result of trailing-edge separation (see Section 4.1.1.3). Since trailing-edge flaps primarily affect trailing-edge separation without significantly altering the nose pressures, they are most effective on thick wings. Leading-edge flaps, on the other hand, delay leading-edge separation without significantly altering the trailing-edge flow and are therefore most effective on thin wings.

The stall angle of attack of an airfoil having a leading-edge flap is quite different from that of an airfoil having a trailing-edge flap. Leading-edge flaps produce increases in lift by enabling the airfoil to reach higher angles of attack. Therefore, the angle of attack at stall is considerably higher for an airfoil having a leading-edge flap than that for the unflapped airfoil. Trailing-edge flaps, on the other hand, produce increases in maximum lift by means of the camber effect and actually stall at an angle of attack below that of the unflapped airfoil. These trends are illustrated in the accompanying sketch. A consideration of these stalling angles is often a critical item in practice.



SKETCH (a) TYPICAL LIFT CURVES FOR LEADING-EDGE AND TRAILING-EDGE FLAPS

Specific comments concerning high-lift trailing-edge devices in common use are given in the following paragraphs. The accompanying sketch illustrates the various types of flaps. Not all of those shown are explicitly discussed.



SKETCH (b) TYPICAL TRAILING-EDGE FLAPS

Plain Flaps

The preceding discussion of trailing-edge flaps is applicable to plain flaps and no further comments are required.

Split Flaps

When a split flap is deflected, a region of reduced pressure exists between the upper surface of the flap and the lower surface of the airfoil. This reduced pressure creates a favorable pressure gradient over the top rear surface of the airfoil. Trailing-edge separation is thus suppressed, and final stall often occurs at the airfoil nose.

Slotted Flaps

The crucial factor in the design of a slotted flap is the slot. The slot sheds the boundary layer at the slot lip and allows a new boundary layer to develop over the flap. The slot also directs air in a direction tangential to the surface of the flap. Flow attachment can therefore be maintained to relatively large flap deflections. For instance, efficiently designed double-slotted flaps can prevent flow separation at deflections as high as 60°.

The design of slots for slotted flaps is very critical. Several rules of thumb have been developed for efficiently designing these flaps. First, the flap (and vane) and airfoil must overlap for all deflections when viewed in planform. Secondly, the jet issuing from the slot should also be directed in a direction tangential to the flap surface. Long shroud lengths often show advantages, since they have better control over the direction of the jet.

The flaps (and vanes) of a slotted flap carry considerably more lift than the corresponding plain flap with the same chord and deflection angle. These surfaces are, in reality, in tandem with the wing and derive beneficial induced-camber effects associated with tandem configurations.

Fowler Flaps

Aerodynamically, Fowler flaps function in the same way as single-slotted flaps. Additional lift benefits are obtained, however, from the increased chord due to translation of these flaps.

Jet Flaps

The recent developments in high-lift technology have led to the widespread consideration of the jet-flap scheme (see Section 6.1.1.1 for a sketch of the various types and a discussion of the salient aspects). Comments regarding the maximum lift increment due to power effects of a jet-flap scheme are given in the following paragraphs.

The increment in lift due to power effects of a jet-flap configuration is strongly dependent upon the trailing-edge jet momentum coefficient C_{μ}. Since the jet-flap theory as developed by Spence assumes inviscid flow, it cannot be utilized to predict the achievable maximum lift coefficient. An expression has been developed in Reference 3 for the increment in maximum lift of a two-dimensional jet-flapped airfoil with supercirculation. The analysis is limited to airfoils that exhibit a leading-edge stall. Under these circumstances it is suggested that the pressure distribution around the leading edge would be similar for the flapped- and plain-wing sections at stall.

Reference 4 summarizes an attempt to correlate test data with the method presented in Reference 3. The predicted values of $\Delta c_{\ell_{max}}$ due to power underestimated the experimental data by a considerable margin. These results tend to indicate that an airfoil with blowing does not stall at the same leading-edge pressure coefficient as the airfoil without blowing, but at considerably lower pressure coefficients. The test data used for the attempted correlation indicated a wide scatter band as a function of C_{μ}. This scatter prevents the application of an empirical modification to the method. Consequently, no method is presented herein. Further investigations are required and more test data needed to yield a more accurate and reliable method.

DATCOM METHODS

The following Datcom methods for trailing-edge and leading-edge flaps are limited to subsonic flow.

1. Trailing-Edge Flaps

An empirical method from Reference 2 for predicting maximum lift increments for plain, split, and slotted flaps is presented in Figures 6.1.1.3-12a through 6.1.1.3-13b. The maximum lift increment is given by

$$\Delta c_{\ell_{max}} = k_1 k_2 k_3 \left(\Delta c_{\ell_{max}}\right)_{base} \qquad 6.1.1.3\text{-a}$$

where

$\left(\Delta c_{\ell_{max}}\right)_{base}$ is the section maximum lift increment for 25-percent chord flaps at the reference flap-deflection angle from Figure 6.1.1.3-12a. (Reference flap-deflection angles are denoted in Figure 6.1.1.3-13a.)

k_1 is a factor accounting for flap-chord-to-airfoil-chord ratios other than 0.25 from Figure 6.1.1.3-12b.

k_2 is a factor accounting for flap deflections other than the reference values from Figure 6.1.1.3-13a.

k_3 is a factor accounting for flap motion as a function of flap deflection from Figure 6.1.1.3-13b.

A comparison of experimental data with results based on these charts is shown in Table 6.1.1.3-A.

2. Leading-Edge Flaps

A method is developed in Reference 5 for predicting the maximum lift increment for leading-edge flaps, slats, and Krueger flaps. The method is based on an extension of thin-airfoil theory, using empirical factors that were developed using available test data.

The available Krueger-flap test data were found to be dependent largely upon the trailing-edge flap deflection. Consequently, the method for Krueger flaps from Reference 5 is not presented, since it does not account for the trailing-edge flap deflections.

The method presented herein gives reasonable results when applied to leading-edge flap deflections less than 30°, as indicated by the comparison of test data with predicted results, shown in Table 6.1.1.3-B.

For leading-edge slats it is not advisable to use the method herein for deflections greater than 20°. The method tends to overpredict the maximum lift increment for larger deflections, as shown in Table 6.1.1.3-B.

The maximum lift increment for leading-edge flaps and slats is given by

$$\Delta c_{\ell_{max}} = c_{\ell_{\delta_{max}}} \eta_{max} \eta_{\delta} \delta_f \frac{c'}{c} \qquad 6.1.1.3\text{-b}$$

where

$c_{\ell_{\delta_{max}}}$ is the theoretical maximum lifting effectiveness obtained from Figure 6.1.1.3-14 as a function of the leading-edge flap-chord ratio c_f/c.

η_{max} is the empirical factor accounting for the maximum lifting efficiency obtained from Figure 6.1.1.3-15 as a function of the ratio of the leading-edge radius to the thickness ratio of the airfoil.

The reason for the discontinuity in the slat curve presented in Figure 6.1.1.3-15 is that older NACA test data are used to establish the left-hand portion of the curve, while more recent test data (as indicated in Reference 5) are used for the right-hand portion. An attempt was made to resolve this discontinuity; however, no modifications were made because of the lack of test data in the region of the discontinuity.

η_{δ} is the empirical factor accounting for changes in flap deflection from the optimum deflection obtained from Figure 6.1.1.3-16 as a function of deflection angle.

δ_f is the leading-edge deflection angle in radians (see Figure 6.1.1.1-51).

$\frac{c'}{c}$ is the ratio of the extended wing chord due to leading-edge flap extension to the retracted wing chord (see Figure 6.1.1.1-51).

Sample Problems

1. Trailing-Edge Flap

Given: The flapped airfoil of Reference 6.

NACA 65-210 airfoil Double-slotted flap $\delta_{f_1} = 15^o$ $\delta_{f_2} = 25^o$

$\delta_f = 40^o$ $c_f/c = 0.312$ $R_{\ell} = 6.0 \times 10^6$

Compute:

$\left(\Delta c_{\ell_{max/base}}\right) = 1.165$ (Figure 6.1.1.3-12a)

$k_1 = 1.250$ (Figure 6.1.1.3-12b, extrapolated)

$k_2 = 0.950$ (Figure 6.1.1.3-13a)

$$\frac{\text{Actual Flap Angle}}{\text{Reference Flap Angle}} = \frac{40}{50} = 0.80$$

$k_3 = 0.870$ (Figure 6.1.1.3-13b)

Solution:

$$\Delta c_{\ell_{max}} = k_1 k_2 k_3 \left(\Delta c_{\ell_{max}}\right)_{base} \quad \text{(Equation 6.1.1.3-a)}$$

$$= (1.250)(0.950)(0.870)(1.165)$$

$$= 1.20$$

This compares with a test value of 1.33 from Reference 6.

2. Leading-Edge Flap

Given: The flapped airfoil of Reference 7.

NACA 64A010 airfoil • Leading-edge radius = 0.687% c

$\frac{t}{c} = 0.10$ Nose flap $\delta_f = 30^o$ $\frac{c_f}{c} = 0.15$ $\frac{c'}{c} = 1.0$

Compute:

$c_{\ell_{\delta_{max}}} = 1.44$ per rad (Figure 6.1.1.3-14)

$\eta_{max} = 0.99$ (Figure 6.1.1.3-15)

$\eta_\delta = 0.82$ (Figure 6.1.1.3-16)

Solution:

$$\Delta c_{\ell_{max}} = c_{\ell_{\delta_{max}}} \eta_{max} \eta_\delta \delta_f \frac{c'}{c} \quad \text{(Equation 6.1.1.3-b)}$$

$$= (1.44)(0.99)(0.82)\ \frac{30}{57.3}\ (1.0)$$

$$= 0.612$$

This compares with a test value of 0.56 from Reference 7.

6.1.2 SECTION PITCHING MOMENT WITH HIGH-LIFT AND CONTROL DEVICES

6.1.2.1 SECTION PITCHING-MOMENT INCREMENT Δc_m DUE TO HIGH-LIFT AND CONTROL DEVICES

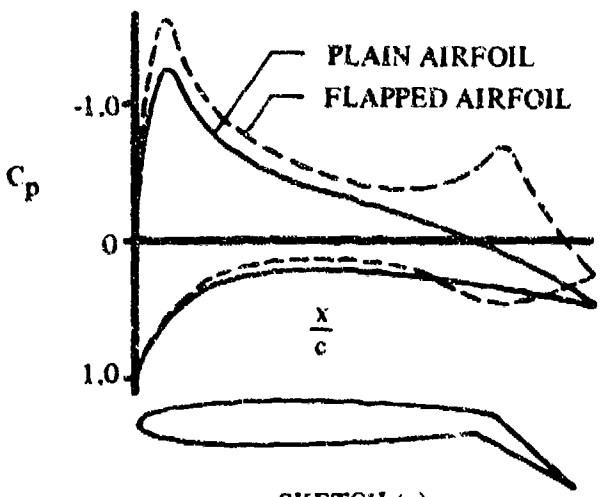
The use of high-lift and control devices alters the basic airfoil load distribution, thus affecting the section pitching moment, as well as the lift.

Methods are presented in this section for estimating the pitching-moment characteristics for most common high-lift devices in use today and for some of the blown flaps being considered for STOL aircraft. These methods are valid only in the subsonic regime in the linear-lift region (preferably near zero angle of attack). The effect of these devices on the variation of pitching moment with angle of attack is presented in Section 6.1.2.2, except for the jet flap, which is presented in this section. Considerations of clarity and simplicity of presentation dictated this deviation from standard Datcom practice.

The assumption is made that the characteristics of a trailing-edge flap are independent of any leading-edge device, and/or the characteristics of a leading-edge device are independent of any mechanical trailing-edge flap. In reality this is not quite true, but the methods of this section are not sufficiently refined to account for these interference effects. This assumption cannot be justified in the case of the more powerful jet flap.

Trailing-Edge Mechanical Flaps

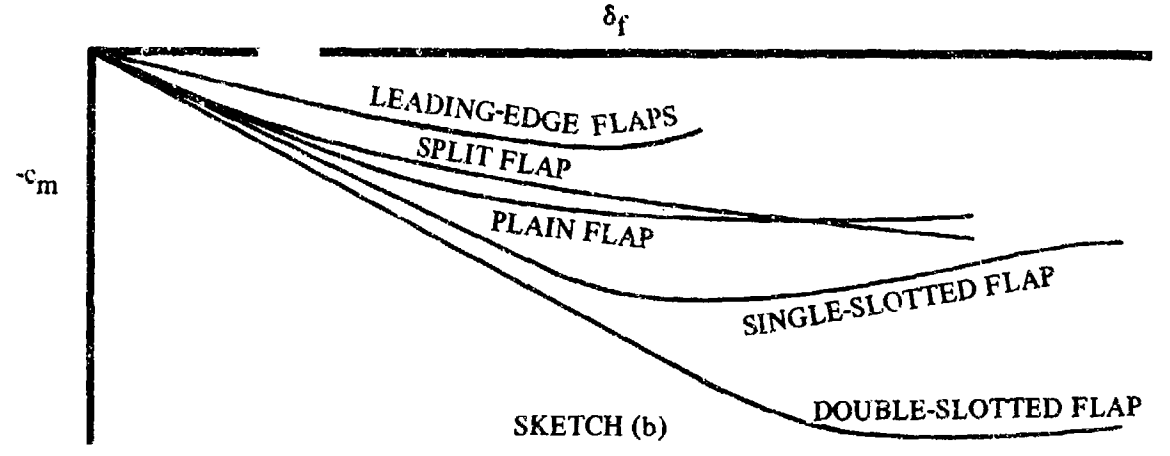
Sketch (a) shows a typical loading on an airfoil with a plain flap deflected and undeflected. The incremental load due to the flap exhibits a peak over the airfoil leading edge and a peak over the hinge line. The higher loading at the hinge predominates, giving a nose-down moment.



SKETCH (a)

For conditions where the flow is attached, the center-of-pressure location of the additional load due to flaps does not shift position with flap deflection. Therefore, the pitching moment is directly proportional to the lift increment. As the flow breaks down, the center of pressure usually moves forward by a small amount, causing a mild pitch-up. The Datcom method is fairly accurate, even for high values of flap deflection.

Sketch (b) illustrates typical flap pitching-moment curves plotted as a function of flap deflection for a given ratio of flap chord to wing chord. The lift and pitching-moment variation with flap angle are usually linear as long as the flow is attached. Plain flaps maintain attached flow and exhibit linear characteristics at small angles of attack and flap deflections. Single-, double-, and triple-slotted flaps assure attached flow for increasingly higher angles of incidence and flap deflections and give linear characteristics over a much larger range. Split flaps have no significant range of linear characteristics as a result of the wide wake caused by the split trailing edge.



SKETCH (b)

Theoretically, the center-of-pressure location is a function of the ratio of the flap chord to airfoil chord, showing a forward shift with increasing flap-chord ratios. Although test data for plain and split flaps do not match the theoretical center-of-pressure location, they do show the same trend as theory. Slotted flaps do not follow this trend. Data for slotted flaps were analyzed for extended airfoil chords of 10 to 40 percent. Virtually all of the data indicated a center-of-pressure location between 41 and 47 percent of the extended airfoil chord, showing no dependence upon the ratio of flap chord to airfoil chord. Therefore, an average center-of-pressure location of 44 percent has been assumed (see Figure 6.1.2.1-35a) for all slotted flaps, independent of the ratio of flap chord to airfoil chord.

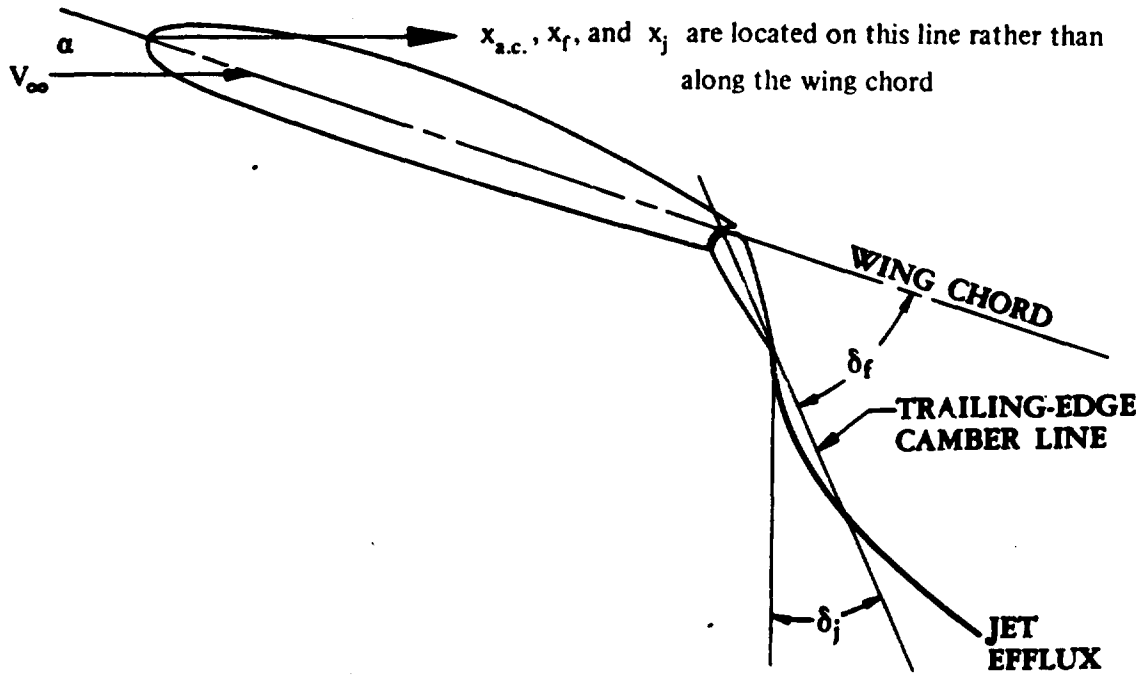
Leading-Edge Mechanical Devices

Leading-edge devices produce a nose-down pitching moment, similar to trailing-edge flaps, because they delay the stall by lowering the high peak loading at the leading edge. The method presented is for conventional leading-edge devices, based on thin-wing theory from Reference 1. Efforts to substantiate this method by using available test data have proved unsatisfactory. The test data exhibit nonlinear characteristics which linear theory is intrinsically unable to handle. Therefore, this method should be applied only to thin airfoils with small leading-edge devices.

Jet Flaps

The pitching-moment increment for a jet-flap airfoil is dependent upon the jet momentum trailing-edge coefficient C'_μ and the ratio of flap chord to the extended wing chord. The method presented herein is Spence's adaptation of thin-airfoil theory as presented in Reference 2. In summary, Spence applies thin-airfoil theory to inviscid, incompressible flow past a thin, two-dimensional wing at small incidence, with a jet emerging at a small angle of incidence from the trailing edge. The flow inside the jet is assumed to be irrotational. In addition, the jet is bounded by vortex sheets that prevent mixing with the mainstream and maintains finite momentum as its thickness decreases to zero. For flaps that extend as well as rotate, a correction is applied to account for the increased chord length.

The definitions of aerodynamic center $x_{a.c.}$ and center of pressure $x_{c.p.}$ are well established for conventional aircraft. However, for jet-flap configurations the jet reaction is a new component that must be accounted for when considering the location of the aerodynamic center and center of pressure. In order to maintain consistency, the Datcom defines the aerodynamic center for jet-flap configurations as that point about which the *total* pitching moment is invariant with the *total* lift; i.e., $dC_m/dC_L = 0$ at a given Mach number and trailing-edge jet momentum coefficient. In essence, the aerodynamic center is a function of the trailing-edge jet momentum coefficient C_μ. For conventional wing sections the aerodynamic center is located on the wing chord line. However, for jet-flap configurations it becomes necessary to define the measurement of $x_{a.c.}$ off the wing-chord line, as shown in Sketch (c), to simplify the calculation of the pitching moment about any reference location.



$$\frac{x_f}{c} = -\frac{c_{m_{\delta_f}}}{c_{\ell_{\delta_f}}} \qquad \frac{x_j}{c} = -\frac{c_{m_{\delta_j}}}{c_{\ell_{\delta_j}}}$$

where

$c_{m_{\delta_f}}$ is the flap pitching-moment effectiveness measured about the leading edge.

$c_{\ell_{\delta_f}}$ is the rate of change of section lift effectiveness due to flap deflection.

$c_{m_{\delta_j}}$ is the rate of change of pitching-moment coefficient measured about the leading edge with respect to the jet deflection. (The parameters $c_{m_{\delta_j}}$ and $c_{\ell_{\delta_j}}$ are due to the jet efflux not being emitted at the same angle as the trailing-edge camber line, i.e., the flap deflection.)

$c_{\ell_{\delta_j}}$ is the rate of change of section lift coefficient with respect to the jet deflection.

SKETCH (c) JET-FLAP AERODYNAMIC CENTER AND CENTER OF LIFT

There are two additional parameters shown and defined in Sketch (c), x_f and x_j. The center-of-lift term x_f is analogous to the conventional flap center-of-pressure location, except that it also includes the reaction component of the jet. For this reason it is not the true "center-of-pressure location"; i.e., it is the location where the total lift increment due to flap deflection is assumed to act.

The term x_j is analogous to a center-of-pressure location of the incremental load due to the jet efflux acting at an angle to the trailing-edge camber line. However, it is not a true center-of-pressure location for this incremental load, because of the inclusion of the reaction component; therefore, it is also referred to as the center of lift.

For more details regarding the fundamental concepts of jet flaps, the reader is referred to the discussion presented in Section 6.1.1.1. (Sketch (b) of Section 6.1.1.1 illustrates some of the blown-flap concepts now being investigated for STOL aircraft.)

Spoilers

Pitching-moment changes due to spoilers are generally smaller than those for flap-type control surfaces. For this reason they are useful on thin, swept wings where wing twist due to control deflection is a problem. Many wind-tunnel programs have therefore been conducted on swept wings, but few have been conducted on airfoil sections. Reference 3, published in 1953, contains a comprehensive bibliography of spoiler studies made up to that time.

Because of the scarcity of two-dimensional spoiler data, no generalized methods are presented in this section for section pitching moment due to spoiler deflection.

DATCOM METHODS

1. Trailing-Edge Mechanical Flaps

Two methods are presented for estimating the section pitching-moment increment due to the deflection of mechanical trailing-edge flaps. Method 1 is applicable to plain, split, and multislotted flaps with or without extensible flaps. Method 2 is applicable only to plain flaps.

In view of the ease of application of Method 2 and the fact that it predicts plain-flap section pitching moments as accurately as Method 1 does, Method 2 is the preferred Datcom plain-flap method.

Method 1 (Plain, Split, and Multislotted Flaps)

This method is empirical in nature and limited to the low-speed regime. The section pitching-moment increment due to trailing-edge flaps, based on the square of the wing chord c^2, is given by

$$\Delta c_m = \Delta c_\ell \left[\frac{x_{ref}}{c} - \left(\frac{x_{c.p.}}{c'} \right) \left(\frac{c'}{c} \right) \right] \qquad 6.1.2.1\text{-a}$$

where

Δc_ℓ is the lift increment for a given flap type and deflection, from test data or as determined by the appropriate method of Section 6.1.1.1.

$\frac{x_{ref}}{c}$ is the desired pitching-moment reference point expressed as a fraction of the basic airfoil chord, measured positive aft from the airfoil leading edge, parallel to the wing chord.

$\frac{x_{c.p.}}{c'}$ is the center-of-pressure location of the incremental load due to flaps, expressed as a fraction of the extended airfoil chord, measured positive aft from the airfoil leading edge, parallel to the wing chord. This parameter is obtained from Figure 6.1.2.1-35a as a function of the ratio of flap chord to airfoil chord c_f/c.

$\frac{c'}{c}$ is the ratio of the extended wing chord to the airfoil chord as shown in Figures 6.1.1.1-44 through -46.

A comparison of low-speed test data with calculated values of Δc_m using this method is presented in Tables 6.1.2.1-A and -C through -E.

Method 2 (Plain Flaps)

Pitching-moment increments for plain trailing-edge flaps are presented in Figure 6.1.2.1-35b. These increments are given about the quarter-chord, based on the square of the airfoil chord c^2, as a function of flap deflection and the ratio of flap chord to airfoil chord c_f/c. This figure is limited to the linear-lift range and subcritical Mach numbers.

A comparison of low-speed test data with Δc_m calculated by this method is presented in Table 6.1.2.1-B.

2. Conventional Leading-Edge Devices

The section pitching-moment increment due to mechanical leading-edge devices, based on the square of the wing chord c^2, is given by thin-airfoil theory as

$$\Delta c_{m_{LE}} = c'_{m_{\delta_{LE}}} \left(\frac{c'}{c}\right)^2 \delta_{f_{LE}} + \left(\frac{x_{ref}}{c} + \frac{c' - c}{c}\right) \Delta c_\ell + c_m \left[\left(\frac{c'}{c}\right)^2 - 1\right] + 0.75\, c_\ell \left(\frac{c'}{c}\right)\left(\frac{c'}{c} - 1\right) \qquad 6.1.2.1\text{-b}$$

where

c'_{m_δ} is the theoretical flap pitching-moment effectiveness (about the leading edge), obtained from Figure 6.1.2.1-36 as a function of the ratio of the leading-edge flap chord to the extended airfoil chord $c_{f_{LE}}/c'$.

$\frac{c'}{c}$ is the ratio of the extended wing chord to the basic airfoil chord as shown in Figure 6.1.1.1-51.

$\delta_{f_{LE}}$ is the deflection of the leading-edge device in degrees (see Figure 6.1.1.1-51).

$\frac{x_{ref}}{c}$ is the desired pitching-moment reference point expressed as a fraction of the basic airfoil chord, measured positive aft from the airfoil leading edge with the leading-edge device retracted, parallel to the wing chord.

Δc_ℓ is the lift increment due to a given leading-edge-device deflection, from test data or as determined by the appropriate method in Section 6.1.1.1, based on c.

c_m is the section pitching-moment coefficient with the flaps retracted, based on c^2. This parameter should be obtained from the test data, if available, or from Section 4.1.2.1.

c_ℓ is the section lift coefficient with the flaps retracted, based on c. This parameter should be obtained from test data, if available, or from Sections 4.1.1.1 and 4.1.1.2.

The use of this method is demonstrated in Sample Problem 3.

3. Jet Flaps

Methods that are adaptable to a handbook application are not available for all jet-flap schemes. The method presented below is applicable to the pure jet-flap concept, and the internally-blown-flap (IBF) and externally-blown-flap (EBF) concepts with a plain trailing-edge flap. For an IBF or EBF concept with a single-slotted or multislotted flap configuration, this method should be used only as a first approximation. No handbook method is currently available to analyze the section pitching-moment increment due to an augmentor-wing concept.

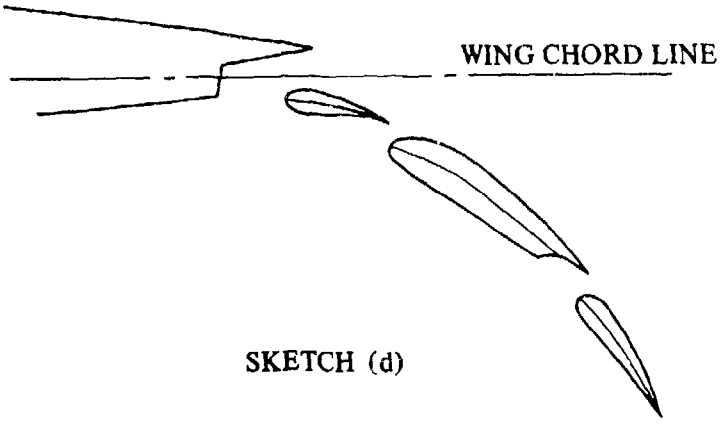
For EBF flaps the user is cautioned that if the flap does not "capture" or "intercept" all of the jet exhaust, the result of this method may be erroneous. Reference 57 considers a design where part of the jet passes below the flap. Furthermore, a technique to be used in analyzing such a design is proposed. Unfortunately, this technique is cumbersome, and no satisfactory cases to check its accuracy have been found in the available literature. Therefore, it is not included in the Datcom. It should be noted, however, that the lack of such a technique is not a serious restriction, since most configurations avoid the problem by use of jet deflectors and/or canted thrust axes to ensure that the entire engine exhaust is flattened and directed at the flap knee.

It should be noted that the airfoil thickness correction used in the method of Section 6.1.1.1 in determining the section lift increment of a jet-flap combination (see Equation 6.1.1.1-p) does not apply to the section pitching moment. Therefore, the lift coefficients calculated in this section for use in determining section pitching moment are not the same as those calculated in Sections 6.1.1.1 and 6.1.1.2 and should be considered only as intermediate values generated during the calculation of the pitching moment. The actual lift of the airfoil must be calculated by using the more exact procedures of Sections 6.1.1.1 and 6.1.1.2.

The user is reminded that the theory on which this method is based is linear and as such cannot predict any nonlinearities; e.g., those that may arise from separated flow.

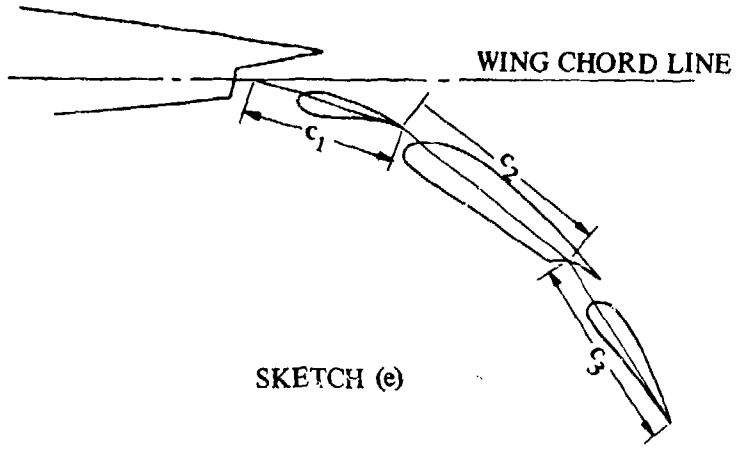
The flap deflection angles and the flap-chord values to be used in this method are not defined in the conventional manner. Instead, the user must use his best judgment to approximate the particular flap system by constructing a simple-hinged multideflected flap system. The primary goal of the simple-hinged multideflected flap system is to duplicate the mean-camber-line distribution of the actual flap system. A schematic illustration is presented in the following discussion (Sketches (d) through (f)) that depicts the determination of the flap chords and flap angles for a triple-slotted-flap system. The treatment of less complex flap systems follows from this example.

Determine the mean-camber-line distributions of the flap components as in Sketch (d).



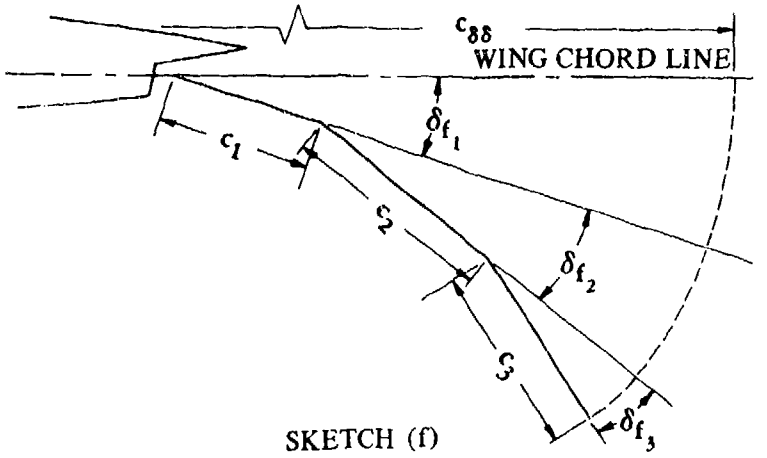
SKETCH (d)

Approximate the actual mean-camber-line distribution with straight-line segments (keeping in mind the total mean-camber-line distribution) as in Sketch (e). Extend the straight-line segments until they intersect each other, so as to define the flap-chord lengths as shown.



SKETCH (e)

Determine the flap deflection angles from the straight-line segments relative to the wing chord line as shown in Sketch (f).



SKETCH (f)

The determination of the extended wing-chord $c_{\delta\delta}$ in Sketch (f) is found by the following procedure. The aft flap segment c_3 is first rotated from its deflected position about the point of intersection of c_2 and c_3, until the two chords coincide. Then the total chord of c_2 and c_3 is rotated about the intersection of c_1 and c_2 until these two chords coincide. Then the total chord of c_1, c_2, and c_3 is rotated about the intersection of the wing chord and c_1 until it intersects the wing chord.

In the method outlined below, the computation of the pitching moment is broken down into components due to the leading-edge device, the angle of attack, the mechanical flap, and the jet flap. This division can be somewhat misleading because in each term there appears the parameter $c_{\delta\delta}/c$, which is the ratio of the airfoil chord with all flaps extended to the basic airfoil chord. Thus each term is actually dependent upon the total extended airfoil chord $c_{\delta\delta}$. For example, a change in $c_{\delta\delta}$ due to a deflection of the leading-edge device will affect the contribution of each component, not just the component due to the leading-edge device.

No substantiation is given for the method presented below; however, the method has been acknowledged in the literature as being accurate to within 10 percent (References 12 and 16). Although an insufficient number of configurations have been analyzed to provide a meaningful substantiation table, the ones that have been analyzed indicate that this method is more accurate in estimating the pitching-moment change with flap angle than in estimating the variation of pitching moment with angle of attack. This may be accounted for by the tendency of wings developing very high lift coefficients to have significant flow separation even at low angles of attack. The variation in the amount of separated flow with angle of attack may be affecting c_{m_α} significantly.

The section pitching-moment increment of an airfoil due to a trailing-edge jet flap at an angle of attack, based on the square of the wing chord c^2, is given by

$$\Delta c_m = (\Delta c_m)_{\delta f_{LE}} + (\Delta c_m)_\alpha + (\Delta c_m)_{\delta f} + (\Delta c_m)_{\delta_j} \qquad 6.1.2.1\text{-c}$$

where

$(\Delta c_m)_{\delta f_{LE}}$ is the pitching-moment increment due to the deflection of a leading-edge device. (If there is no leading-edge device, $(\Delta c_m)_{\delta f_{LE}} = 0$.)

$(\Delta c_m)_\alpha$ is the pitching-moment increment due to the angle of attack of the airfoil. (If $\alpha = 0$, $(\Delta c_m)_\alpha = 0$.)

$(\Delta c_m)_{\delta f}$ is the pitching-moment increment due to trailing-edge flaps. The flap system is treated as a series of plain flaps using the principle of superposition. The pitching moments of all of these flaps are then summed to give the total. This is illustrated schematically in Sketch (g) by using a triple-slotted flap. The treatment of less complex flap systems follows from this example. (For airfoils with no trailing-edge mechanical flaps, $(\Delta c_m)_{\delta f} = 0$.)

$(\Delta c_m)_{\delta_j}$ is the pitching-moment increment due to the jet sheet acting at an angle δ_j to the trailing-edge camber line. This term may be present with a pure jet flap, or in the case of EBF and IBF systems where the total turning angle of the jet exceeds the total deflection angle of the mechanical flap segments. (If $\delta_j = 0$, $(\Delta c_m)_{\delta_j} = 0$.)

SKETCH (g)

The above terms of Equation 6.1.2.1-c are evaluated by using Steps 1 through 4, respectively, below.

Step 1. Determine $(\Delta c_m)_{\delta_{f_{LE}}}$ by

$$(\Delta c_m)_{\delta_{f_{LE}}} = \Delta c_1 \, x_1 - \Delta c_2 \, x_2 + \Delta c_{m_3} \qquad 6.1.2.1\text{-d}$$

a. Evaluate the following expressions:

$$\Delta c_1 = \frac{\delta_{f_{LE}}}{57.3} K \, c_{\ell_{\delta_a}} \qquad 6.1.2.1\text{-e}$$

$$\Delta c_2 = \frac{\delta_{f_{LE}}}{57.3} K \, c_{\ell_\alpha} \qquad 6.1.2.1\text{-f}$$

where

$\Delta c_1, \Delta c_2$ are terms analagous to section lift coefficients. However, the thickness correction is not applied.

$\delta_{f_{LE}}$ is the deflection of the leading-edge device in degrees, as shown in Figure 6.1.1.1-51.

K is equal to $c_{\delta\delta}/c$, the ratio of the extended wing chord to the retracted wing chord. (Note that the extended wing chord includes the extensions of both leading- and trailing-edge flaps. The definition of the extended chord lengths is shown in Figures 6.1.1.1-44 through -46 for trailing-edge flaps and Figure 6.1.1.1-51 for leading-edge flaps.)

$c_{\ell_{\delta_a}}$ is the section lift effectiveness due to the deflection of a hypothetical flap of chord c_a.

$$c_a = c_{\delta\delta} - c_{f_{LE}} \qquad 6.1.2.1\text{-g}$$

where $c_{f_{LE}}$ is the chord of the leading-edge flap defined in Figure 6.1.1.1-51. This parameter is obtained from Figure 6.1.1.1-49 as a function of $c_a/c_{\delta\delta}$* and the trailing-edge jet momentum C'_μ. C'_μ is the section nondimensional trailing-edge jet momentum coefficient based on the extended airfoil chord $c_{\delta\delta}$, $C'_\mu = C_\mu \frac{c}{c_{\delta\delta}}$ (see Sketch (a) Section 6.1.1.1).

*When using Figure 6.1.1.1-49 in this section, it is necessary to substitute $c_a/c_{\delta\delta}$ or $c_f/c_{\delta\delta}$ for c_f/c' on the figure.

c_{ℓ_α} is the jet-flap lift-curve slope obtained from Figure 6.1.1.1-49 at $c_f/c_{\delta\delta} = 1$,* as a function of the trailing-edge jet momentum coefficient C'_μ.

b. Determine the corresponding moment arms:

$$x_1 = \frac{x_m}{c} + \left(\frac{c'_{LE}}{c} - 1\right) - \frac{x_a}{c_{\delta\delta}} \frac{c_{\delta\delta}}{c} \qquad 6.1.2.1\text{-h}$$

$$x_2 = \frac{x_m}{c} + \left(\frac{c'_{LE}}{c} - 1\right) - \frac{x_{a.c.}}{c_{\delta\delta}} \frac{c_{\delta\delta}}{c} \qquad 6.1.2.1\text{-i}$$

where

$\frac{x_m}{c}$ is the desired pitching-moment reference point expressed as a fraction of the basic airfoil chord, measured positive aft from the basic airfoil leading edge, parallel to the wing chord.

$\frac{c'_{LE}}{c}$ is the ratio of the airfoil chord with only the leading-edge device extended to the basic airfoil chord.

$\frac{x_a}{c_{\delta\delta}}$ is the center-of-lift location of the incremental load due to flap deflection. This parameter is obtained from Figure 6.1.2.1-37 as a function of $c_a/c_{\delta\delta}$ and the trailing-edge jet momentum C'_μ. It is measured positive aft from the extended-airfoil leading edge, parallel to the free stream.

$\frac{x_{a.c.}}{c_{\delta\delta}}$ is the aerodynamic-center location obtained from Figure 6.1.2.1-37 at $c_f/c_{\delta\delta} = 1.0$, as a function of C'_μ. It is measured positive aft from the extended-airfoil leading edge, parallel to the free stream.

$\frac{c_{\delta\delta}}{c}$ is defined in Step 1a. (See definition of K.)

c. Determine Δc_{m_3} from

$$\Delta c_{m_3} = C_\mu \frac{c_{f_{LE}}}{c} \sin \delta_{f_{LE}} \qquad 6.1.2.1\text{-j}$$

*When using Figure 6.1.1.1-49 in this section, it is necessary to substitute $c_a/c_{\delta\delta}$ or $c_f/c_{\delta\delta}$ for c_f/c' on the figure.

where

C_μ is the section nondimensional trailing-edge jet momentum coefficient based on the basic airfoil chord (see Sketch (a) Section 6.1.1.1).

$\frac{c_{f_{LE}}}{c}$ is the ratio of the chord of the leading-edge flap, as defined in Figure 6.1.1.1-51, to the basic airfoil chord.

$\delta_{f_{LE}}$ is defined in Step 1a.

Step 2. Determine $(\Delta c_m)_\alpha$ by

$$(\Delta c_m)_\alpha = \Delta c_4 \, x_2 + \Delta c_{m4} \qquad 6.1.2.1\text{-k}$$

a. Evaluate Δc_4 from

$$\Delta c_4 = \frac{\alpha}{57.3} K \, c_{\ell_\alpha} \qquad 6.1.2.1\text{-}\ell$$

where

Δc_4 is a term analagous to the section lift coefficient. However, the thickness correction is not applied.

α is the angle of attack of the airfoil in degrees.

K and c_{ℓ_α} are defined in Step 1a above.

b. Evaluate Δc_{m4} from

$$\Delta c_{m4} = -C_\mu \left[\frac{x_m}{c} + \left(\frac{c'_{LE}}{c} - 1 \right) \right] \frac{\alpha}{57.3} \qquad 6.1.2.1\text{-m}$$

All terms have been previously defined in the preceding steps.

Step 3. Determine $(\Delta c_m)_{\delta_f}$ from

$$(\Delta c_m)_{\delta_f} = \sum_{i=1}^{n} (\Delta c_5)_i \, (x_5)_i \qquad 6.1.2.1\text{-n}$$

The subscript n refers to the total flap segments; i.e., in triple-slotted flaps, n = 3, double-slotted flaps, n = 2, and single-slotted or plain flaps, n = 1. The subscript i refers to a particular flap segment, where the forward segment is 1 and the aft segment is n.

a. Evaluate $(\Delta c_5)_i$ from

$$(\Delta c_5)_i = \frac{\delta_{f_i}}{57.3} K c_{\ell_{\delta f_i}} \qquad 6.1.2.1\text{-o}$$

where

$(\Delta c_5)_i$ is a term analagous to the section lift coefficient. However, the thickness correction is not applied.

δ_{f_i} is the deflection of the i^{th} flap segment in degrees. The value of the last flap segment used in this instance depends upon the effective jet angle $\delta_{j_{eff}}$, determined by using Equation 6.1.4.1-d of Section 6.1.4.1 or obtained from test data. If $\delta_{j_{eff}} > \sum_{i=1}^{n} \delta_{f_i}$, then the last flap deflection is that determined from constructing the straight line elements relative to the wing-chord line as depicted in Sketches (f) and (g). If $\delta_{j_{eff}} \leq \sum_{i=1}^{n} \delta_{f_i}$, then the last flap deflection is given by

$$\delta_{f_n} = \delta_{j_{eff}} - \sum_{i=1}^{n-1} \delta_{f_i} \qquad 6.1.2.1\text{-p}$$

$c_{\ell_{\delta f_i}}$ is the rate of change of section lift coefficient with respect to flap deflection. The value is obtained from Figure 6.1.1.1-49 as a function of the trailing-edge jet momentum coefficient C'_μ and the ratio of the flap chord (of the i^{th} flap segment) to the extended airfoil chord $c_{f_i}/c_{\delta\delta}$. For flaps with Fowler-type motion, the flap chord is defined as shown in Sketch (g).

K is defined in Step 1a.

b. Determine the corresponding moment arm

$$(x_5)_i = \frac{x_m}{c} + \left(\frac{c'_{LE}}{c} - 1\right) - \frac{x_{f_i}}{c_{\delta\delta}} \frac{c_{\delta\delta}}{c} \qquad 6.1.2.1\text{-q}$$

where

$\frac{x_{f_i}}{c_{\delta\delta}}$ is the center-of-lift location of the incremental load due to the deflection of the i^{th} flap segment. This parameter is obtained from Figure 6.1.2.1-37 as a function of the trailing-edge jet momentum C'_μ and the ratio of the flap chord to the extended wing-chord $c_{f_i}/c_{\delta\delta}$.

All other terms have been defined in Step 1b above.

Step 4. Determine $(\Delta c_m)_{\delta_j}$ from

$$(\Delta c_m)_{\delta_j} = \Delta c_6 \, x_6 \qquad 6.1.2.1\text{-r}$$

a. Evaluate Δc_6 from

$$\Delta c_6 = \frac{\delta_j}{57.3} K \, c_{\ell_{\delta_j}} \qquad 6.1.2.1\text{-s}$$

where

Δc_6 is a term analagous to the section lift coefficient. However, the thickness correction is not applied.

δ_j is the deflection of a pure jet flap, in degrees, relative to the trailing-edge camber line (see Sketch (g)). For IBF and EBF systems if

$$\delta_{j_{eff}} > \sum_{i=1}^{n} \delta_{f_i}, \text{ then}$$

$$\delta_j = \delta_{j_{eff}} - \sum_{i=1}^{n} \delta_{f_i} \qquad 6.1.2.1\text{-t}$$

If not, then $\delta_j = 0$. Terms are defined in Step 3a.

$c_{\ell_{\delta_j}}$ is the rate of change of section lift coefficient with respect to jet deflection, obtained from Figure 6.1.1.1-49 at $c_f/c_{\delta\delta} = 0$, as a function of the trailing-edge jet momentum coefficient C'_μ.

K is defined in Step 1a.

b. Determine the corresponding moment arm

$$x_6 = \frac{x_m}{c} + \left(\frac{c'_{LE}}{c} - 1\right) - \frac{x_j}{c_{\delta\delta}} \frac{c_{\delta\delta}}{c} \qquad 6.1.2.1\text{-u}$$

where

$\frac{x_j}{c_{\delta\delta}}$ is the center-of-lift location of the incremental load due to the jet deflection. This parameter is obtained from Figure 6.1.2.1-37 at $c_f/c_{\delta\delta} = 0$, as a function of the trailing-edge jet momentum coefficient C'_μ.

All other terms have been defined in Step 1b above.

Theoretically, this equation, within the context of linearized theory, is exact only for an airfoil of zero thickness. Unlike the lift equation, no comparable wing-chord thickness correction exists for the pitching-moment increment.

Sample Problems

1. Plain Trailing-Edge Flap (Method 1)

Given: A flapped airfoil from Reference 11.

Clark Y airfoil $c_f/c = 0.30$ $\delta_f = 45^o$ $t/c = 0.117$

$R_\ell = 0.61 \times 10^6$ $\tan\frac{1}{2}\phi'_{TE} = 0.142$ $x_{ref}/c = 0.25$ $c'/c = 1.0$

Compute:

$(c_{\ell_\delta})_{theory} = 4.51$ per rad (Figure 6.1.1.1-39a)

$\frac{c_{\ell_\alpha}}{(c_{\ell_\alpha})_{theory}} = 0.721$ (Figure 4.1.1.2-8a)

$\frac{c_{\ell_\delta}}{(c_{\ell_\delta})_{theory}} = 0.516$ (Figure 6.1.1.1-39b)

$K' = 0.518$ (Figure 6.1.1.1-40)

$$\Delta c_{\ell} = \delta_f \left[\frac{c_{\ell_\delta}}{(c_{\ell_\delta})_{theory}} \right] (c_{\ell_\delta})_{theory} K' \qquad \text{(Equation 6.1.1.1-c)}$$

$$= \frac{45}{57.3} (0.516)(4.51)(0.518)$$

$$= 0.947$$

$x_{c.p.}/c' = 0.425$ (Figure 6.1.2.1-35a)

Solution:

$$\Delta c_m = \Delta c_{\ell} \left[\frac{x_{ref}}{c} - \left(\frac{x_{c.p.}}{c'} \right) \left(\frac{c'}{c} \right) \right] \qquad \text{(Equation 6.1.2.1-a)}$$

$$= (0.947)\ [0.25 - (0.425)(1)]$$

-0.166 (based on c^2 and measured about c/4)

This compares with a test value of -0.195 from Reference 11.

2. Plain Trailing-Edge Flap (Method 2)

Given: A flapped airfoil from Reference 40.

NACA 65_1-210 airfoil $\quad c_f/c = 0.20 \quad \delta_f = 15^o \quad x_{ref}/c = 0.25$

Solution:

$\Delta c_m = -0.130$ (based on c^2 and measured about c/4) (Figure 6.1.2.1-35b)

This compares with a test value of -0.142 from Reference 40.

3. Plain Leading-Edge Flap

Given: The flapped airfoil of Reference 9.

NACA 0006 airfoil $\quad c_{f_{LE}}/c = 0.15 \quad \delta_{f_{LE}} = 20^o \quad M = 0.15$

$x_{ref}/c = 0.25 \quad \Delta c_{\ell} = -0.057$ (Example 8, Section 6.1.1.1)

$c'/c = 1.0 \quad \alpha = 0 \quad c_{\ell} = 0 \quad c_m = 0$

Compute:

$c_{m_{\delta_{LE}}} = -0.00116$ per deg (Figure 6.1.2.1-36)

$$\Delta c_{m_{LE}} = c'_{m_{\delta_{LE}}} \left(\frac{c'}{c}\right)^2 \delta_{f_{LE}} + \left[\frac{x_{ref}}{c} + \frac{c' - c}{c}\right] \Delta c_{\ell} + c_m \left[\left(\frac{c'}{c}\right)^2 - 1\right] + 0.75\, c_{\ell}\left(\frac{c'}{c}\right)\left(\frac{c'}{c} - 1\right)$$

(Equation 6.1.2.1-b)

$= -0.00116\,(1.0)^2\,(20) + (0.25 + 0)(-0.057) + 0[(1.0)^2 - 1.0] + 0.75\,(0)(1)(1 - 1)$

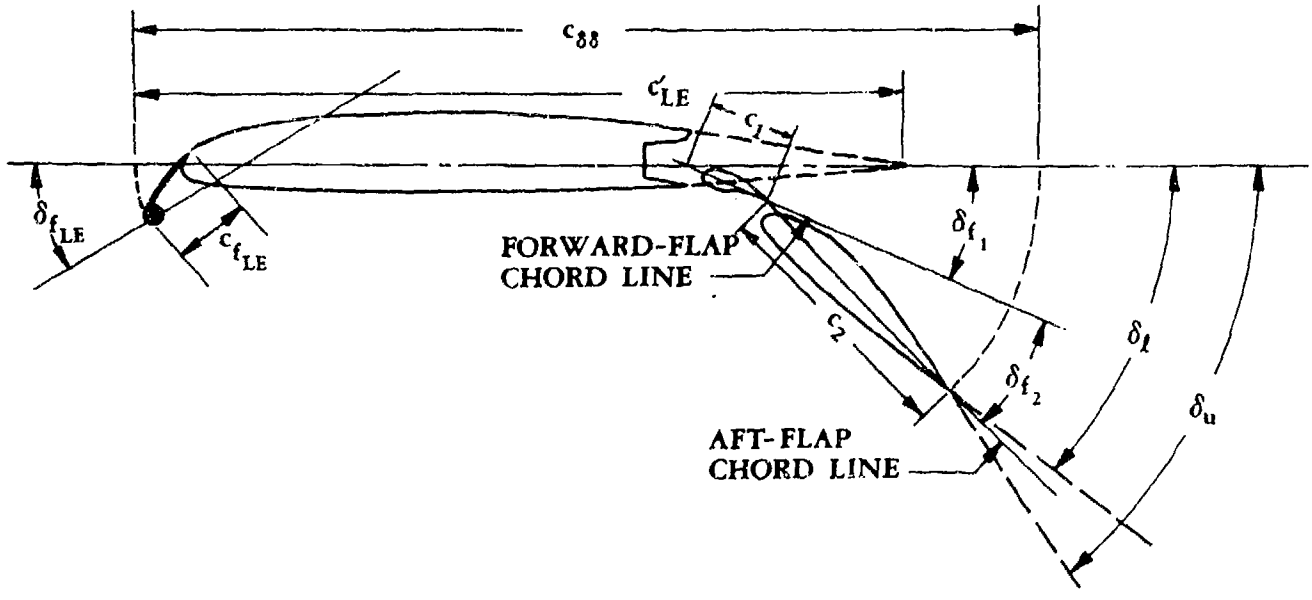
$= -0.0232 - 0.0143$

$= -0.0375$ (based on c^2 and measured about c/4)

This compares with a test value of −0.026 from Reference 9.

4. Jet Flaps

Given: The IBF airfoil with a double-slotted trailing-edge Fowler flap and leading-edge Krueger flap.



$C_\mu = 5.0$	$\frac{c_{\delta\delta}}{c} = 1.174$	$\frac{c_{f_{LE}}}{c} = 0.105$	$\frac{c'_{LE}}{c} = 1.068$	
$\frac{c_2}{c} = 0.306$	$\frac{c_1}{c} = 0.074$	$\frac{x_m}{c} = 0.25$	$\alpha = 3.0^o$	
$\delta_{f_{LE}} = 30^o$	$\delta_{f_1} = 30^o$	$\delta_{f_2} = 15^o$	$\delta_u = 56^o$	$\delta_\ell = 38^o$

Compute:

Step 1. $(\Delta c_m)_{\delta f_{LE}}$

$$K = \frac{c_{\delta\delta}}{c} = 1.174$$

$$c_a = c_{\delta\delta} - c_{f_{LE}} \quad \text{(Equation 6.1.2.1-g)}$$

$$\frac{c_a}{c_{\delta\delta}} = 1 - \frac{c_{f_{LE}}}{c} \Big/ \frac{c_{\delta\delta}}{c}$$

$$= 1 - \frac{0.105}{1.174}$$

$$= 0.9106$$

$$C'_\mu = \frac{C_\mu}{c_{\delta\delta}/c}$$

$$= \frac{5.0}{1.174}$$

$$= 4.259$$

$$\left.\begin{aligned} c_{\ell_{\delta_a}} &= 13.83 \quad \text{per rad} \\ c_{\ell_\alpha} &= 14.00 \quad \text{per rad} \end{aligned}\right\} \text{(Figure 6.1.1.1-49)}$$

$$\Delta c_1 = \frac{\delta_{f_{LE}}}{57.3} K\, c_{\ell_{\delta_a}} \quad \text{(Equation 6.1.2.1-e)}$$

$$= \frac{30}{57.3}(1.174)(13.83)$$

$$= 8.501$$

$$\Delta c_2 = \frac{\delta_{f_{LE}}}{57.3} K\, c_{\ell_\alpha} \quad \text{(Equation 6.1.2.1-f)}$$

$$= \frac{30}{57.3}(1.174)(14.00)$$

$$= 8.605$$

$$\left.\begin{aligned} \frac{x_a}{c_{\delta\delta}} &= 0.235 \\ \frac{x_{a.c.}}{c_{\delta\delta}} &= 0.202 \end{aligned}\right\} \quad \text{(Figure 6.1.2.1-37)}$$

$$x_1 = \frac{x_m}{c} + \left(\frac{c'_{LE}}{c} - 1\right) - \frac{x_a}{c_{\delta\delta}} \frac{c_{\delta\delta}}{c} \quad \text{(Equation 6.1.2.1-h)}$$

$$= 0.25 + (1.068 - 1) - (0.235)(1.174)$$

$$= 0.0421$$

$$x_2 = \frac{x_m}{c} + \left(\frac{c'_{LE}}{c} - 1\right) - \frac{x_{a.c.}}{c_{\delta\delta}} \frac{c_{\delta\delta}}{c} \quad \text{(Equation 6.1.2.1-i)}$$

$$= 0.25 + (1.068 - 1) - (0.202)(1.174)$$

$$= 0.0809$$

$$\Delta c_{m_3} = C_\mu \frac{c_{f_{LE}}}{c} \sin \delta_{f_{LE}} \quad \text{(Equation 6.1.2.1-j)}$$

$$= (5.0)(0.105)(\sin 30^o)$$

$$= 0.2625$$

$$(\Delta c_m)_{\delta f_{LE}} = \Delta c_1 \, x_1 - \Delta c_2 \, x_2 + \Delta c_{m_3} \quad \text{(Equation 6.1.2.1-d)}$$

$$= (8.501)(0.0421) - (8.605)(0.0809) + (0.2625)$$

$$= -0.0757$$

Step 2. $(\Delta c_m)_\alpha$

$$\Delta c_4 = \frac{\alpha}{57.3} K \, c_{\ell_\alpha} \quad \text{(Equation 6.1.2.1-ℓ)}$$

$$= \frac{3.0}{57.3} (1.174)(14.00)$$

$$= 0.861$$

$$\Delta c_{m_4} = -C_\mu \left[\frac{x_m}{c} + \left(\frac{c'_{LE}}{c} - 1\right)\right] \frac{\alpha}{57.3} \quad \text{(Equation 6.1.2.1-m)}$$

$$= -(5.0)[0.25 + (1.068 - 1)] \frac{(3.0)}{57.3}$$

$$= -0.0832$$

$$(\Delta c_m)_\alpha = \Delta c_4 \, x_2 + \Delta c_{m_4} \quad \text{(Equation 6.1.2.1-k)}$$

$$= (0.861)(0.0809) - 0.0832$$

$$= -0.0135$$

Step 3. $(\Delta c_m)_{\delta_f}$

n = 2, since there are two flap segments

$$\delta_{j_{eff}} = \frac{1}{2}(\delta_u + \delta_\ell) \quad \text{(Equation 6.1.4.1-d)}$$

$$= \frac{1}{2}(56 + 38)$$

$$= 47^o$$

Therefore, since $\delta_{j_{eff}} > \sum_{i=1}^{n} \delta_{f_i} = (\delta_{f_1} + \delta_{f_2}) = 45^o$, $\delta_{f_2} = 15^o$ (see Step 3a)

$$\frac{c_{f_1}}{c} = \frac{c_1}{c} + \frac{c_2}{c} \quad \text{(See Sketch (g))}$$

$$= 0.074 + 0.306$$

$$= 0.380$$

$$\frac{c_{f_1}}{c_{\delta\delta}} = \frac{c_{f_1}}{c} \Big/ \frac{c_{\delta\delta}}{c}$$

$$= 0.380/1.174$$

$$= 0.3237$$

For i = 1 (forward flap segment)

$$c_{\ell_{\delta_{f_1}}} = 12.33 \text{ per rad} \quad \text{(Figure 6.1.1.1-49)}$$

$$(\Delta c_5)_1 = \frac{\delta_{f_1}}{57.3} K \, c_{\ell_{\delta_{f_1}}} \quad \text{(Equation 6.1.2.1-o)}$$

$$= \frac{30}{57.3}(1.174)(12.33)$$

$$= 7.579$$

$$\frac{x_{f_1}}{c_{\delta\delta}} = 0.490 \quad \text{(Figure 6.1.2.1-37)}$$

$$(x_5)_1 = \frac{x_m}{c} + \left(\frac{c'_{LE}}{c} - 1\right) - \frac{x_{f_1}}{c_{\delta\delta}} \frac{c_{\delta\delta}}{c} \quad \text{(Equation 6.1.2.1-q)}$$

$$= 0.25 + (1.068 - 1) - (0.490)(1.174)$$

$$= -0.2573$$

For i = 2 (aft flap segment)

$$\frac{c_{f_2}}{c_{\delta\delta}} = \frac{c_{f_2}}{c} \Big/ \frac{c_{\delta\delta}}{c}$$

$$= 0.306/1.174 = 0.2606$$

$$c_{\ell_{\delta_{f_2}}} = 12.05 \quad \text{per rad} \quad \text{(Figure 6.1.1.1-49)}$$

$$(\Delta c_5)_2 = \frac{\delta_{f_2}}{57.3} K \, c_{\ell_{\delta_{f_2}}} \quad \text{(Equation 6.1.2.1-o)}$$

$$= \frac{15}{57.3}(1.174)(12.05)$$

$$= 3.703$$

$$\frac{x_{f_2}}{c_{\delta\delta}} = 0.521 \quad \text{(Figure 6.1.2.1-37)}$$

$$(x_5)_2 = \frac{x_m}{c} + \left(\frac{c_{LE}}{c} - 1\right) - \frac{x_{f_2}}{c_{\delta\delta}} \frac{c_{\delta\delta}}{c} \quad \text{(Equation 6.1.2.1-q)}$$

$$= 0.25 + (1.068 - 1) - (0.521)(1.174)$$

$$= -0.2937$$

$$(\Delta c_m)_{\delta_f} = \sum_{i=1}^{n} (\Delta c_5)_i (x_5)_i \quad \text{(Equation 6.1.2.1-n)}$$

$$= (\Delta c_5)_1 (x_5)_1 + (\Delta c_5)_2 (x_5)_2$$

$$= (7.579)(-0.2573) + (3.703)(-0.2937)$$

$$= -3.0376$$

Step 4. $(\Delta c_m)_{\delta_j}$

$c_{\ell_{\delta_j}} = 10.07$ per rad (Figure 6.1.1.1-49)

Since $\delta_{j_{eff}} > \sum_{i=1}^{n} \delta_{f_1}$ (Step 3), then

$$\delta_j = \delta_{j_{eff}} - \sum_{i=1}^{n} \delta_{f_i}$$

$$= \delta_{j_{eff}} - (\delta_{f_1} + \delta_{f_2})$$

$$= 47 - (30 + 15)$$

$$= 2^o$$

$$\Delta c_6 = \frac{\delta_j}{57.3} K\, c_{\ell_{\delta_j}} \quad \text{(Equation 6.1.2.1-s)}$$

$$= \frac{2}{57.3} (1.174)(10.07)$$

$$= 0.4126$$

$$\frac{x_j}{c_{\delta\delta}} = 0.658 \quad \text{(Figure 6.1.2.1-37)}$$

$$x_6 = \frac{x_m}{c} + \left(\frac{c'_{LE}}{c} - 1\right) - \frac{x_j}{c_{\delta\delta}} \frac{c_{\delta\delta}}{c} \quad \text{(Equation 6.1.2.1-u)}$$

$$= 0.25 + (1.068 - 1) - (0.658)(1.174)$$

$$= -0.4545$$

$$(\Delta c_m)_{\delta_j} = \Delta c_6 \, x_6 \quad \text{(Equation 6.1.2.1-r)}$$

$$= (0.4164)(-0.4545)$$

$$= -0.1875$$

Solution:

$$\Delta c_m = (\Delta c_m)_{\delta_{f_{LE}}} + (\Delta c_m)_\alpha + (\Delta c_m)_{\delta_f} + (\Delta c_m)_{\delta_j} \quad \text{(Equation 6.1.2.1-c)}$$

$$= -0.0757 - 0.0135 - 3.0376 - 0.1875$$

$$= -3.314 \quad \text{(based on } c^2\text{)}$$

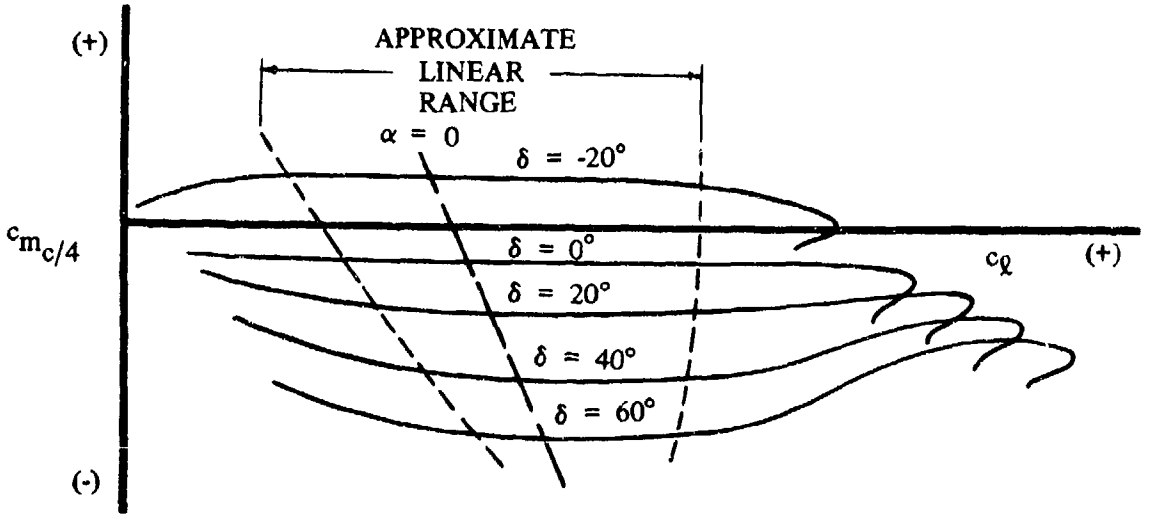
6.1.2.2 SECTION DERIVATIVE c_{m_α} WITH HIGH-LIFT AND CONTROL DEVICES

Mechanical Flaps

According to thin-airfoil theory, camber, such as that due to flaps, does not affect the moment-curve slope of an airfoil section. Experimental data verify this for the angle-of-attack and flap-deflection ranges for which the flow is attached over the airfoil and flap surfaces. This aspect of the subject is discussed with respect to lift for various types of flaps in Section 6.1.1.2.

A typical set of data is shown in Sketch (a) for plain trailing-edge flaps.



SKETCH (a)

The approximate linear range is noted in the sketch. At angles of attack above the linear range the flow separates over the flap surface, and the additional loading due to the flap is lost. A pitch-up tendency results. At angles of attack below the linear range the flow separates on the underside of the airfoil, causing a forward shift in center of pressure and a nose-up moment change.

Theoretically, the pitching-moment-curve slope is affected both by leading- and trailing-edge devices that extend beyond the chord of the basic airfoil. These changes, predicted by thin-airfoil theory, along with a recommended empirical factor for trailing-edge devices, are presented in Reference 1. Attempts to substantiate these equations by using available test data of References 2 through 8 have proved unsatisfactory. The test data from these references do not indicate a consistent dependence of pitching-moment-curve slope upon airfoil-chord extension as predicted by thin-airfoil theory.

Jet Flaps

The aerodynamic-center location for a jet-flap airfoil is dependent upon the trailing-edge jet momentum coefficient C_μ and upon the extent to which leading- and trailing-edge flaps extend beyond the basic airfoil.

Considerations of clarity and simplicity of presentation dictated a deviation from normal Datcom practice in that the effect of jet flaps on c_{m_α} was included in Section 6.1.2.1, which deals with the pitching-moment increment Δc_m.

DATCOM METHODS

1. Leading- and Trailing-Edge Mechanical Flaps

The parameter dc_m/dc_ℓ for various flap deflections is the same as that for zero flap deflection for angles of attack near zero. However, the linear range for this parameter becomes very small at the higher flap deflections.

2. Jet Flaps

The variation of pitching moment with angle of attack for airfoil sections equipped with jet flaps is covered in the jet-flap method of Section 6.1.2.1. The range of applicability and the limitations of the method are discussed there and in Section 6.1.1.1.

6.1.2.3 SECTION PITCHING MOMENT NEAR MAXIMUM LIFT WITH HIGH-LIFT AND CONTROL DEVICES

It is shown in reference 1 that near maximum-lift conditions the pitching-moment increment due to flap deflection is a function of the corresponding lift increment and is nearly independent of flap and airfoil geometry. The summary chart from this reference is presented in this section for estimating pitching-moment increments due to flap deflection at high angles of attack. The flap types covered include plain, slotted, and Fowler trailing-edge flaps and leading-edge flaps and slats. The chart is applicable only to that part of the c_m versus c_ℓ curve just below the moment break.

DATCOM METHOD

Section pitching-moment increments due to high-lift and control devices are obtained from figure 6.1.2.3-3. The section-lift increment Δc_ℓ used in reading this chart is obtained from the appropriate method of Section 6.1.1.1. The section-lift increment for airfoils with both leading-edge and trailing-edge devices is obtained by adding the individual increments calculated by the methods of Section 6.1.1.1.

The design chart is based on the test data of references 2 through 28. The accuracy of the method, within the boundaries of the test points on the chart, is dependent upon the accuracy of the value of Δc_ℓ used in reading the design chart. The limitations of the method are the same as those of the methods of Section 6.1.1.1 for determining the section-lift increments.

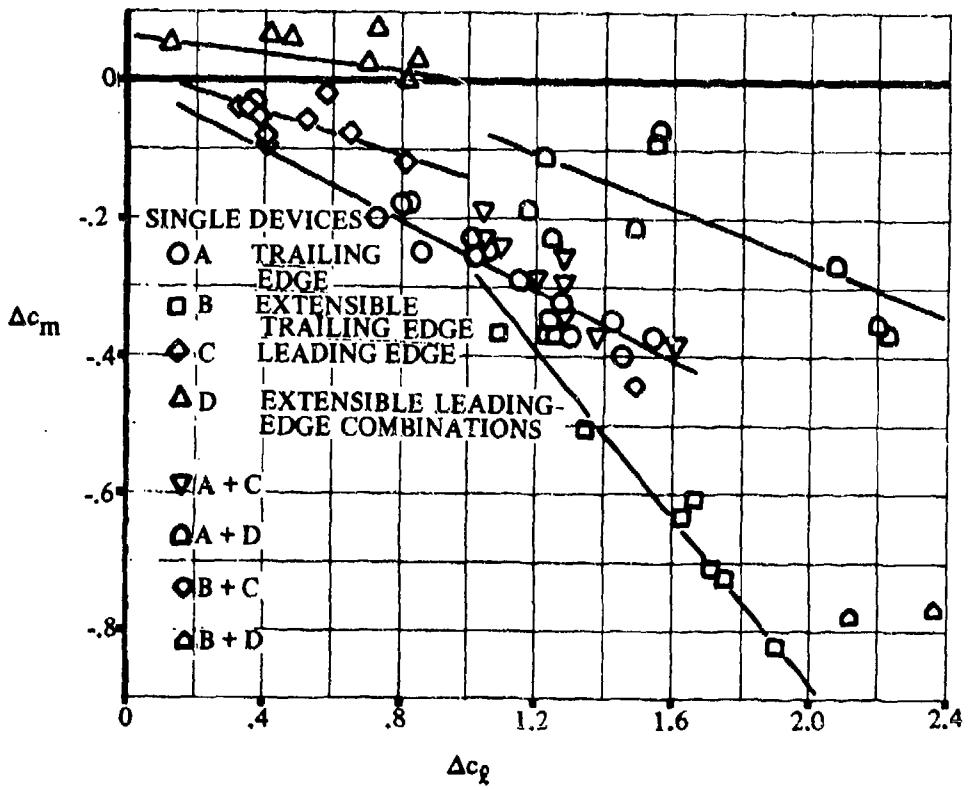

FIGURE 6.1.2.3-3 SECTION PITCHING-MOMENT INCREMENTS OF VARIOUS TYPES OF HIGH-LIFT DEVICES

6.1.3 SECTION HINGE MOMENT OF HIGH-LIFT AND CONTROL DEVICES

Hinge moments are affected by many factors, such as balance ratio, balance shape, basic airfoil characteristics, trailing-edge angle, trailing-edge bluntness, gap size and geometry, tab controls and trimmers, etc. Hinge moments are also nonlinear with angle of attack and flap deflection, particularly at moderate to large angles. The hinge moments of trailing-edge controls are sensitive to boundary-layer conditions and hence to Reynolds-number effects. All of the above items cause the prediction of hinge moments to be very difficult. Test data on the particular configuration under consideration or one closely resembling it should always be preferred to characteristics obtained from generalized methods. (Summaries of early hinge-moment test data used in determining the effects of various factors on hinge moments can be found in References 1 and 2.)

The methods presented in subsequent sections are limited to the range of flap deflections and angles of attack for which the hinge moments are linear, i.e., those conditions for which the flow is attached over the control surface. The angles of attack and flap deflections at which the flow separates over a plain, sealed control are interrelated and depend upon the flap-chord-to-wing-chord ratio. Approximate boundaries for linear control effectiveness are presented in Figure 6.1.3-2. This chart, taken from Reference 3, is based on test data on an NACA 0009 airfoil.

The sign convention for hinge moments is that a positive hinge moment tends to rotate the control-surface trailing edge down, i.e., a positive control deflection.

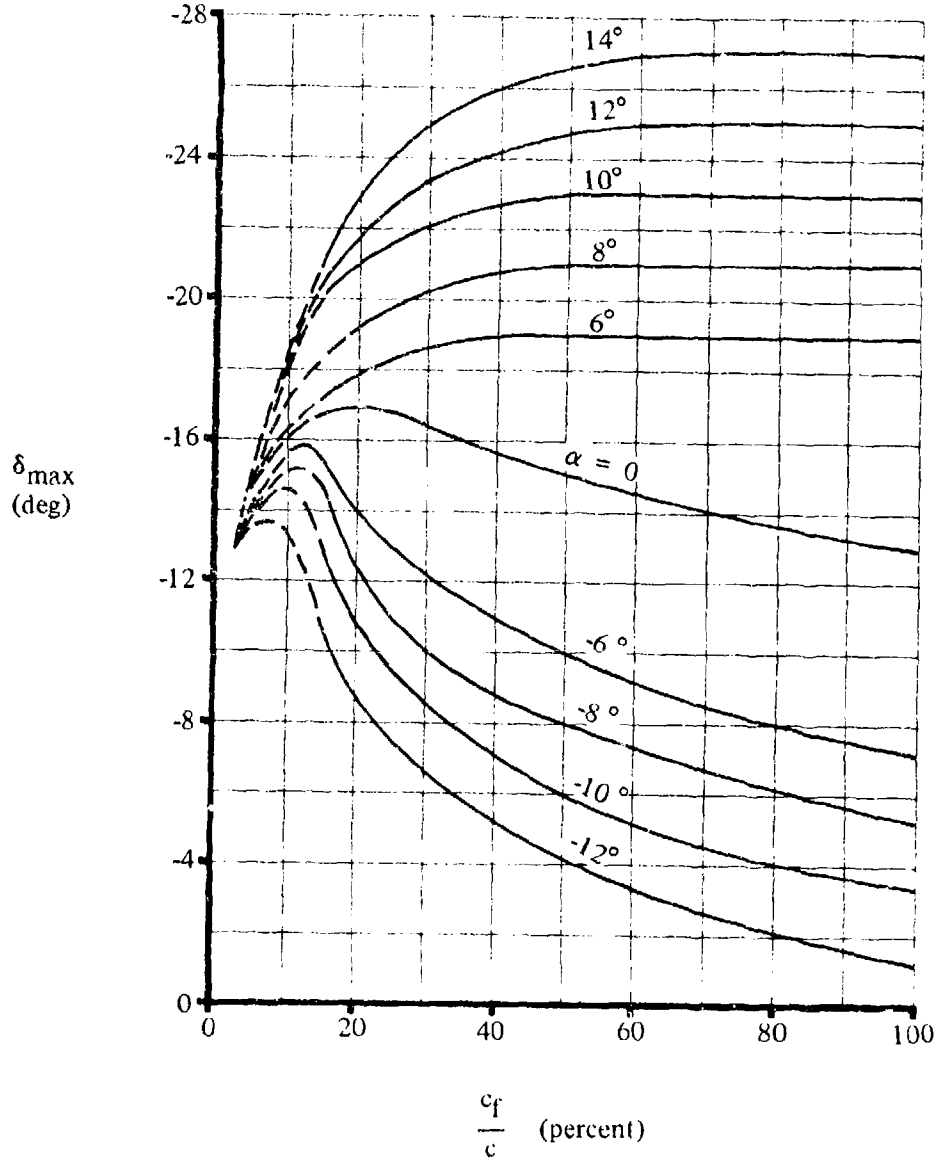

FIGURE 6.1.3-2 APPROXIMATE MAXIMUM CONTROL-SURFACE DEFLECTIONS FOR LINEAR CONTROL CHARACTERISTICS OF A PLAIN, SEALED FLAP (NACA 0009 AIRFOIL)

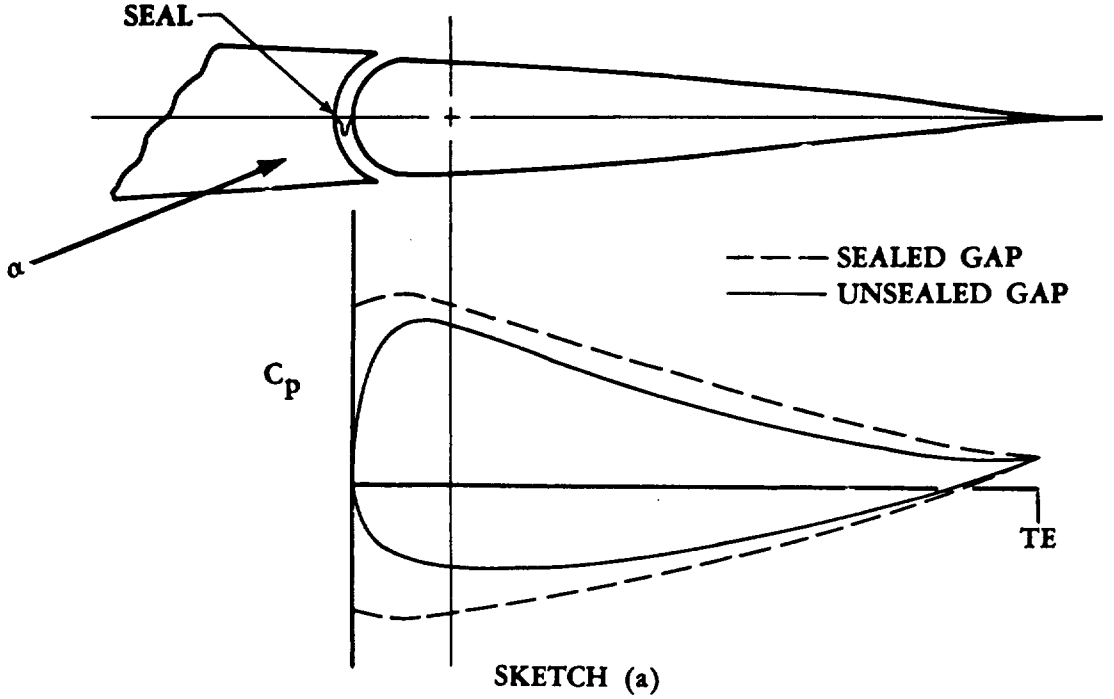
6.1.3.1 SECTION HINGE-MOMENT DERIVATIVE c_{h_α} OF HIGH-LIFT AND CONTROL DEVICES

For the angle-of-attack range where the flow is attached over the control surface, the variation of hinge moment with angle of attack is linear. At some angle of attack, depending upon the control deflection and airfoil and control geometry, the flow separates from the flap surface. The rate of change of hinge moment with flap deflection increases beyond this point at an increased rate. This increase can be attributed to the increased loading at the trailing edge on the leeward side that accompanies separation, i.e., the aft movement of the center-of-pressure location. The approximate angle of attack at which the flow separates from the surface of a plain, sealed flap on an NACA 0009 airfoil is shown as a function of flap deflection angle and flap-chord-to-control-chord ratio in Figure 6.1.3-2.

Those additional parameters that restrict the linear range are large trailing-edge angles, large nose-balance ratios, blunt (control) nose shapes, and relatively large airfoil thickness ratios. The linear hinge-moment range is generally smaller than the corresponding linear lift-increment range due to control deflection.

Seal and Gap Effects

Unsealing the gap between the nose of the control surface and the basic airfoil affects the hinge-moment derivative of both plain and balanced controls. For most cases, the hinge-moment derivative c_{h_α} becomes more positive when the gap is unsealed. Experimental data indicate that this effect tends to be larger for balanced controls. The method presented herein does not quantitatively account for the effect of unsealing the gap. In effect, seals or gaps produce a change in the pressure distribution along the control surface. Therefore, many factors must be considered when analyzing the effects of gaps or seals, i.e., type and/or location of seal, nose shape, balancing, and the particular pressure distribution of the airfoil. Sketch (a) illustrates the pressure distributions for a



SKETCH (a)

sealed and unsealed gap on a particular control. (This pressure distribution should not be construed as being true for all configurations.) In viewing the change in the pressure distribution, the effect of the hinge-line location (balanced control) becomes evident when determining the effect of the seal or gap on the hinge-moment derivative.

In view of the difficulty of predicting the effects of seals and gaps, experimental data should be used whenever possible. Figures 6.1.3.1-9 and -10 (from Reference 1) show the effects of fixing transition and sealing the tab gap on a modified NACA 65_1-012 airfoil. For these data, the flap-chord-to-wing-chord ratio is 0.25, the tab-chord-to-flap-chord ratio is 0.25, and the flap gap is sealed.

DATCOM METHOD

A. SUBSONIC

The method presented for estimating the hinge moment of trailing-edge controls due to angle of attack at low speeds is taken from Reference 2. It is based on the theories and data of References 3, 4, and 5, and applies to sealed controls (at the nose) in the linear hinge-moment range only. It is not valid for horn-balanced controls. The hinge-moment derivative c_{h_α} is based on the control chord squared c_f^2 (where the control chord c_f is measured from the hinge line aft to the trailing edge).

The method is broken down into a logical sequence of calculations that account for various factors in the following order:

1. Radius-nose, sealed, plain trailing-edge control for which the thickness condition

$$\tan\frac{\phi'_{TE}}{2} = \tan\frac{\phi''_{TE}}{2} = \tan\frac{\phi_{TE}}{2} = \frac{t}{c}$$

   is satisfied.

2. Thickness distribution when

$$\tan\frac{\phi'_{TE}}{2} = \tan\frac{\phi''_{TE}}{2} = \tan\frac{\phi_{TE}}{2} = \frac{t}{c}$$

   is not satisfied.

3. Various control nose shapes and the effect of nose balance.

4. Effects of Mach number.

The semiempirical method for determining the section hinge-moment derivative c_{h_α} is as follows:

Step 1. Calculate the hinge-moment derivative c'_{h_α} for a radius-nose, sealed, trailing-edge flap for the following thickness condition:

$$\tan\frac{\phi'_{TE}}{2} = \tan\frac{\phi''_{TE}}{2} = \tan\frac{\phi_{TE}}{2} = \frac{t}{c}$$

by

$$c'_{h_\alpha} = \left[\frac{c'_{h_\alpha}}{(c_{h_\alpha})_{theory}}\right](c_{h_\alpha})_{theory} \quad \text{(per radian)} \qquad 6.1.3.1\text{-a}$$

where

ϕ'_{TE} is the trailing-edge angle defined as the angle between straight lines passing through points at 90 and 99 percent of the chord on the upper and lower airfoil surfaces.

ϕ''_{TE} is the trailing-edge angle defined as the angle between straight lines passing through points at 95 and 99 percent of the chord on the upper and lower airfoil surfaces.

ϕ_{TE} is the trailing-edge angle defined as the angle between tangents to the upper and lower airfoil surfaces at the trailing edge.

$\dfrac{c'_{h_\alpha}}{(c_{h_\alpha})_{theory}}$ is the ratio of the actual to the theoretical hinge-moment derivative for a radius-nose, sealed-gap, plain trailing-edge flap, obtained from Figure 6.1.3.1-11a.

$(c_{h_\alpha})_{theory}$ is the theoretical hinge-moment derivative for airfoils having $\tan\frac{\phi'_{TE}}{2} = \tan\frac{\phi''_{TE}}{2} = \tan\frac{\phi_{TE}}{2} = \frac{t}{c}$.
This parameter is obtained from Figure 6.1.3.1-11b.

The parameter $c_{\ell_\alpha}/(c_{\ell_\alpha})_{theory}$ used in reading this chart is obtained from Figure 4.1.1.2-8a.

Step 2. If the thickness condition in Step 1 is satisfied, Step 2 may be omitted. However, if the thickness condition in Step 1 is not satisfied, correct the hinge-moment derivative c'_{h_α} of Step 1 to account for the particular thickness distribution by

$$c''_{h_\alpha} = c'_{h_\alpha} + 2(c_{\ell_\alpha})_{theory}\left[1 - \frac{c_{\ell_\alpha}}{(c_{\ell_\alpha})_{theory}}\right]\left(\tan\frac{\phi''_{TE}}{2} - \frac{t}{c}\right) \quad \text{(per radian)}$$

6.1.3.1-b

where

c'_{h_α} is obtained from Equation 6.1.3.1-a in Step 1.

$(c_{\ell_\alpha})_{theory}$ is the theoretical section lift-curve slope obtained from Figure 4.1.1.2-8b as a function of airfoil thickness ratio.

The parameters $c_{\ell_\alpha}/(c_{\ell_\alpha})_{theory}$ and $\frac{\phi''_{TE}}{2}$ are obtained as noted above in Step 1.

For a beveled trailing edge, ϕ''_{TE} should be taken as equal to the angle of the bevel.

It is stated in Reference 2 that under the restriction that there is no separated flow, c_{h_α} for a radius-nose control can be determined by using the above equations with an accuracy of ±0.05 per radian.

Step 3. Correct the hinge-moment derivative to account for nose-shape and nose-balance effects by using the following equation (taken from Reference 5):

$$(c_{h_\alpha})_{balance} = c''_{h_\alpha}\left[\frac{(c_{h_\alpha})_{balance}}{c''_{h_\alpha}}\right] \quad \text{(per radian)} \qquad 6.1.3.1\text{-c}$$

where

c''_{h_α} is obtained from Step 2, or is equal to c'_{h_α} from Step 1 if the thickness correction is not required.

$\frac{(c_{h_\alpha})_{balance}}{c''_{h_\alpha}}$ is obtained from Figure 6.1.3.1-12a for noses of various shapes. The nose shapes corresponding to the curves in Figure 6.1.3.1-12a are shown in Figure 6.1.3.1-12b. The balance ratio used in Figure 6.1.3.1-12a is defined by

$$\text{Balance ratio} = \sqrt{\left(\frac{c_b}{c_f}\right)^2 - \left(\frac{t_c}{2c_f}\right)^2} \qquad 6.1.3.1\text{-d}$$

where

c_b is the chord of the balance.

c_f is the chord of the control aft of the hinge line.

t_c is the thickness of the control at the hinge line.

Figure 6.1.3.1-12a is taken from Reference 6 and is based on a limited amount of experimental data on sealed controls. Small changes in nose shape, trailing-edge contour, and air flow may have significant effects on the hinge-moment derivative of balanced control surfaces.

Step 4. Mach-number effects should be approximated by the use of test data whenever possible. However, when no test data are available, the Mach-number effects may be roughly approximated by using the Prandtl-Glauert correction; i.e.,

$$(c_{h_\alpha})_M = \frac{(c_{h_\alpha})_{\text{low speed}}}{\sqrt{1 - M^2}}$$

Sample Problem

Given: The flapped airfoil of Reference 7.

NACA 0015 airfoil Plain trailing-edge flap $c_f/c = 0.30$

Round-nose control $c_b/c_f = 0.35$ $t_c/(2c_f) = 0.1527$

Sealed gap $\tan\frac{\phi'_{TE}}{2} = 0.164$ $\tan\frac{\phi''_{TE}}{2} = 0.169$ $\tan\frac{\phi_{TE}}{2} = 0.169$

Low speed $R_\ell = 2.76 \times 10^6$

Compute:

Determine the hinge-moment derivative for a radius-nose, sealed, trailing-edge flap

$(c_{h_\alpha})_{\text{theory}} = -0.507$ per rad (Figure 6.1.3.1-11b)

$\frac{c_{\ell_\alpha}}{(c_{\ell_\alpha})_{\text{theory}}} = 0.760$ (Figure 4.1.1.2-8a)

$\frac{c'_{h_\alpha}}{(c_{h_\alpha})_{\text{theory}}} = 0.320$ (Figure 6.1.3.1-11a)

$$c'_{h_\alpha} = \left[\frac{c'_{h_\alpha}}{(c_{h_\alpha})_{\text{theory}}}\right](c_{h_\alpha})_{\text{theory}} \quad \text{(Equation 6.1.3.1-a)}$$

$= (0.320)(-0.507)$

$= -0.162$ per rad

Determine if the thickness condition is satisfied; i.e.,

$$\tan\frac{\phi'_{TE}}{2} = \tan\frac{\phi''_{TE}}{2} = \tan\frac{\phi_{TE}}{2} = \frac{t}{c}$$

$$0.164 \neq 0.169 = 0.169 \neq 0.15$$

Determine the hinge-moment derivative accounting for the thickness distribution

$$(c_{\ell_\alpha})_{theory} = 7.04 \text{ per rad} \quad \text{(Figure 4.1.1.2-8b)}$$

$$c''_{h_\alpha} = c'_{h_\alpha} + 2(c_{\ell_\alpha})_{theory}\left[1 - \frac{c_{\ell_\alpha}}{(c_{\ell_\alpha})_{theory}}\right]\left(\tan\frac{\phi''_{TE}}{2} - \frac{t}{c}\right) \quad \text{(Equation 6.1.3.1-b)}$$

$$= -0.162 + 2(7.04)[1 - 0.760](0.169 - 0.150)$$

$$= -0.0978 \text{ per rad}$$

Determine the effect of nose shape and nose balance

$$\text{Balance ratio} = \sqrt{\left(\frac{c_b}{c_f}\right)^2 - \left(\frac{t_c}{2c_f}\right)^2} \quad \text{(Equation 6.1.3.1-d)}$$

$$= \sqrt{(0.35)^2 - (0.1527)^2}$$

$$= 0.315$$

$$\frac{(c_{h_\alpha})_{balance}}{c''_{h_\alpha}} = 0.50 \quad \text{(Figure 6.1.3.1-12a)}$$

$$(c_{h_\alpha})_{balance} = c''_{h_\alpha}\left[\frac{(c_{h_\alpha})_{balance}}{c''_{h_\alpha}}\right] \quad \text{(Equation 6.1.3.1-c)}$$

$$= (-0.0978)(0.50)$$

$$= -0.0489 \text{ per rad}$$

$$= -0.000853 \text{ per deg}$$

This compares with a test value of −0.00145 per degree from Reference 7.

B. TRANSONIC

No method is available for predicting the section hinge-moment derivative c_{h_α} at transonic speeds.

C. SUPERSONIC

The method for determining c_{h_α} at supersonic speeds is based on the theory of Reference 8. The theory applies to airfoils with sharp leading and trailing edges, where the angles of attack and flap-deflection angles are small. In addition, the flow field is assumed to be everywhere supersonic and inviscid.

DATCOM METHOD

The hinge-moment derivative c_{h_α} at supersonic speeds for a symmetric, straight-sided flap with $c_f/c < 1/2$, regardless of the airfoil section ahead of the flap, is given by

$$c_{h_\alpha} = -C_1 + C_2 \phi_{TE} \qquad 6.1.3.1\text{-e}$$

where C_1 and C_2 are thickness correction factors to the supersonic flat-plate derivative.

$$C_1 = \frac{2}{\sqrt{M^2 - 1}} \text{ per radian}$$

$$C_2 = \frac{(\gamma + 1)M^4 - 4(M^2 - 1)}{2(M^2 - 1)^2} \text{ per radian}$$

ϕ_{TE} is the trailing-edge angle in radians.

γ is the ratio of specific heats, $\gamma = 1.4$.

For a symmetric, circular-arc airfoil with $c_f/c < 1/2$, c_{h_α} is given by

$$c_{h_\alpha} = -C_1 + \left(\frac{\Delta c_{h_\alpha}}{t/c}\right)\frac{t}{c} \qquad 6.1.3.1\text{-f}$$

where C_1 is defined above, and

$\frac{\Delta c_{h_\alpha}}{t/c}$ is a thickness correction factor for symmetric, circular-arc airfoils obtained from Figure 6.1.3.1-13.

The method becomes somewhat complicated for more general airfoil shapes. Other airfoil shapes are treated in Reference 8.

Sample Problem

Given: Symmetric, circular-arc airfoil.

$t/c = 0.06$ $\qquad c_f/c = 0.30$ $\qquad M = 2.0$

Compute:

$$C_1 = \frac{2}{\sqrt{M^2 - 1}} \frac{1}{57.3} = 0.020 \text{ per deg}$$

$$\frac{\Delta c_{h_\alpha}}{t/c} = 0.0008 \text{ per deg} \quad \text{(Figure 6.1.3.1-13)}$$

Solution:

$$c_{h_\alpha} = -C_1 + \left(\frac{\Delta c_{h_\alpha}}{t/c}\right)\frac{t}{c} \quad \text{(Equation 6.1.3.1-f)}$$

$$= -0.020 + (0.0008)(0.06)$$

$$= -0.01995 \text{ per deg}$$

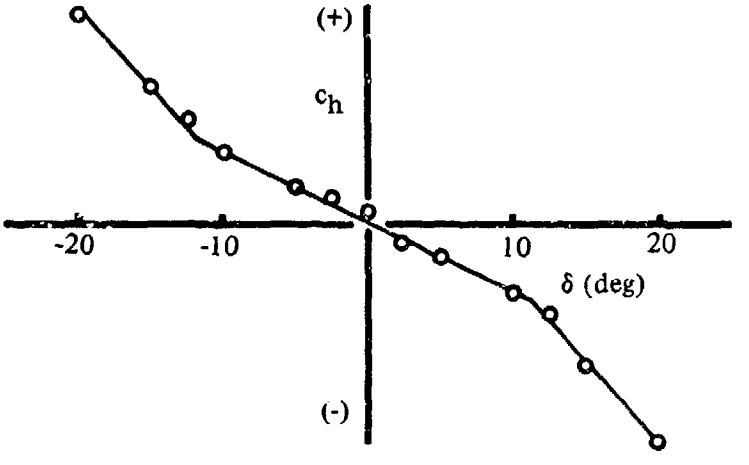
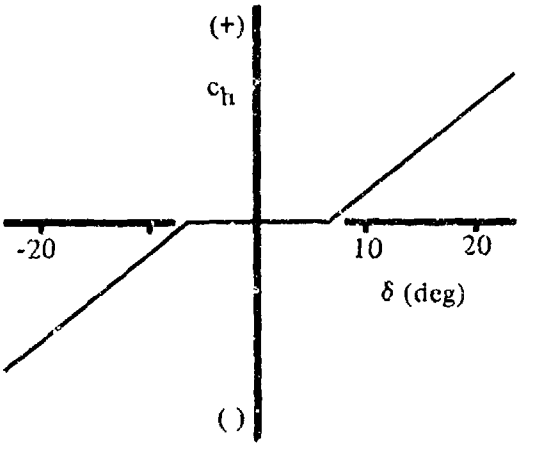
6.1.3.2 SECTION HINGE-MOMENT DERIVATIVE c_{h_δ} OF HIGH-LIFT AND CONTROL DEVICES

For small control deflections, where the flow is attached over the control surface, the variation of hinge moment with control deflection is linear. At some deflection angle, depending upon the angle of attack and airfoil and control geometry, the flow separates from the flap surface. The rate of change of hinge moment with flap deflection increases beyond this point at an increased rate, as shown in Sketch (a). This increase can be attributed to the increased loading at the trailing edge on the leeward side that accompanies separation; i.e., the aft movement of the center-of-pressure location. The approximate deflection angle at which the flow separates from the surface of a plain, sealed flap on an NACA 0009 airfoil is shown as a function of angle of attack and flap-chord-to-control-chord ratio in Figure 6.1.3-2.



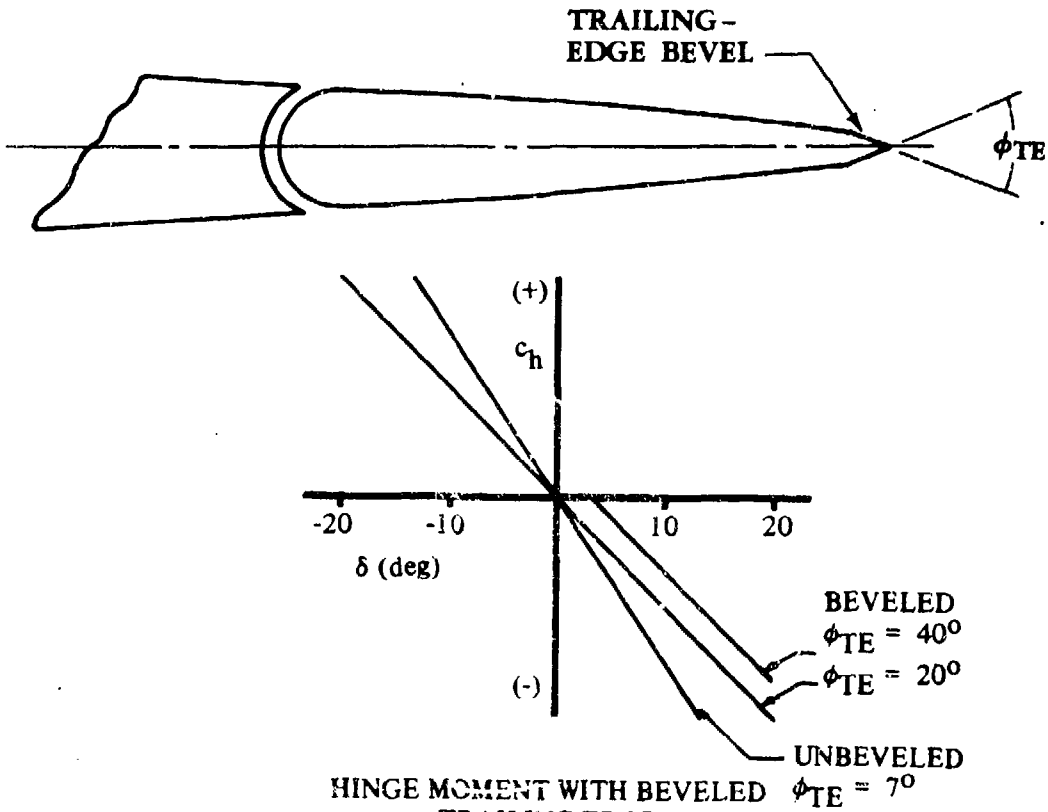
TYPICAL CURVE OF HINGE MOMENT
SKETCH (a)

The additional parameters that restrict the linear range are large trailing-edge angles, large nose-balance ratios, blunt (control) nose shapes, and relatively large airfoil thickness ratios. The effect of large nose-balance ratios is shown in Sketch (b) (from Reference 1).



HINGE MOMENT WITH VERY
LARGE NOSE BALANCE
SKETCH (b)

The effect of beveled trailing edges is shown in Sketch (c) (from Reference 1). The linear hinge-moment range is generally smaller than the corresponding linear lift-increment range due to control deflection.



SKETCH (c)

Unsealing the gap between the nose of the control surface and the basic airfoil affects the hinge-moment derivative of both plain and balanced controls. The method presented herein does not quantitatively account for the effect of unsealing the gap (see Section 6.1.3.1 for a discussion of the salient aspects). Figures 6.1.3.2-10 and -11 (from Reference 2) illustrate the effect of fixing transition and sealing the tab gap on a modified NACA 65_1-012 airfoil. For these data, the flap-chord-to-wing-chord ratio is 0.25, the tab-chord-to-flap-chord ratio is 0.25, and the flap gap is sealed.

DATCOM METHOD

A. SUBSONIC

The method presented for estimating the hinge moment due to trailing-edge control deflection at low speeds is taken from Reference 3 and closely parallels the method presented in Section 6.1.3.1 for predicting the hinge-moment derivative c_{h_α}. This method is based on the theories and data of References 4, 5, and 6. The method applies to sealed controls (at the nose) in the linear hinge-moment range only. It is not valid for horn-balanced controls. The hinge-moment derivative c_{h_δ} is based on the control chord squared c_f^2 (where the control chord c_f is measured from the hinge line aft to the trailing edge).

The method is broken down into a logical sequence of calculations that account for various factors in the following order:

1. Radius-nose, sealed, plain trailing-edge control for which the condition

$$\tan\frac{\phi'_{TE}}{2} = \tan\frac{\phi''_{TE}}{2} = \tan\frac{\phi_{TE}}{2} = \frac{t}{c}$$

is satisfied.

2. Thickness distribution when

$$\tan\frac{\phi'_{TE}}{2} = \tan\frac{\phi''_{TE}}{2} = \tan\frac{\phi_{TE}}{2} = \frac{t}{c}$$

is not satisfied.

3. Various control nose shapes and the effect of nose balance.

4. Effects of Mach number.

The semiempirical method for determining the section hinge-moment derivative c_{h_δ} is as follows:

Step 1. Calculate the hinge-moment derivative c'_{h_δ} for a radius-nose, sealed, trailing-edge flap for the following thickness condition

$$\tan\frac{\phi'_{TE}}{2} = \tan\frac{\phi''_{TE}}{2} = \tan\frac{\phi_{TE}}{2} = \frac{t}{c}$$

by

$$c'_{h_\delta} = \left[\frac{c'_{h_\delta}}{(c_{h_\delta})_{theory}}\right](c_{h_\delta})_{theory} \quad \text{(per radian)} \qquad 6.1.3.2\text{-a}$$

where

ϕ'_{TE} is the trailing-edge angle defined as the angle between straight lines passing through points at 90 and 99 percent of the chord on the upper and lower airfoil surfaces.

ϕ''_{TE} is the trailing-edge angle defined as the angle between straight lines passing through points at 95 and 99 percent of the chord on the upper and lower airfoil surfaces.

ϕ_{TE} is the trailing-edge angle defined as the angle between tangents to the upper and lower airfoil surfaces at the trailing edge.

$\frac{c'_{h_\delta}}{(c_{h_\delta})_{theory}}$ is the ratio of the actual to the theoretical hinge-moment derivative for a radius-nose, sealed-gap, plain trailing-edge flap, obtained from Figure 6.1.3.2-12a.

The parameter $c_{\ell_\alpha}/(c_{\ell_\alpha})_{theory}$ used in reading this chart is obtained from Figure 4.1.1.2-8a.

$(c_{h_\delta})_{theory}$ is the theoretical hinge-moment derivative for airfoils having

$$\tan\frac{\phi'_{TE}}{2} = \tan\frac{\phi''_{TE}}{2} = \tan\frac{\phi_{TE}}{2} = \frac{t}{c}$$

This parameter is obtained from Figure 6.1.3.2-12b.

Step 2. If the thickness condition in Step 1 is satisfied, Step 2 may be omitted. However, if the thickness condition in Step 1 is not satisfied, correct the hinge-moment derivative c'_{h_δ} of Step 1 to account for the particular thickness distribution by

$$c''_{h_\delta} = c'_{h_\delta} + 2(c_{\ell_\delta})_{theory}\left[1 - \frac{c_{\ell_\delta}}{(c_{\ell_\delta})_{theory}}\right]\left(\tan\frac{\phi''_{TE}}{2} - \frac{t}{c}\right) \quad \text{(per radian)}$$

6.1.3.2-b

where

c'_{h_δ} is obtained from Equation 6.1.3.2-a in Step 1.

$(c_{\ell_\delta})_{theory}$ is the theoretical lift due to flap deflection, obtained from Figure 6.1.1.1-39a.

$\frac{c_{\ell_\delta}}{(c_{\ell_\delta})_{theory}}$ is the ratio of the actual to the theoretical lift due to flap deflection, obtained from Figure 6.1.1.1-39b as a function of $c_{\ell_\alpha}/(c_{\ell_\alpha})_{theory}$ and c_f/c.

The parameters $c_{\ell_\alpha}/(c_{\ell_\alpha})_{theory}$ and $\tan\frac{\phi''_{TE}}{2}$ are obtained as noted in Step 1.

For a beveled trailing edge, ϕ''_{TE} should be taken as equal to the angle of bevel.

It is stated in Reference 3 that under the restriction that there is no separated flow, c_{h_δ} for a radius-nose control can be determined from the above equations with an accuracy of ±0.05 per radian.

Step 3. Correct the hinge-moment derivative to account for nose-shape and nose-balance effects (taken from Reference 5) by

$$(c_{h_\delta})_{balance} = c''_{h_\delta} \left[\frac{(c_{h_\delta})_{balance}}{c''_{h_\delta}} \right] \text{ (per radian)} \qquad 6.1.3.2\text{-c}$$

where

c''_{h_δ} is obtained from Equation 6.1.3.2-b, or is equal to c'_{h_δ} in Step 1, if the thickness correction is not required.

$\frac{(c_{h_\delta})_{balance}}{c''_{h_\delta}}$ is obtained from Figure 6.1.3.2-13 for noses of various shapes. The nose shapes corresponding to the curves in Figure 6.1.3.2-13 are shown in Figure 6.1.3.1-12b of Section 6,1.3.1. The balance ratio as used in Figure 6.1.3.2-13 is defined by Equation 6.1.3.1-d of Section 6.1.3.1.

Figure 6.1.3.2-13 is taken from Reference 6 and is based on a limited amount of experimental data on sealed controls. Small changes in nose shape, trailing-edge contour, and air flow may have significant effects on the hinge-moment derivative of balanced control surfaces.

Step 4. Mach-number effects should be approximated by the use of test data whenever possible. However, when no test data are available, the Mach-number effects may be roughly approximated by using the Prandtl-Glauert correction; i.e.,

$$(c_{h_\delta})_M = \frac{(c_{h_\delta})_{low\ speed}}{\sqrt{1 - M^2}} \qquad 6.1.3.2\text{-e}$$

Sample Problem

Given: The flapped airfoil of Reference 8. This is the same configuration as that of the sample problem of Paragraph A, Section 6.1.3.1.

NACA 0015 airfoil Plain trailing-edge flap $c_f/c = 0.30$

Round-nose control $c_b/c_f = 0.35$ $t_c/(2c_f) = 0.1527$

Sealed gap $\tan\frac{\phi'_{TE}}{2} = 0.164$ $\tan\frac{\phi''_{TE}}{2} = 0.169$ $\tan\frac{\phi_{TE}}{2} = 0.169$

Low speed $R_\ell = 2.76 \times 10^6$

Compute:

Determine the hinge-moment derivative for a radius-nose, sealed, trailing-edge flap

$$(c_{h_\delta})_{theory} = -0.825 \text{ per rad} \quad \text{(Figure 6.1.3.2-12b)}$$

$$\frac{c_{\ell_\alpha}}{(c_{\ell_\alpha})_{theory}} = 0.760 \quad \text{(Figure 4.1.1.2-8a)}$$

$$\frac{c'_{h_\delta}}{(c_{h_\delta})_{theory}} = 0.780 \quad \text{(Figure 6.1.3.2-12a)}$$

$$c'_{h_\delta} = \left[\frac{c'_{h_\delta}}{(c_{h_\delta})_{theory}}\right](c_{h_\delta})_{theory} \quad \text{(Equation 6.1.3.2-a)}$$

$$= (0.780)(-0.825)$$

$$= -0.644 \text{ per rad}$$

Determine if the thickness condition is satisfied; i.e.,

$$\tan\frac{\phi'_{TE}}{2} = \tan\frac{\phi''_{TE}}{2} = \tan\frac{\phi_{TE}}{2} = \frac{t}{c}$$

$$0.164 \neq 0.169 = 0.169 \neq 0.15$$

Determine the hinge-moment derivative accounting for the thickness distribution

$$(c_{\ell_\delta})_{theory} = 4.60 \text{ per rad} \quad \text{(Figure 6.1.1.1-39a)}$$

$$\frac{c_{\ell_\delta}}{(c_{\ell_\delta})_{theory}} = 0.605 \quad \text{(Figure 6.1.1.1-39b)}$$

$$c''_{h_\delta} = c'_{h_\delta} + 2(c_{\ell_\delta})_{theory}\left[1 - \frac{c_{\ell_\delta}}{(c_{\ell_\delta})_{theory}}\right]\left(\tan\frac{\phi''_{TE}}{2} - \frac{t}{c}\right) \quad \text{(Equation 6.1.3.2-b)}$$

$$= -0.644 + 2(4.60)[1 - 0.605](0.169 - 0.150)$$

$$= -0.575 \text{ per rad}$$

Determine the effect of nose shape and nose balance

$$\text{Balance ratio} = \sqrt{\left(\frac{c_b}{c_f}\right)^2 - \left(\frac{t_c}{2c_f}\right)^2} \quad \text{(Equation 6.1.3.1-d)}$$

$$= \sqrt{(0.35)^2 - (0.1527)^2}$$

$$= 0.315$$

$$\frac{(c_{h_\delta})_{\text{balance}}}{c''_{h_\delta}} = 0.42 \quad \text{(Figure 6.1.3.2-13)}$$

$$(c_{h_\delta})_{\text{balance}} = c''_{h_\delta}\left[\frac{(c_{h_\delta})_{\text{balance}}}{c''_{h_\delta}}\right] \quad \text{(Equation 6.1.3.2-c)}$$

$$= (-0.575)(0.42)$$

$$= -0.2415 \text{ per rad}$$

$$= -0.00421 \text{ per deg}$$

This compares with a test value of −0.0030 per degrec from Reference 8.

B. TRANSONIC

No method is available for predicting the section hinge-moment derivative c_{h_δ} at transonic speeds.

C. SUPERSONIC

The method for determining c_{h_δ} at supersonic speeds is based on the theory of Reference 7. The theory applies to airfoils with sharp leading and trailing edges, where the angles of attack and flap deflection angles are small. In addition, the flow field is assumed to be everywhere supersonic and inviscid.

DATCOM METHOD

The hinge-moment derivative c_{h_δ} at supersonic speeds for a symmetric, straight-sided flap with $c_f/c < 1/2$, regardless of the airfoil section ahead of the flap, is given by

$$c_{h_\delta} = -C_1 + C_2 \phi_{TE} \qquad 6.1.3.2\text{-d}$$

where C_1 and C_2 are thickness correction factors to the supersonic flat-plate derivative.

$$C_1 = \frac{2}{\sqrt{M^2 - 1}} \text{ per radian}$$

$$C_2 = \frac{(\gamma + 1)M^4 - 4(M^2 - 1)}{2(M^2 - 1)^2} \text{ per radian}$$

ϕ_{TE} is the trailing-edge angle in radians.

γ is the ratio of specific heats, $\gamma = 1.4$.

For a symmetric, circular-arc airfoil with $c_f/c < 1/2$, c_{h_δ} is given by

$$c_{h_\delta} = -C_1 + \left(\frac{\Delta c_{h_\delta}}{t/c}\right)\frac{t}{c} \qquad 6.1.3.2\text{-e}$$

where C_1 is defined above, and

$\frac{\Delta c_{h_\delta}}{t/c}$ is a thickness correction factor for symmetric, circular-arc airfoils, obtained from Figure 6.1.3.1-13.

The method becomes somewhat complicated for more general airfoil shapes. Other airfoil shapes are treated in Reference 7.

Sample Problem

Given: Symmetric, circular-arc airfoil.

$t/c = 0.06$ $\qquad$ $c_f/c = 0.30$ $\qquad$ $M = 2.0$

Compute:

$$C_1 = \frac{2}{\sqrt{M^2 - 1}}\frac{1}{57.3} = 0.020 \text{ per deg}$$

$$\frac{\Delta c_{h_\delta}}{t/c} = 0.0008 \text{ per deg} \quad \text{(Figure 6.1.3.1-13)}$$

Solution:

$$c_{h_\delta} = -C_1 + \left(\frac{\Delta c_{h_\delta}}{t/c}\right)\frac{t}{c} \quad \text{(Equation 6.1.3.2-e)}$$

$$= -0.020 + (0.0008)(0.06)$$

$$= -0.01995 \text{ per deg}$$

6.1.3.3 SECTION HINGE-MOMENT DERIVATIVE $(c_{h_f})_{\delta_t}$ OF CONTROL SURFACE DUE TO CONTROL TABS

A deflected tab on a control surface causes pressure changes on the surfaces of the tab and control. Because of the large moment arms associated with these incremental pressures, large changes in control-surface hinge moments result. In addition, these incremental changes in the pressure distribution can be influenced by a sealed or unsealed surface where the tab meets the control.

DATCOM METHOD

The following method is taken from Reference 1 and is based on the two-dimensional NACA 0009 airfoil test data for round-nose, unbalanced controls with sealed flap and tab gaps. This method is limited to the low-speed linear hinge-moment range and should be restricted to tab deflections of approximately $\pm 18^{\circ}$ and the combinations of control deflection and angle of attack as indicated in Figure 6.1.3-2.

The change in the low-speed section hinge-moment coefficient of a control due to tab deflection, measured at constant values of angle of attack and flap deflection, can be expressed as

$$\left(\frac{\partial c_{h_f}}{\partial \delta_t}\right)_{\alpha, \delta_f} = \left(\frac{\partial c_{h_f}}{\partial \delta_t}\right)_{c_\ell, \delta_f} - \left(\frac{\partial c_{h_f}}{\partial c_\ell}\right)_{\delta_t, \delta_f} \left(\frac{\partial c_\ell}{\partial \alpha}\right)_{\delta_t, \delta_f} \left(\frac{\partial \alpha}{\partial \delta_t}\right)_{c_\ell, \delta_f} \qquad 6.1.3.3\text{-a}$$

where

$\left(\frac{\partial c_{h_f}}{\partial \delta_t}\right)_{c_\ell, \delta_f}$ is the change in control section hinge-moment coefficient due to tab deflection, measured at constant values of lift and flap deflection. This value is obtained from Figure 6.1.3.3-4a.

$\left(\frac{\partial c_{h_f}}{\partial c_\ell}\right)_{\delta_t, \delta_f}$ is the change in control section hinge-moment coefficient due to lift variation, measured at constant values of tab and flap deflection. This value is obtained from Figure 6.1.3.3-4b (modified from Reference 1 to reflect the characteristics of a flat-sided flap contour -- like a conventional elevator).

$\left(\frac{\partial c_\ell}{\partial \alpha}\right)_{\delta_t, \delta_f}$ is the section lift-curve slope of the primary panel (wing, horizontal tail, etc.) at constant values of tab and flap deflection. This value can be obtained from Section 4.1.1.2.

$\left(\frac{\partial \alpha}{\partial \delta_t}\right)_{c_\ell, \delta_f}$ is the rate of change of angle of attack due to a change in tab deflection in the linear range at constant values of lift and flap deflection. This value can be obtained from Figure 6.1.3.3-5.

The above method does not quantitatively account for the effect of unsealing the tab gap. In view of the difficulty of predicting the effects of seals and gaps, experimental data should be used whenever possible. Figure 6.1.3.3-6a (from Reference 2) shows the effects of fixing transition and sealing the tab gap on a modified NACA 65_1-012 airfoil. For these data, the flap-chord-to-wing-chord ratio is 0.25, the tab-chord-to-flap-chord ratio is 0.25, and the flap gap is sealed.

The effects of tab nose shape are also not accounted for in the above method, and experimental data should be used whenever possible. However, the effect of tab nose shape as a function of nose balance is presented in Figure 6.1.3.3-6b (from Reference 2) for a NACA 65_1-012 airfoil with a tab gap of 0.004c and transition strips at 0.01c.

Other parameters not accounted for in this method include the effects of airfoil thickness and trailing-edge angle. Unfortunately, not enough data are available to evaluate the effects of either of these variables on the section hinge-moment derivative. Additional test data, including the effects of these variables on a limited number of flapped configurations, are presented in References 3 through 9.

Sample Problem

Given: The flap and tab configuration of Reference 2.

NACA 65_1-012 airfoil — Plain trailing-edge flap (sealed)

$c_f/c = 0.25$ — Round-nose flap

Plain trailing-edge tab (sealed) — $c_t/c_f = 0.25$ — Round-nose tab

Low speed — $R_\ell = 4.59 \times 10^6$

Compute:

$$\left(\frac{\partial c_{h_f}}{\partial \delta_t}\right)_{c_\ell, \delta_f} = -0.0124 \text{ per deg} \quad \text{(Figure 6.1.3.3-4a)}$$

$$\left(\frac{\partial c_{h_f}}{\partial c_\ell}\right)_{\delta_t, \delta_f} = -0.046 \quad \text{(Figure 6.1.3.3-4b)}$$

$$\left(\frac{\partial \alpha}{\partial \delta_t}\right)_{c_\ell, \delta_f} = -0.255 \quad \text{(Figure 6.1.3.3-5)}$$

$c_{\ell_\alpha} = 0.11$ per deg (Table 4.1.1-B)

Solution:

$$\left(\frac{\partial c_{h_f}}{\partial \delta_t}\right)_{\alpha,\,\delta_f} = \left(\frac{\partial c_{h_f}}{\partial \delta_t}\right)_{c_\ell,\,\delta_f} - \left(\frac{\partial c_{h_f}}{\partial c_\ell}\right)_{\delta_t,\,\delta_f} \left(\frac{\partial c_\ell}{\partial \alpha}\right)_{\delta_t,\,\delta_f} \left(\frac{\partial \alpha}{\partial \delta_t}\right)_{c_\ell,\,\delta_f}$$

(Equation 6.1.3.3-a)

$$= -0.0124 - (-0.046)(0.11)(-0.255)$$

$$= -0.0124 - 0.0013$$

$$= -0.0137 \text{ per deg}$$

This compares with test values of –0.0115 per degree with transition strips and –0.0138 per degree without transition strips, from Reference 2.

6.1.3.4 SECTION HINGE-MOMENT DERIVATIVE $(c_{h_t})_{\delta_f}$ OF CONTROL TAB DUE TO CONTROL SURFACE

A deflected flap or control surface causes pressure changes on the surfaces of the tab and control. These pressure changes on the tab generally result in a change in the tab hinge moment.

DATCOM METHOD

The following method is taken from Reference 1 and is based on the two-dimensional NACA 0009 airfoil test data for round-nose, unbalanced controls, with sealed flap and tab gaps. This method is limited to the low-speed linear hinge-moment range and should be restricted to flap deflections of approximately $\pm 18^{o}$ and the combinations of control deflection and angle of attack as indicated in Figure 6.1.3-2.

The change in the low-speed tab section hinge-moment coefficient due to flap deflection, measured at constant values of angle of attack and tab deflection, can be expressed as

$$\left(\frac{\partial c_{h_t}}{\partial \delta_f}\right)_{\alpha, \delta_t} = \left(\frac{\partial c_{h_t}}{\partial \delta_f}\right)_{c_\ell, \delta_t} - \left(\frac{\partial c_{h_t}}{\partial c_\ell}\right)_{\delta_f, \delta_t} \left(\frac{\partial c_\ell}{\partial \alpha}\right)_{\delta_f, \delta_t} \left(\frac{\partial \alpha}{\partial \delta_f}\right)_{c_\ell, \delta_t} \qquad 6.1.3.4\text{-a}$$

where

$\left(\frac{\partial c_{h_t}}{\partial \delta_f}\right)_{c_\ell, \delta_t}$ is the change in tab section hinge-moment coefficient due to control deflection, measured at constant values of lift and tab deflection. This value is obtained from Figure 6.1.3.4-4a.

$\left(\frac{\partial c_{h_t}}{\partial c_\ell}\right)_{\delta_f, \delta_t}$ is the change in tab section hinge-moment coefficient with respect to lift coefficient, measured at constant values of flap and tab deflections. This value is obtained from Figure 6.1.3.4-4b.

$\left(\frac{\partial c_\ell}{\partial \alpha}\right)_{\delta_f, \delta_t}$ is the section lift-curve slope of the primary panel (wing, horizontal tail, etc.) at constant values of tab and flap deflection. This value can be obtained from Section 4.1.1.2.

$\left(\frac{\partial \alpha}{\partial \delta_f}\right)_{c_\ell, \delta_t}$ is the rate of change of angle of attack due to a change in flap deflection in the linear range at constant values of lift and tab deflection. This value can be obtained from Figure 6.1.3.4-5.

The above method does not quantitatively account for the effect of unsealing the tab gap. In view of the difficulty of predicting the effects of seals and gaps, experimental data should be used whenever possible. Figure 6.1.3.4-6a (from Reference 2) shows the effects of fixing transition and sealing the tab gap on a modified NACA 65_1-012 airfoil. For these data, the flap-chord-to-wing-chord ratio is 0.25, the tab-chord-to-flap-chord ratio is 0.25, and flap gap is sealed.

The effects of tab nose shape are not accounted for in the above method and experimental data should be used whenever possible. However, the effect of tab nose shape as a function of nose balance is presented in Figure 6.1.3.4-6b (from Reference 2) for a NACA 65_1-012 airfoil with a tab gap of 0.004c and transition strips at 0.01c.

Other parameters not accounted for in the above method include the effects of airfoil thickness and trailing-edge angle. Unfortunately, not enough test data are available to evaluate the effects of either of these variables on the section hinge-moment derivative. Additional test data, including the effects of these variables on a limited number of flapped configurations, are presented in References 3 through 9 of Section 6.1.3.3.

Sample Problem

Given: The flap and tab configuration of Reference 2.

NACA 65_1-012 airfoil		Plain trailing-edge flap (sealed)	
$c_f/c = 0.25$	Round-nose flap	Plain trailing-edge tab (sealed)	
$c_t/c_f = 0.25$	Round-nose tab	Low speed	$R_\ell = 4.59 \times 10^6$

Compute:

$$\left(\frac{\partial c_{h_t}}{\partial \delta_f}\right)_{c_\ell, \delta_t} = -0.00188 \text{ per deg} \quad \text{(Figure 6.1.3.4-4a)}$$

$$\left(\frac{\partial c_{h_t}}{\partial c_\ell}\right)_{\delta_f, \delta_t} = -0.011 \quad \text{(Figure 6.1.3.4-4b)}$$

$$\left(\frac{\partial \alpha}{\partial \delta_f}\right)_{c_\ell, \delta_t} = -0.569 \quad \text{(Figure 6.1.3.4-5)}$$

c_{ℓ_α} = 0.11 per deg (Table 4.1.1-B)

Solution:

$$\left(\frac{\partial c_{h_t}}{\partial \delta_f}\right)_{\alpha, \delta_t} = \left(\frac{\partial c_{h_t}}{\partial \delta_f}\right)_{c_\ell, \delta_t} - \left(\frac{\partial c_{h_t}}{\partial c_\ell}\right)_{\delta_f, \delta_t} \left(\frac{\partial c_\ell}{\partial \alpha}\right)_{\delta_f, \delta_t} \left(\frac{\partial \alpha}{\partial \delta_f}\right)_{c_\ell, \delta_t}$$

(Equation 6.1.3.4-a)

$$= -0.00188 - (-0.011)(0.11)(-0.569)$$

$$= -0.00188 - 0.00069$$

$$= -0.00257 \text{ per deg}$$

This compares with test values of −0.0012 per degree with transition strips and −0.0026 per degree without transition strips, from Reference 2.

A. SUBSONIC

Mechanical Flaps

The method used to estimate lift due to flap deflection at subsonic speeds is designed to make maximum use of experimental airfoil section data when such data are available. This approach is taken from Reference 1, wherein various existing methods have been combined to obtain a simple procedure with general application.

Jet Flaps

Two methods are presented for estimating the jet-flap lift increment at small angles of attack (see Section 6.1.1.1 for a sketch of the various jet-flap types and a discussion of the salient aspects). More accurate and sophisticated lift methods than those presented here have been developed for analyzing jet-flap configurations (such as the method presented in Reference 2). However, the more sophisticated methods are not amenable to a handbook solution; i.e., they require the use of a computer. Other modifications and approaches to the jet-flap problem are presented and discussed in detail in Reference 3.

The first method (taken from Reference 4) evaluates the lift increment due to both flap deflection and power effects for an internally-blown-flap (IBF) configuration. This method is based on the theoretical two-dimensional jet-flap lift increment modified by Maskell's theoretical correction factor for finite-aspect-ratio effects and a crude part-span factor to account for partial-span flaps. This method has not been substantiated because of the lack of published three-dimensional IBF data. However, the method has yielded results within ten percent of test data for those cases that have been evaluated (References 4 and 5).

The second method (taken from Reference 6) is used to evaluate the lift increment due only to power effects for an externally-blown-flap (EBF) configuration. This method is based on Spence's two-dimensional jet-flap lift increment, modified by Hartunian's theoretical correction factor for finite-aspect-ratio effects and the ratio of flapped wing area to reference wing area to account for partial-span effects. Substantiation of this method has not been presented here; however, a substantiation of the method does appear in Reference 6 with an indicated average error of about 10 percent.

The nondimensional trailing-edge jet momentum coefficient for three-dimensional jet-flap configurations is denoted by C_J. The relationship to the two-dimensional jet momentum coefficient C_μ (see Section 6.1.1.1 for definition) can be expressed as

$$C_J = \frac{1}{qS} \int_{-b/2}^{b/2} J \, dy$$

$$= \frac{1}{S} \int_{-b/2}^{b/2} c\, C_\mu \, dy \qquad \text{6.1.4.1-1}$$

where

J is the jet momentum at the trailing edge.

dy is the spanwise wing increment.

q is the free-stream dynamic pressure.

S is the reference wing area.

b is the wing span.

c is the wing chord.

DATCOM METHODS

1. Mechanical Leading- and Trailing-Edge Devices

The lift increment developed by deflection of a control surface is given by

$$\Delta C_L = \Delta c_\ell \left(\frac{C_{L_\alpha}}{c_{\ell_\alpha}} \right) \left[\frac{(\alpha_\delta)_{C_L}}{(\alpha_\delta)_{c_\ell}} \right] K_b \qquad 6.1.4.1\text{-a}$$

where

Δc_ℓ is the section lift increment due to control deflection. Test data on the particular flapped airfoil are preferred, but the increment can be estimated by the applicable method of Section 6.1.1.1.

C_{L_α} is the lift-curve slope of the wing with the flap retracted, based on the wing reference area, obtained from the appropriate wing method of Paragraph A of Section 4.1.3.2.

c_{ℓ_α} is the section lift-curve slope of the basic airfoil, including the effects of compressibility, obtained from Section 4.1.1.2.

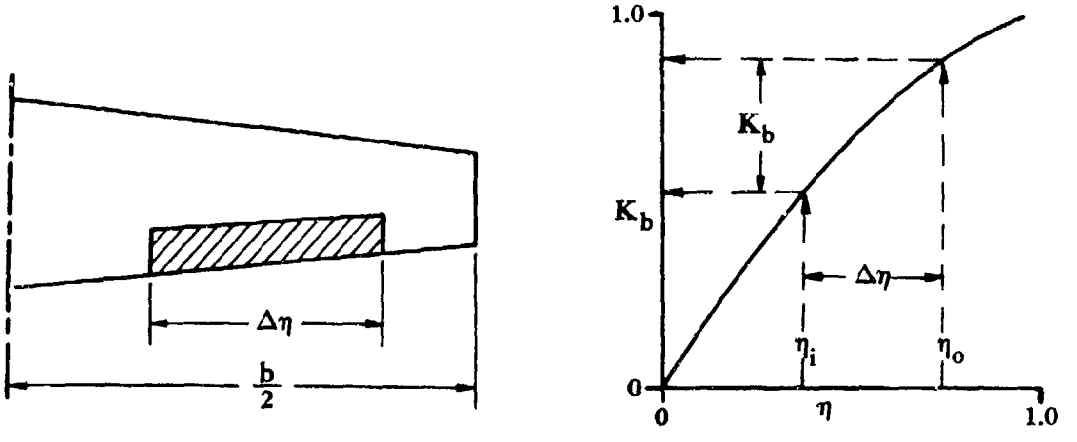
$\frac{(\alpha_\delta)_{C_L}}{(\alpha_\delta)_{c_\ell}}$ is the ratio of the three-dimensional flap-effectiveness parameter to the two-dimensional flap-effectiveness parameter, obtained from Figure 6.1.4.1-14 as a function of wing aspect ratio and the theoretical value of $(\alpha_\delta)_{c_\ell}$. The theoretical value of $(\alpha_\delta)_{c_\ell}$ is obtained from the inset chart of Figure 6.1.4.1-14.

When experimental values of the section lift increment Δc_ℓ are used in Equation 6.1.4.1-a, the value of $(\alpha_\delta)_{c_\ell}$ used to obtain $(\alpha_\delta)_{C_L}/(\alpha_\delta)_{c_\ell}$ from Figure 6.1.4.1-14 should be calculated using

$$(\alpha_\delta)_{c_\ell} = -\frac{(\Delta c_\ell)_{\text{experiment}}}{(c_{\ell_\alpha})\ \delta_f}$$

with one exception; i.e., for area-suction- and blowing-type flaps, use the inset chart of Figure 6.1.4.1-14.

K_b is the flap-span factor obtained from Figure 6.1.4.1-15 as illustrated in Sketch (a). (Note: η is the span station, $\eta = \frac{\text{control span ordinate}}{b/2}$.)



SKETCH (a)

It should be noted that the control deflection angles and all dimensions are measured in planes parallel or perpendicular to the plane of symmetry.

This method is restricted to the limitations of the methods used to evaluate the section lift increments from Section 6.1.1.1.

Equation 6.1.4.1-a is applicable to leading-edge flaps and slats, and plain, split, and slotted trailing-edge flaps. The lift increment due to combinations of leading-edge and trailing-edge devices may be estimated by applying Equation 6.1.4.1-a to each device separately and adding the individual increments.

For the case of arbitrary spanwise distribution of control chord (constant-chord controls on tapered wings or tapered controls on untapered wings), the control can be divided into spanwise steps and the lift increment found by the summation of ΔC_L values due to each spanwise step based on the average values of Δc_ℓ and $(\alpha_\delta)_{c_\ell}$ over that spanwise step.

Low-speed values of ΔC_L at $\alpha = 0$, calculated using the Datcom method, are compared with test values in Figures 6.1.4.1-16a, -16b, and -16c for wing-control combinations employing plain, split, and slotted trailing-edge controls, respectively. All parameters used in the calculations were estimated by using methods from the appropriate sections of the Datcom. The values of $(\alpha_\delta)_{c_\ell}$ used in the calculations were obtained from the inset of Figure 6.1.4.1-14. The ranges of Reynolds numbers and geometric parameters of the test configurations are noted on the correlation charts.

2. Jet-Flap IBF Configuration

The lift increment due to flap deflection and power effects for an IBF configuration is given by

$$\Delta C_L = \Delta c_\ell \left[\frac{A_t + \frac{2C'_J}{\pi}}{A_t + 2 + 0.604(C'_J)^{1/2} + 0.876\, C'_J} \right] \frac{S_{W_f}}{S_W} \qquad 6.1.4.1\text{-b}$$

where

Δc_ℓ is the section lift increment due to flap deflection and power effects. Test data on the particular flapped airfoil are preferred, but the increment can be estimated by the jet-flap method of Section 6.1.1.1. (When using Section 6.1.1.1 the value of C'_J is substituted for the value of C'_μ.)

A_t is the aspect ratio of the wing based on the total wing area S_t, including any increase in wing area due to flap extension.

C'_J is the three-dimensional trailing-edge jet momentum coefficient, based on the blown-flap affected wing area S_{W_f}, i.e.,

$$C'_J = C_J \frac{S_W}{S_{W_f}}$$

$\frac{S_{W_f}}{S_W}$ is the ratio of the blown-flap affected wing area (schematically illustrated in Section 2.2.2) to the wing reference area. The blown-flap affected area includes any increase in wing area due to flap extension.

As indicated above, this method has not been thoroughly substantiated and therefore should be applied with caution.

It should be noted that the total lift coefficient for an IBF configuration can be found by adding the lift increment from Equation 6.1.4.1-b to the flaps-retracted power-off lift coefficient, obtained from test data or the appropriate methods of Section 4.

3. Jet-Flap EBF Configuration

The effective jet deflection angle $\delta_{j_{eff}}$ and the trailing-edge momentum coefficient C_J are not specifically defined for EBF configurations. This is due to the jet sheet being somewhat diffuse rather than infinitesimally thin as assumed in jet-flap theory. For this reason it becomes necessary to obtain the effective jet angle from static force tests, or to relate the jet angle to the trailing-edge flap geometry. From correlation of test data (indicated in Reference 6), the best results are obtained when the engine exhaust jet momentum is used directly to define the trailing-edge momentum coefficient. Any losses in thrust must therefore be considered in the determination of drag.

The lift increment due to power effects for an EBF configuration is given by

$$\Delta C_L = 4\pi d_o \left[\frac{\pi A_t + 2C_J'}{\pi A_t + c_{\ell_\alpha}' + 2.01\, C_J'}\right] \frac{\delta_{j_{eff}}}{57.3} \frac{S_{W_f}}{S_W} \qquad 6.1.4.1\text{-c}$$

where

$4\pi d_o$ is the theoretical effect of blowing on the lift derivative. This parameter is obtained from Figure 6.1.4.1-18 as a function of the flap chord ratio c_f/c' and trailing-edge jet momentum coefficient C_J'. (See Figure 6.1.4.1-19a for a schematic definition of c_f/c'.)

A_t is the aspect ratio of the wing based on the total wing area S_t, including any increase in wing area due to flap extension.

C_J' is the three-dimensional trailing-edge jet momentum coefficient, based on the blown-flap-affected wing area S_{W_f}, i.e., $C_J' = C_J\, S_W/S_{W_f}$.

c_{ℓ_α} is the two-dimensional jet-flap lift-curve slope uncorrected for thickness effects. This term is obtained from Figure 6.1.1.1-49, using the trailing-edge jet momentum coefficient C_J' in place of C_μ'.

$\delta_{j_{eff}}$ is the effective jet deflection angle with respect to the airfoil chord, in degrees. If possible, this value should be obtained from static force tests. When test data are not available, the effective flap deflection angle may be approximated by using

$$\delta_{j_{eff}} = \frac{1}{2}(\delta_u + \delta_\ell) \qquad 6.1.4.1\text{-d}$$

where the values for δ_u and δ_ℓ are shown schematically in Figure 6.1.4.1-19b.

$\frac{S_{W_f}}{S_W}$ is the ratio of the flap-affected wing area (schematically illustrated in Section 2.2.2) to the wing reference area. The flap-affected area includes any increase in wing area due to flap extension.

It should be noted that the total lift coefficient for an EBF configuration can be found by adding the lift increment from Equation 6.1.4.1-c, the power-off mechanical-flap lift increment from Equation 6.1.4.1-a, and the flap-retracted power-off lift coefficient, obtained from test data or the appropriate methods of Section 4.

Sample Problems

1. Mechanical Flaps

Given: The sweptback wing of Reference 7.

$A = 3.78$ $\lambda = 0.586$ $\Lambda_{c/2} = 45.46^o$

NACA 65A006 airfoil Plain trailing-edge flap $c_f/c = 0.224$

$b_f/b = 0.469$ $\eta_i = 0.141$ $\eta_o = 0.610$ $\delta_f = 22.1^o$ (streamwise)

Low speed; $\beta = 1.0$ $R_\ell = 6.1 \times 10^6$

$\tan(\phi'_{TE}/2) = 0.0717$ (streamwise airfoil section geometry)

Compute:

c_{ℓ_α} and Δc_ℓ (Sections 4.1.1.2 and 6.1.1.1)

$$\frac{c_{\ell_\alpha}}{(c_{\ell_\alpha})_{theory}} = 0.887 \quad \text{(Figure 4.1.1.2-8a)}$$

$$(c_{\ell_\alpha})_{theory} = 6.58 \text{ per rad} \quad \text{(Figure 4.1.1.2-8b)}$$

$$c_{\ell_\alpha} = \frac{1.05}{\beta}\left[\frac{c_{\ell_\alpha}}{(c_{\ell_\alpha})_{theory}}\right](c_{\ell_\alpha})_{theory} \quad \text{(Equation 4.1.1.2-a)}$$

$$= (1.05)(0.887)(6.58) = 6.13 \text{ per rad}$$

$$(c_{\ell_\delta})_{theory} = 3.77 \text{ per rad} \quad \text{(Figure 6.1.1.1-39a)}$$

$$\frac{c_{\ell_\delta}}{(c_{\ell_\delta})_{theory}} = 0.817 \quad \text{(Figure 6.1.1.1-39b)}$$

$K' = 0.780$ (Figure 6.1.1.1-40)

$$\Delta c_\ell = \delta_f\left[\frac{c_{\ell_\delta}}{(c_{\ell_\delta})_{theory}}\right](c_{\ell_\delta})_{theory} K' \quad \text{(Equation 6.1.1.1-c)}$$

$$= \left(\frac{22.1}{57.3}\right)(0.817)(3.77)(0.780)$$

$$= 0.927$$

Wing lift-curve slope (Section 4.1.3.2)

$$\kappa = \frac{c_{\ell_\alpha}}{2\pi} = \frac{6.13}{2\pi} = 0.976$$

$$\frac{A}{\kappa}\left(\beta^2 + \tan^2 \Lambda_{c/2}\right)^{1/2} = \frac{3.78}{0.976}\left[1.0 + (1.0162)^2\right]^{1/2} = 5.52$$

$$\frac{C_{L_\alpha}}{A} = 0.798 \text{ per rad} \quad \text{(Figure 4.1.3.2-49)}$$

$$C_{L_\alpha} = 3.016 \text{ per rad}$$

$(\alpha_\delta)_{c_\ell} = -0.576$ (Inset, Figure 6.1.4.1-14)

$$\frac{(\alpha_\delta)_{C_L}}{(\alpha_\delta)_{c_\ell}} = 1.083 \quad \text{(Figure 6.1.4.1-14)}$$

$$\left.\begin{aligned}(K_b)_{\eta_i} &= 0.190 \\ (K_b)_{\eta_o} &= 0.740\end{aligned}\right\} \text{(Figure 6.1.4.1-15)}$$

$$K_b = (K_b)_{\eta_o} - (K_b)_{\eta_i} = 0.550$$

Solution:

$$\Delta C_L = \Delta c_\ell \left(\frac{C_{L_\alpha}}{c_{\ell_\alpha}}\right)\left[\frac{(\alpha_\delta)_{C_L}}{(\alpha_\delta)_{c_\ell}}\right] K_b \quad \text{(Equation 6.1.4.1-a)}$$

$$= (0.927)\,\frac{3.016}{6.13}\,(1.083)(0.550)$$

$$= 0.272$$

This compares with a test value of 0.255 from Reference 7.

2. Jet-Flap IBF Configuration

Given: The IBF configuration of Reference 5.

NACA 4424 airfoil $\quad \delta_f = 30^o \quad \delta_j = 22^o$

$\frac{c_f}{c} = 0.11 \quad \frac{c'}{c} = 1.0 \quad A = 6.0 \quad A_t = 6.0$

$C_j = 2.80 \quad \frac{t}{c} = 0.24 \quad \frac{S_{W_f}}{S_W} = 0.783 \quad \frac{S_t}{S_W} = 1.0$

Compute:

$$C_J' = C_J \frac{S_W}{S_{W_f}}$$

$$= (2.80) \frac{1}{0.783}$$

$$= 3.576$$

k_t = 0.80 (average airfoil)

$c_{\ell_{\delta_f}}$ = 10.0 per rad

$c_{\ell_{\delta_j}}$ = 8.9 per rad

Figure 6.1.1.1-49

$$\Delta c_\ell = \left\{ \left[1 + k_t \left(\frac{t}{c'} \right) \right] \delta_f \left(c_{\ell_{\delta_f}} - C_\mu' \right) + C_\mu' \delta_f \right.$$

$$\left. + \left[1 + k_t \left(\frac{t}{c'} \right) \right] \delta_j \left(c_{\ell_{\delta_j}} - C_\mu' \right) + C_\mu' \delta_j \right\} \frac{c'}{c} \qquad \text{(Equation 6.1.1.1-k)}$$

$$= [1 + (0.80)(0.24)] \frac{30}{57.3} (10.0 - 3.576) + 3.576 \frac{30}{57.3}$$

$$+ [1 + (0.80)(0.24)] \frac{22}{57.3} (8.9 - 3.576) + 3.576 \frac{22}{57.3}$$

$$= 4.01 + 1.87 + 2.44 + 1.37$$

$$= 9.69$$

Solution:

$$\Delta C_L = \Delta c_\ell \left[\frac{A_t + \frac{2C_J'}{\pi}}{A_t + 2 + 0.604 (C_J')^{1/2} + 0.876 C_J'} \right] \frac{S_{W_f}}{S_W} \qquad \text{(Equation 6.1.4.1-b)}$$

$$= 9.69 \left[\frac{6.0 + \frac{2(3.576)}{\pi}}{6.0 + 2.0 + 0.604 (3.576)^{1/2} + 0.876 (3.576)} \right] 0.783$$

$$= 5.12 \text{ (lift increment due to flap deflection and power effects)}$$

This compares with a test value of 5.03 from Reference 5.

3. Jet-Flap EBF Configuration

Given: The EBF configuration of Reference 8.

$\frac{c_f}{c} = 0.556$ $\quad \frac{c'}{c} = 1.336$ (without leading-edge extension) $\quad \frac{t}{c} \simeq 0.12$

$S_W = 8.43\ ft^2$ $\quad S_{W_f} = 9.58\ ft^2$ $\quad S_t = 10.84\ ft^2$

$A = 7.23$ $\quad A_t = 5.62$ $\quad C_J = 1.74$

$\delta_u = 61^o$ $\quad \delta_\ell = 50^o$

Compute:

$$C_J' = C_J\left(\frac{S_W}{S_{W_f}}\right)$$

$$= 1.74\left(\frac{8.43}{9.58}\right) = 1.53$$

$$\delta_{j_{eff}} = \frac{1}{2}(\delta_u + \delta_\ell) \quad \text{(Equation 6.1.4.1-d)}$$

$$= \frac{1}{2}(61 + 50)$$

$$= 55.5^o$$

$$\frac{c_f}{c'} = \left(\frac{c_f}{c}\right)\left(\frac{c}{c'}\right)$$

$$= \frac{0.556}{1.336} = 0.416$$

$c_{\ell_\alpha}' = 9.66$ per rad (Figure 6.1.1.1-49)

$4\pi d_o = 3.48$ (Figure 6.1.4.1-18)

Solution:

$$\Delta C_L = 4\pi d_o\left[\frac{\pi A_t + 2C_J'}{\pi A_t + c_{\ell_\alpha}' + 2.01\,C_J'}\right]\left(\frac{\delta_{j_{eff}}}{57.3}\right)\left(\frac{S_{W_f}}{S_W}\right) \quad \text{(Equation 6.1.4.1-c)}$$

$$= 3.48\left[\frac{\pi(5.62) + (2)(1.53)}{\pi(5.62) + 9.66 + (2.01)(1.53)}\right]\left(\frac{55.5}{57.3}\right)\left(\frac{9.58}{8.43}\right)$$

$$= 2.61 \text{ (lift increment due to power effects only)}$$

This compares with a test value of 2.45 from Reference 8.

B. TRANSONIC

No accurate method is available for predicting the control derivative C_{L_δ} at transonic speeds. Mixed flow conditions and interrelated shockwave and boundary-layer-separation effects cause extreme nonlinearities in this parameter in the transonic regime. The method presented herein is based on the observation that experimental data indicate that C_{L_δ} follows the same trend as the lift-curve slope through the transonic regime.

DATCOM METHOD

A first-order approximation to the control derivative C_{L_δ} at transonic speeds for mechanical trailing-edge flaps is given by

$$C_{L_\delta} = C_{L_{\delta M=0.6}} \left(\frac{C_{l_\delta}}{C_{l_{\delta M=0.6}}} \right) \qquad 6.1.4.1\text{-e}$$

where

$C_{L_{\delta M=0.6}}$ is the lift effectiveness, calculated by the method of Paragraph A of this section, at M = 0.6, i.e.,

$$C_{L_\delta} = \frac{\Delta C_L}{\delta_f}$$

$\frac{C_{l_\delta}}{C_{l_{\delta M=0.6}}}$ is the ratio of the rolling-effectiveness parameter at the Mach number in question to that at M = 0.6, obtained by the method of Paragraph B of Section 6.2.1.1.

C. SUPERSONIC

At supersonic speeds, the lift effectiveness of plain trailing-edge controls is predicted by the theoretical method presented in Reference 9. The restrictions used in the derivation of the method are as follows:

1. Leading and trailing edges of the control surface are swept ahead of the Mach lines from the deflected controls.

2. Control root and tip chords are parallel to the plane of symmetry.

3. Controls are located either at the wing tip or far enough inboard so that the outermost Mach lines from the deflected controls do not cross the wing tip.

4. Innermost Mach lines from the deflected controls do not cross the wing root chord.

5. Wing planform has leading edges swept ahead of the Mach lines and has streamwise tips.

6. Controls are not influenced by the tip conical flow from the opposite wing panel or by the interaction of the wing-root Mach cone with the wing tip.

DATCOM METHOD

The trailing-edge flap effectiveness C_{L_δ} at supersonic speeds for a symmetric, straight-sided flap is given by

$$C_{L_\delta} = \left(1 - \frac{C_2}{C_1}\phi_{TE}\right) C'_{L_\delta} \frac{S_f}{S_W} \qquad 6.1.4.1\text{-f}$$

where $\left(1 - \frac{C_2}{C_1}\phi_{TE}\right)$ is a thickness correction factor to the supersonic flat-plate derivative.

$$C_1 = \frac{2}{\sqrt{M^2 - 1}} \text{ (per radian)}$$

$$C_2 = \frac{(\gamma + 1)M^4 - 4(M^2 - 1)}{2(M^2 - 1)^2} \text{ (per radian)}$$

ϕ_{TE} is the trailing-edge angle in radians, measured normal to the control hinge line.

γ is the ratio of specific heats, $\gamma = 1.4$.

C'_{L_δ} is the lift effectiveness of one symmetric, straight-sided flap, based on the area of the flap. This parameter is obtained from Figures 6.1.4.1-20a through 6.1.4.1-20j for flaps located at the wing tip and from Figure 6.1.4.1-25 for flaps located inboard from the wing tip.

$\frac{S_f}{S_W}$ is the ratio of the total flap area (both sides of wing) to the total wing area.

It should be noted that control deflection angles are measured streamwise.

Not enough supersonic test data are available to allow substantiation of this method.

Sample Problem

Given: A wing-flap configuration with the following characteristics:

$S_W = 46.5$ sq ft $\qquad \bar{c}_W = 4.0$ ft $\qquad b_W = 12.0$ ft

$\lambda_W = 0.55$ $\qquad \Lambda_{LE} = 42^o$ $\qquad \Lambda_{TE} = 27.7^o$

Symmetric, straight-sided inboard flap

$\Lambda_{HL} = 30.8^{o}$ $S_f = 4.71$ sq ft $b_f = 6.5$ ft $\lambda_f = 0.715$ $\phi_{TE} = 3^{o}$

Additional Characteristics:

$M = 1.90$; $\beta = 1.62$

Compute:

$$C_1 = \frac{2}{\sqrt{M^2 - 1}} = 1.235 \text{ per rad}$$

$$C_2 = \frac{(\gamma + 1)M^4 - 4(M^2 - 1)}{2(M^2 - 1)^2} \text{ per rad}$$

$$= \frac{(2.4)(1.90)^4 - 4\,[(1.90)^2 - 1]}{2[(1.90)^2 - 1]^2} = \frac{20.84}{13.62} = 1.53 \text{ per rad}$$

$$\frac{\tan \Lambda_{TE}}{\beta} = \frac{0.5250}{1.62} = 0.324$$

$\beta C'_{L_\delta} = 0.074$ per deg (Figure 6.1.4.1-25)

$C'_{L_\delta} = 0.0457$ per deg

Solution:

$$C_{L_\delta} = \left(1 - \frac{C_2}{C_1}\phi_{TE}\right) C'_{L_\delta} \frac{S_f}{S_W} \quad \text{(Equation 6.1.4.1-f)}$$

$$= \left[1 - \left(\frac{1.53}{1.235}\right)\left(\frac{3.0}{57.3}\right)\right] (0.0457)\ \frac{4.71}{46.5}$$

$$= 0.00433 \text{ per deg}$$

6.1.4.2 WING LIFT-CURVE SLOPE WITH HIGH-LIFT AND CONTROL DEVICES

According to linear wing theory, camber, such as that due to flaps, does not affect the lift-curve slope. Linear theory also predicts that, for translating types of leading- or trailing-edge flaps, the lift-curve slope will increase as a result of the additional wing area. Recently, linear theory has also been applied to wings with blown flaps and shows an increase in lift-curve slope with increasing trailing-edge jet momentum. Within the limitation that the flow does not separate from the surface of the wing or flap, experimental data verify these predictions.

The effects of these devices on the two-dimensional airfoil section lift-curve slope are discussed in Section 6.1.1.2. The discussion and methods of that section are directly applicable to the three-dimensional wing.

DATCOM METHODS

1. Leading- and Trailing-Edge Mechanical Flaps

For wings with nontranslating leading- and trailing-edge flaps, the lift-curve slope of the flap-deflected wing is assumed to be the same as that of the flap-retracted wing, as given in Section 4.1.3.2. This assumption is valid for the linear-lift range of angles of attack and flap deflection.

For wings with translating leading- and trailing-edge flaps, a correction is made to the flaps-up lift-curve slope by means of the equation

$$\left(C_{L_\alpha}\right)_\delta = \left[\left(\frac{c'}{c} - 1\right)\frac{S_{W_f}}{S_W}\right]\left(C_{L_\alpha}\right)_{\delta=0} + \left(C_{L_\alpha}\right)_{\delta=0} \qquad \text{6.1.4.2-a}$$

where

$\left(C_{L_\alpha}\right)_\delta$ is the lift-curve slope of the flap-deflected wing, based on the area of the flap-retracted wing.

$\left(C_{L_\alpha}\right)_{\delta=0}$ is the lift-curve slope of the flap-retracted wing from test data or Section 4.1.3.2.

$\frac{S_{W_f}}{S_W}$ is the ratio of the flap-affected wing area to the wing reference area. The area S_{W_f} is schematically illustrated in Section 2.2.2, and does not include any increase in wing due to flap extensions.

$\frac{c'}{c}$ is the ratio of the extended wing chord to the chord of the flap-retracted wing. In measuring c' of a single-slotted trailing-edge flap or a leading-edge slat, the flap or slat is rotated from its deflected position about the point of intersection of the flap or slat chord with the wing chord until the two coincide. In measuring c' of a double-slotted flap, the aft flap is first rotated from its deflected position about the point of intersection of the aft-flap chord and the chord of the forward flap until the two chords coincide; then both flaps are rotated from the deflection of the

forward flap about the point of intersection of the forward-flap chord with the wing chord until these two coincide. (See Figures 6.1.1.1-44 through -46, and -51.)

For the case of arbitrary spanwise distribution of flap chord (constant-chord flaps on tapered wings or tapered flaps on untapered wings), the flap can be divided into spanwise steps and the correction factor to be applied to the flaps-up lift-curve slope found by the summation of the correction factors due to each spanwise step based on the average value of c'/c and S_{W_f}/S_W over that spanwise step.

2. Jet Flaps

The method presented herein for estimating the lift-curve slope of a wing with a blown flap is a modification of the method presented in Reference 1. Similar methods appear in References 2 and 3. The assumptions made in the development of the method are as follows: inviscid flow, elliptical loading, high-aspect-ratio configuration, full-span trailing-edge flaps, and constant spanwise sectional momentum coefficient. Despite these limitations, the theory has been successfully adapted to handle configurations outside the range of these assumptions. Specifically, this method is strictly valid only for the pure jet-flap and the internally-blown-flap (IBF) systems; however, it has been applied with good success to wings with externally-blown flaps (EBF).

This method uses an aspect-ratio correction factor based on Hartunian's work (Reference 4). Mathematically, the aspect-ratio correction factor allows the method to be applied to wings of any aspect ratio. However, the validity of the method for aspect ratios less than five is unknown. The fact that the data presented in Figure 6.1.4.2-9 allow the method to be applied to low-aspect-ratio configurations must not be construed to mean that the Datcom recommends such use.

The corrections of the method for part-span blowing and large trailing-edge flap deflections are not inherent in Hartunian's aspect-ratio correction factor.

An implicit assumption of this method is that the flow on the unblown wing is attached. Unfortunately, the blown-flap systems now being tested do not always exhibit attached flow for an unblown condition. However, such designs are acceptable, since blowing provides a type of automatic boundary-layer control that causes the flow to reattach. But it does prohibit the use of experimental data to determine the lift-curve slope of the unblown flap-deflected wing where separation is a possibility.

The lift-curve slope (near zero angle of attack) of a wing with a trailing-edge jet flap, based on the flap-retracted wing area, is given by

$$C_{L_\alpha} = \left(C_{L_\alpha}\right)_\delta \left\{\left[K(A_t, C_J') - 1\right] K_b + 1\right\} + \frac{C_J \left(\cos \delta_{j_{eff}} - 1\right)}{57.3} \qquad 6.1.4.2\text{-b}$$

where

$\left(C_{L_\alpha}\right)_\delta$ is the lift-curve slope of the unblown flap-deflected wing, with attached flow. This parameter can be obtained from experimental data if no separation exists, or from the mechanical-flap method of this section.

$K(A_t C_J')$ is the jet momentum aspect-ratio correction factor obtained from Figure 6.1.4.2-9 as a function of A_t and C_J', where

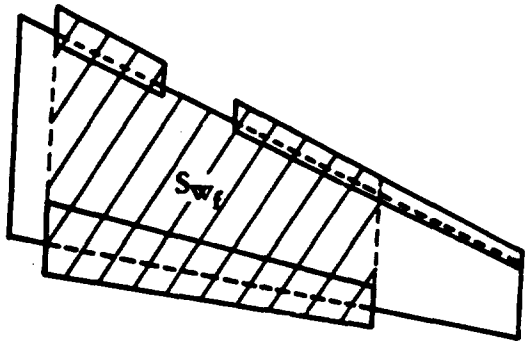
A_t is the aspect ratio of the wing based on the total wing area S_t, including any increase in wing area due to flap extension.

C_J' is the three-dimensional trailing-edge jet momentum coefficient based on the blown-flap affected area S_{W_f}; i.e.,

$$C_J' = C_J \frac{S_W}{S_{W_f}}$$

where

S_{W_f}/S_W is the ratio of the blown-flap affected area (schematically illustrated in Sketch (a)) to the wing reference area. The blown-flap affected area includes any increase in wing area due to flap extensions.



SKETCH (a)

K_b is the flap-span factor from Figure 6.1.4.1-15, using the $\lambda = 1$ curve, as illustrated in Sketch (a) of Section 6.1.4.1.

C_J is the trailing-edge jet momentum coefficient based on the flap-retracted wing area.

$\delta_{j_{eff}}$ is the effective jet deflection angle with respect to the airfoil chord, in degrees. If possible, this value should be obtained from static force tests. When test data are not available for an externally-blown-flap (EBF) configuration, the effective flap deflection angle may be approximated by using Equation 6.1.4.1-d, i.e.,

$$\delta_{j_{eff}} = \frac{1}{2}(\delta_u + \delta_\ell)$$

where the values for δ_u and δ_ℓ are shown schematically in Figure 6.1.4.1-19b.

A data summary and substantiation of this method are presented in Table 6.1.4.2-A.

Sample Problems

1. Leading-edge slat

Given: The wing of Reference 5 with a 50-percent-span leading-edge slat.

$A = 6.0 \qquad \Lambda_{c/2} = 32.8^{\circ} \qquad \lambda = 0.50 \qquad c'/c = 1.10 \qquad S_{W_f}/S_W = 0.429$

Low speed; $\beta = 1.0 \qquad \kappa = 1.0$ (assumed)

Compute:

$$\frac{A}{\kappa}\left[\beta^2 + \tan^2 \Lambda_{c/2}\right]^{1/2} = (6.0)\left[1.0 + (0.6445)^2\right]^{1/2} = 7.14$$

$$\frac{(C_{L_\alpha})_{\delta=0}}{A} = 0.67 \text{ per rad} \quad \text{(Figure 4.1.3.2-49)}$$

$$(C_{L_\alpha})_{\delta=0} = 4.02 \text{ per rad} = 0.0702 \text{ per deg}$$

Solution:

$$(C_{L_\alpha})_\delta = \left[\left(\frac{c'}{c} - 1\right)\frac{S_{W_f}}{S_W}\right](C_{L_\alpha})_{\delta=0} + (C_{L_\alpha})_{\delta=0} \quad \text{(Equation 6.1.4.2-a)}$$

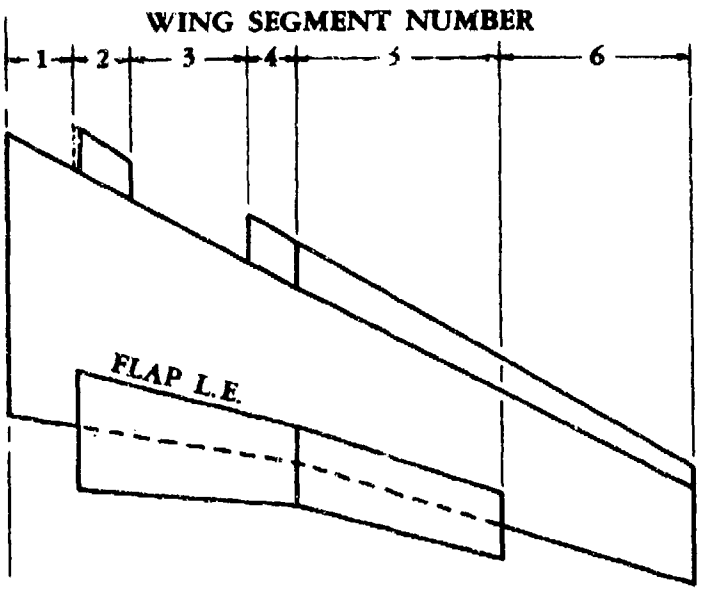
$$= [(1.10 - 1.0)(0.420)]\ 0.0702 + 0.0702$$

$$= 0.0732 \text{ per deg (based on } S_W)$$

This compares with a test value of 0.0720 per degree from Reference 5.

2. Jet Flap

Given: The sweptback wing-body configuration of Reference 6 with a trailing-edge double-slotted EBF system.



Note: All leading-edge and trailing-edge devices are shown rotated into the wing plane.

Wing Characteristics:

$A = 7.75$ $S_W = 7.87\ ft^2$ $b = 95.08$ in.

$\lambda = 0.336$ $c_r = 19.49$ in. $c_t = 6.54$ in.

$\bar{c} = 13.22$ in. $y_{\bar{c}} = 19.33$ in.

To facilitate calculations, the wing has been divided into segments as shown in the preceding sketch. The divisions are made at the sweep discontinuity and at the discontinuities in leading- and trailing-edge flaps.

Sections	$S(ft^2)$ (flaps retracted)	c'/c	$S_t(ft^2)$ (flaps extended)
1	1.253	1.000	1.253
2	0.909	1.421	1.311
3	1.650	1.253	2.069
4	0.617	1.521	0.933
5	2.076	1.521	3.178
6	1.365	1.268	1.847
Value for the entire wing	7.870		$10.59\ ft^2$

Flap Characteristics:

Double-slotted trailing-edge flap:

Forward segment: $c_f/c = 0.22$ $\delta_{f_1} = 30^o$

Aft segment: $c_f/c = 0.24$ $\delta_{f_2} = 30^o$

$\eta_i = 0.102$ $\eta_o = 0.720$ $\delta_{j_{eff}} = 60^o$

Krueger leading-edge flap:

Inboard segment: $c_f/c = 0.168$

Outboard segment: $c_f/c = 0.268$

Additional Characteristics:

$R_\ell = 0.35 \times 10^6$ $\quad V = 50$ ft/sec $\quad C_J = 3.18$

Low speed; $\beta = 1.0$ $\quad \kappa = 1.0$ (assumed) $\quad \Lambda_{c/2} = 21.1^\circ$ (average value)

Compute:

Determine the unblown lift-curve slope for both leading- and trailing-edge flap extension.

$$\frac{A}{\kappa}\left[\beta^2 + \tan^2 \Lambda_{c/2}\right]^{1/2} = \frac{7.75}{1.0}\left[1.0 + (0.3859)^2\right]^{1/2} = 8.307$$

$$\frac{(C_{L_\alpha})_{\delta=0}}{A} = 0.602 \text{ per rad} \quad \text{(Figure 4.1.3.2-49)}$$

$$(C_{L_\alpha})_{\delta=0} = 4.666 \text{ per rad} = 0.0814 \text{ per deg}$$

Since the wing has been divided into 6 segments, Equation 6.1.4.2-a should be written as

$$(C_{L_\alpha})_\delta = \sum_{n=1}^{6}\left[\left(\frac{c'}{c} - 1\right)\frac{S_{W_f}}{S_W}\right](C_{L_\alpha})_{\delta=0} + (C_{L_\alpha})_{\delta=0} \quad \text{(Equation 6.1.4.2-a)}$$

$$= \left[(1.0 - 1.0)\frac{0}{7.87} + (1.421-1.0)\frac{0.909}{7.87} + (1.253-1.0)\frac{1.650}{7.87} + (1.521-1.0)\frac{0.617}{7.87}\right.$$

$$\left. + (1.521-1.0)\frac{2.076}{7.87} + (1.278-1.0)\frac{1.365}{7.87}\right]0.0814 + 0.0814$$

$$= (0.3264)(0.0814) + 0.0814$$

$$= 0.108$$

Determine the blown lift-curve slope for both leading- and trailing-edge flap extension.

$$A_t = \frac{(95.08)^2}{(144)(10.59)} = 5.928$$

The value of S_{W_f} is found by adding the flap-extended wing area for segments 2 through 5; i.e., $S_{W_f} = 7.491$ ft^2.

$$C_J' = C_J\frac{S_W}{S_{W_f}}$$

$$= 3.18\frac{7.87}{7.491}$$

$$= 3.34$$

$$K(A_t, C_J') = 1.795 \quad \text{(Figure 6.1.4.2-9)}$$

$$\left.\begin{aligned}(K_b)_{\eta_i} &= 0.13 \\ (K_b)_{\eta_o} &= 0.82\end{aligned}\right\} \quad \text{(Figure 6.1.4.1-15)}$$

$$K_b = 0.82 - 0.13 = 0.69$$

Solution:

$$C_{L_\alpha} = (C_{L_\alpha})_\delta \left\{[K(A_t, C_J') - 1]\, K_b + 1\right\} + \frac{C_J(\cos \delta_{j_{eff}} - 1)}{57.3} \quad \text{(Equation 6.1.4.2-b)}$$

$$= (0.108)\left\{[1.795 - 1](0.69) + 1\right\} + \frac{3.18(0.50 - 1)}{57.3}$$

$$= 0.167 - 0.0277$$

$$= 0.139 \text{ per deg}$$

This compares with a test value of 0.130 per degree from Reference 6.

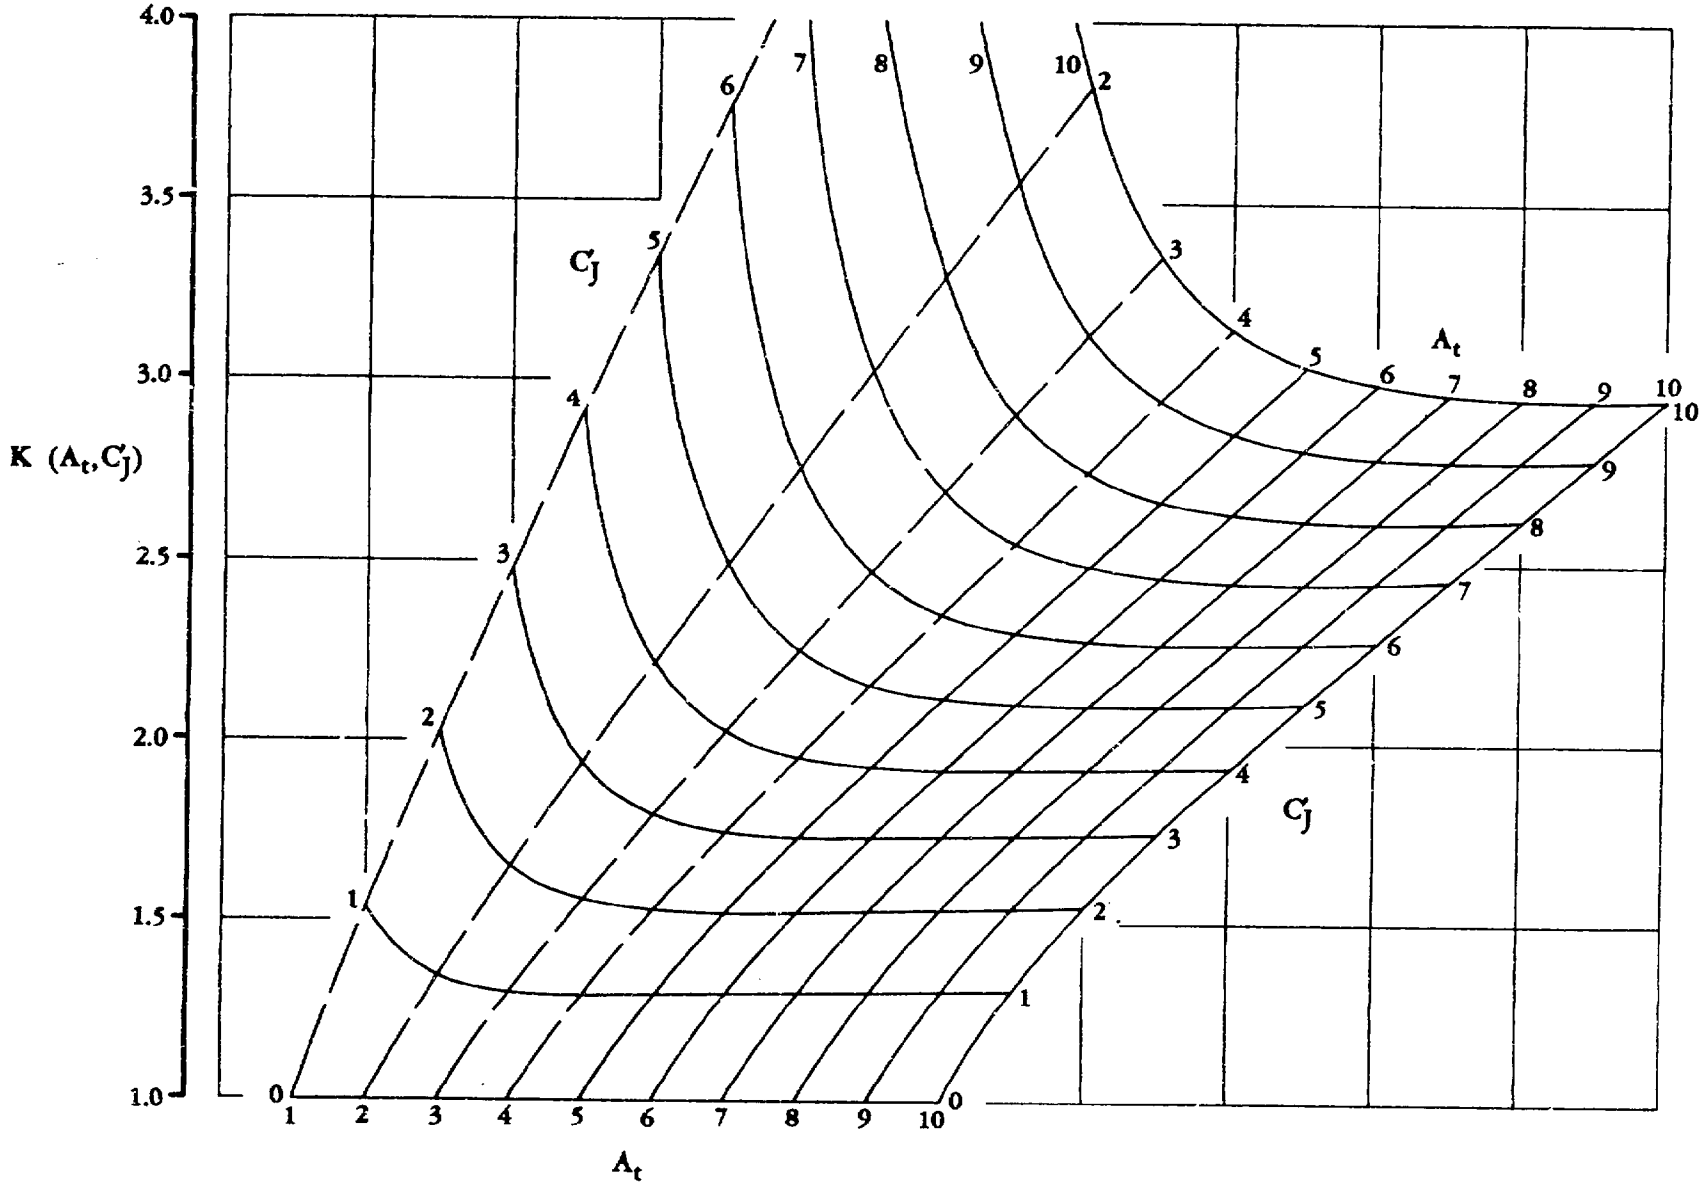

FIGURE 6.1.4.2-9 JET MOMENTUM FACTOR FOR BLOWN FLAPS

6.1.4.3 WING MAXIMUM LIFT WITH HIGH-LIFT AND CONTROL DEVICES

The estimation of wing maximum-lift coefficient is at best approximate. The stalling characteristics of various kinds of wings often take on an entirely different character from the stalling characteristics of airfoil sections. Stall may begin at the wing tips or may occur initially at the inboard flapped sections, depending upon the amount of sweep, taper ratio, and the difference in stall angle between the flapped and unflapped sections. Leading-edge devices can markedly alter the character of the stall. Large crossflow components on the wing at the stall make estimates based on section data inaccurate.

Tabulated data from 142 reports are presented in Reference 1. Results are shown for many planforms with and without various configurations of leading- and trailing-edge flaps, fences, and slats. Values of $C_{L_{max}}$ and $\alpha_{C_{L_{max}}}$ are given in tabular form. Summary data from Reference 1 are shown in Figures 6.1.4.3-7 through 6.1.4.3-9.

Figure 6.1.4.3-7 illustrates the effect of sweep on the maximum lift effectiveness of trailing-edge flaps. It can be seen that at high angles of sweep, flap deflection can actually decrease maximum lift. This results partially from the additional induced effects when flaps are deflected, causing the tips to stall. Figure 6.1.4.3-8 shows representative effects on $C_{L_{max}}$ of two sweptback wings with varying flap-span ratios.

Because of their boundary-layer-control properties, double-slotted flaps are capable of producing larger $C_{L_{max}}$ increments.

Maximum lift increments of leading-edge and trailing-edge flaps cannot, in general, be added when these devices are used in combination. A brief summary of maximum lift coefficients for swept wings is presented in Figure 6.1.4.3-9.

Separate methods are presented herein for estimating the wing maximum lift due to each of the following: mechanical trailing-edge flaps, slats, and jet flaps (externally-blown flaps only).

Mechanical Trailing-Edge Flaps

The Datcom method for trailing-edge flaps is semiempirical and converts two-dimensional data into three-dimensional characteristics as affected by wing planform, airfoil section characteristics across the span, flap type and geometry, and flap span. The method is intended to be used as a first-order approximation of wing maximum-lift coefficients when experimental data are not available.

Slats

The Datcom method for slats is an empirical method that assumes a section maximum-lift value of 1.28. This method estimates the maximum obtainable lift increment for a particular slat span, slat-chord-to-wing-chord ratio, and wing quarter-chord sweep. If a test value for the slat section maximum lift is available, it can be substituted for the assumed value of 1.28. Attempts to use the predicted section maximum-lift value from Section 6.1.1.3 have been unsatisfactory, as the resulting estimates underpredicted the test values. The method has not been substantiated beyond the test data that were used to formulate the method (which indicated a variation in agreement). Therefore, the method is intended to be used only as a first approximation of the slat maximum-lift increment when experimental data are not available.

Jet Flaps

The jet-flap method presented is for predicting the maximum-lift coefficient for an externally-blown-flap (EBF) configuration; no method is currently presented for an internally-blown-flap (IBF) configuration. The Datcom method for EBF configurations is an empirical approximation

taken from Reference 2. The maximum-lift coefficient therein is reasoned to be a function of the total camber of the wing, and blowing is considered to act as an effective camber increase. The measurement of the increase in camber is taken to be the component of thrust normal to the airfoil. This method is intended to be a first-order approximation of the maximum-lift increment due to power effects. Substantiation of this method is not presented here; however, a substantiation of the method does appear in References 2 and 3.

A semiempirical method for an EBF configuration, based on the assumption of a leading-edge stall and the use of basic jet-flap theory, is given in Reference 3. The method provides good correlation with measured values when an empirical factor is added. However, the use of this method depends upon the availability of test data for the effective jet deflection angle, the measured turning efficiency, and the power-off stall angle of attack. If these test data are available, this method is preferable to the Datcom method presented herein.

DATCOM METHODS

1. Mechanical Trailing-Edge Flaps

The increment in maximum-lift coefficient due to trailing-edge flap deflection is given by the equation

$$\Delta C_{L_{max}} = \Delta c_{\ell_{max}} \frac{S_{W_f}}{S_W} K_\Lambda \qquad 6.1.4.3\text{-a}$$

where

$\Delta c_{\ell_{max}}$ is the increment in airfoil section maximum-lift coefficient due to trailing-edge flaps, obtained from Section 6.1.1.3.

$\frac{S_{W_f}}{S_W}$ is the ratio of the flap-affected wing area to the total wing area. The flap-affected wing area does not include any increase in wing area due to flap extension.

K_Λ is an empirically derived correction factor that accounts for the effects of wing planform. This parameter is obtained from Figure 6.1.4.3-10 as a function of the sweepback of the wing quarter-chord line.

It should be noted that the flap deflection angles and all dimensions are measured in planes parallel or perpendicular to the plane of symmetry.

2. Slats

The increment in maximum-lift coefficient due to leading-edge slat deflection, based on the wing reference area, is given by

$$\Delta C_{L_{max}} = 1.28 \left(\frac{c_f/c}{0.18}\right) \left(\frac{b_{slat}}{b_e}\right)^2 \cos^2 \Lambda_{c/4} \qquad 6.1.4.3\text{-b}$$

where

$\frac{c_f}{c}$ is the ratio of the leading-edge-slat chord to the wing chord (see Figure 6.1.1.1-51).

$\frac{b_{slat}}{b_e}$ is the ratio of the total slat span to the exposed wing span. For a segmented leading-edge slat, b_{slat} is the total span of the segments. (See Section 4.3.1.2 for the definition of the exposed wing span.)

$\Lambda_{c/4}$ is the sweep of the quarter chord.

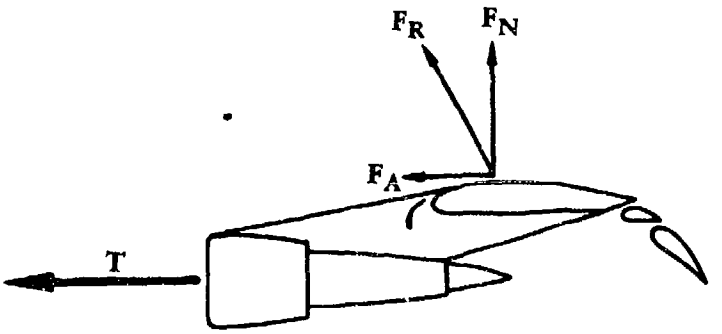
3. Jet Flaps

The increment in maximum-lift coefficient due to power effects for an EBF configuration is approximated from Figure 6.1.4.3-12, as a function of the thrust normal to the airfoil, defined as

$$\eta_t C_J \sin \delta_{j_{eff}}$$

where

η_t is the static turning efficiency defined as the resultant force divided by the gross thrust. This value should be obtained from test data if available, or it may be approximated for double- or triple-slotted flaps from Figure 6.1.4.3-11, as a function of the effective jet deflection angle. (See Sketch (a).)



$$\delta_{j_{eff}} = \tan^{-1} (F_N/F_A)$$

$$\eta_t = F_R/T$$

SKETCH (a)

C_J is the nondimensional trailing-edge jet momentum coefficient based on the gross engine thrust and the wing reference area. (See Section 6.1.4.1 for a definition.)

$\delta_{j_{eff}}$ is the effective jet deflection angle with respect to the airfoil chord. If possible, this value should be obtained from static force tests. When test data are not available, the effective flap deflection angle may be approximated by using Equation 6.1.4.1-d; i.e.,

$$\delta_{j_{eff}} = \frac{1}{2} (\delta_u + \delta_\ell)$$

where δ_u and δ_ℓ are defined in Section 6.1.4.1.

Sample Problems

1. Mechanical Trailing-Edge Flaps

Given: The wing-flap configuration of Reference 2.

$A = 5.1$ $\quad \lambda = 0.383$ $\quad \Lambda_{c/4} = 46^{o}$

NACA 64-210 airfoil (Ł286c) $\quad (t/c)_{streamwise} = 0.072$

Single-slotted flap $\quad c_f/c = 0.258$ $\quad \delta_f = 15.6^{o}$

$\frac{S_{W_f}}{S_W} = 0.378$ $\quad R_{\ell} = 6.0 \times 10^{6}$

Compute:

$\Delta c_{\ell_{max}}$ (Section 6.1.1.3)

$\left(\Delta c_{\ell_{max}}\right)_{base} = 1.045$ (Figure 6.1.1.3-12a)

$k_1 = 1.010$ (Figure 6.1.1.3-12b)

$k_2 = 0.605$ (Figure 6.1.1.3-13a)

$\frac{\text{Actual flap angle}}{\text{Reference flap angle}} = \frac{15.6}{45} = 0.347$

$k_3 = 0.445$ (Figure 6.1.1.3-13b)

$\Delta c_{\ell_{max}} = k_1 k_2 k_3 \left(\Delta c_{\ell_{max}}\right)_{base}$ (Equation 6.1.1.3-a)

$= (1.010)\ (0.605)\ (0.445)\ (1.045)$

$= 0.284$

$K_{\Lambda} = 0.730$ (Figure 6.1.4.3-10)

Solution:

$\Delta C_{L_{max}} = \Delta c_{\ell_{max}} \frac{S_{W_f}}{S_W} K_{\Lambda}$ (Equation 6.1.4.3-a)

$= (0.284)\ (0.378)\ (0.730)$

$= 0.0784$ (based on S_W)

This compares with a test value of 0.075 from Reference 2.

2. Slats

Given: The wing-body configuration of an A4D-1 Flight Trainer

$$\frac{c_f}{c} = 0.177 \qquad \Lambda_{c/4} = 33.2^{o} \qquad \frac{b_{slat}}{b_e} = 0.535$$

Compute:

$$\Delta C_{L_{max}} = 1.28 \left(\frac{c_f/c}{0.18}\right)\left(\frac{b_{slat}}{b_e}\right)^2 \cos^2 \Lambda_{c/4} \qquad \text{(Equation 6.1.4.3-b)}$$

$$= (1.28) \left(\frac{0.177}{0.18}\right) (0.535)^2 (0.700)$$

$$= 0.252 \text{ (based on } S_W)$$

This compares with a test value of 0.295.

3. Jet-Flap EBF Configuration

Given: The wing-body configuration of Reference 5.

$C_J = 3.18$ $\qquad \delta_f = 60^{o}$ $\qquad \delta_u \simeq 73^{o}$ $\qquad \delta_\ell \simeq 52^{o}$

Double-Slotted Flaps

Compute:

$$\delta_{j_{eff}} = \frac{1}{2} (\delta_u + \delta_\ell) \qquad \text{(Equation 6.1.4.1-d)}$$

$$= \frac{1}{2} (73 + 52)$$

$$= 62.5^{o}$$

$\eta_t = 0.583$ (Figure 6.1.4.3-11)

$\eta_t C_j \sin \delta_{j_{eff}} = (0.583)\ (3.18)\ (0.887) = 1.644$

$\Delta C_{L_{max}} = 4.65$ (Figure 6.1.4.3-12, lift increment due only to power effects, based on S_W)

This compares with a test value of 5.35 from Reference 5.

6.1.5 WING PITCHING MOMENT WITH HIGH-LIFT AND CONTROL DEVICES

The following sections give the effect of flap deflection on wing pitching-moment coefficient at subsonic, transonic, and supersonic speeds. Section data from other portions of the Datcom are used. Although the methods are developed for trailing-edge flaps, they can be applied to leading-edge flaps, slats, and spoilers, provided the proper section data are available or can be estimated. However, the methods presented are applicable to the angle-of-attack and flap-deflection ranges for which linear aerodynamic control characteristics exist. A chart showing the linear-lift range for a particular airfoil is shown in Section 6.1.3. In general, the linear-lift range for wings is considerably shorter than that shown in this chart, particularly for swept and low-aspect-ratio wings. For swept wings, the effects of spanwise boundary-layer flow, induced camber, and leading-edge vortices are pronounced and tend to nonlinearize the control or flap characteristics. For low-aspect-ratio wings, section characteristics are not important and, generally, the linear range is shorter than those of their section counterparts.

Leading- and trailing-edge flaps frequently have a pronounced effect upon the longitudinal stability characteristics of wings. Reference 1 gives a summary of these effects. Figures 6.1.5-2a and 6.1.5-2b are reproduced from this reference. Figure 6.1.5-2a shows the increase in stability that can be obtained from leading-edge flaps, slats, and fences. The basic curve is also shown in Section 4.1.4.3. Figure 6.1.5-2b shows the effect of spanwise extent of leading- and trailing-edge flaps on longitudinal stability for a particular wing.

6.1.5.1 PITCHING-MOMENT INCREMENT ΔC_m DUE TO HIGH-LIFT AND CONTROL DEVICES

A. SUBSONIC

Methods are presented in this section for estimating the pitching-moment characteristics for most common high-lift devices in use today and for some of the blown flaps being considered for STOL aircraft. These methods are valid only in the linear-lift region (preferably near zero angle of attack). The effect of these devices on the variation of pitching moment with angle of attack is presented in Section 6.1.5.2, except for the jet flap, which is presented in this section. Considerations of clarity and simplicity of presentation dictated this deviation from standard Datcom practice. The reader is referred to Sections 6.1.1.1 and 6.1.2.1 for a discussion of the salient aspects regarding the various types of high-lift devices.

The assumption is made that the characteristics of a trailing-edge flap are independent of any leading-edge device, and/or the characteristics of a leading-edge device are independent of any mechanical trailing-edge flap. In reality this is not quite true, but the methods of this section are not sufficiently refined to account for these interference effects. This assumption cannot be justified in the case of the more powerful jet flap.

Trailing-Edge Mechanical Flaps

Two methods are presented for estimating the pitching-moment increment due to trailing-edge mechanical flaps at small angles of attack and low speeds. Both methods are applicable to all types of flaps and to high-flap-deflection ranges, provided proper section data are used.

Method 1 (Reference 1) is substantially easier to apply than Method 2 (Reference 2). A data summary and substantiation of Method 1 are presented in Table 6.1.5.1-A. The resulting mean error of the pitching-moment increment due to flap deflection is ±0.053. For configurations with quarter-chord sweep angles greater than 45°, caution should be exercised, since the accuracy of the method is questionable in this range.

Method 2 uses linear theory for subsonic compressible flow, together with two-dimensional airfoil data adjusted for the effects of sweep. The additional feature of this method is that it requires the determination of the spanwise loading of the wing due to flap deflection. It is this feature that makes this method cumbersome to use. This method is not substantiated here; however, a substantiation of the method does appear in Reference 2 with a reported mean error of pitching-moment increment due to flap deflection of ±0.02.

Leading-Edge Mechanical Devices

Although the second method described above should be equally applicable to leading-edge devices, no substantiation of such use has been found. The use of a method as complex as this one cannot be justified when the small pitching moments and nonlinear characteristics of leading-edge devices are considered. Therefore, a simpler method is presented for estimating the effect of conventional leading-edge devices on the pitching moment. This method is based on the thin-airfoil, two-dimensional method, uncorrected for three-dimensional effects. Although the accuracy of the method is not as good as desired, no trends in three-dimensional parameters, such as aspect ratio, taper ratio, or sweep, have been observed that would improve the accuracy.

The lack of accuracy is to be expected, since the linear theory is intrinsically unable to handle the large deflections typical of leading-edge devices or to predict the nonlinear characteristics evident in the test data.

Jet Flaps

The method presented herein (taken in part from Reference 3) adapts the jet-flap method for airfoils, presented in Section 6.1.2.1, for use on finite-aspect-ratio wings. As such, it applies to the same concepts and is subject to the same limitations that are listed in that section. The user is referred to the discussions in Sections 6.1.1.1 and 6.1.2.1 for a complete understanding of this method.

The jet-flap method assumes that the entire flap is immersed in a uniform-jet-flow field. For externally-blown-flap (EBF) systems on swept wings, where this assumption is obviously not valid, the method contains a procedure for making an approximate estimate of the spanwise distribution of the jet. However, this cannot be expected to yield better than a rough estimate of the true pitching moment. This is due to the fact that the pitching moment cannot be accurately estimated without a detailed knowledge of the spanwise extent of the wing influenced by the jet.

Unfortunately, the jet spreading problem is very difficult to treat, and to date little in the way of analytical or empirical methods has been developed. Solution of the problem, which is simply to determine the spanwise distribution of trailing-edge jet momentum, requires that the flow details of the impingement, spreading, and turning process be known. Such a flow solution, which involves the viscid/inviscid interaction of the jet impinging on the wing-flap system, is clearly beyond the scope of the Datcom.

The wing pitching moment is calculated by applying correction factors for finite aspect ratio to Spence's adaptation of thin-airfoil theory to the two-dimensional jet-flap problem. The correction factors adjust the center-of-lift location and the magnitude of the lift increment. The first is from Reference 4 and is based on conventional flap data; the second is from Reference 38 and is based on Maskell's theoretical correction for three-dimensional effects. This method does not account for sweep or taper effects, except insofar as they affect the geometric relationship between the center of gravity and the wing. This should not be a serious restriction, since the jet-flap system is usually applied to high-aspect-ratio wings with low to moderate sweepback. The maximum sweep angle and taper ratio for which this method is valid have not been determined.

DATCOM METHODS

1. Trailing-Edge Mechanical Flaps

Method 1

This method assumes a constant flap-chord-to-wing-chord ratio. In the case of arbitrary spanwise distribution of flap chord (constant-chord flaps on tapered wings or tapered flaps on untapered wings), the flaps should be divided into spanwise steps. The pitching-moment contributions from each spanwise step are then calculated and added together to obtain the total increment for the flap.

At low angles of attack, the change in pitching-moment increment due to flap deflection based on $S_W \bar{c}_W$ taken about $\bar{c}_W/4$ is given by

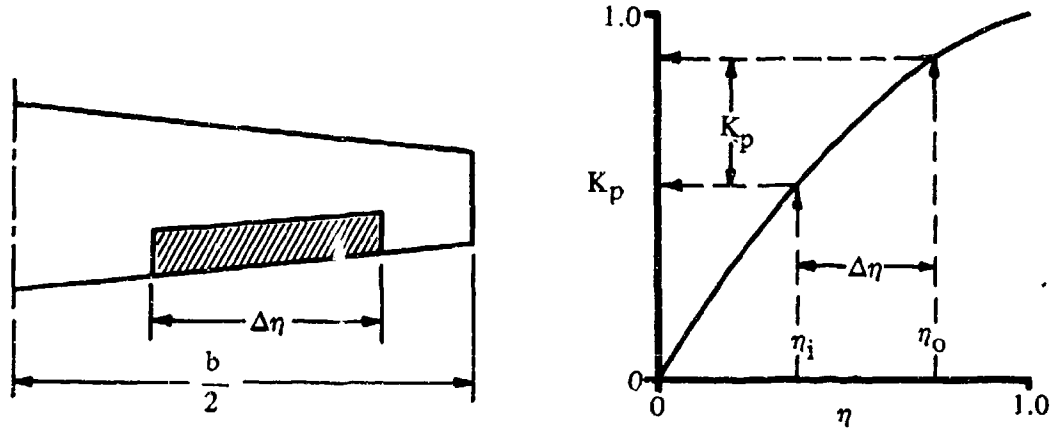
$$\Delta C_{m_f} = \Delta C_m + K_\Lambda \left(\frac{A}{1.5}\right) \Delta C_L \tan \Lambda_{c/4} \qquad 6.1.5.1\text{-a}$$

where

$$\Delta C_m = K_p \left\{ \left(\frac{\Delta C'_m}{\Delta C_L}\right) \Delta C_L \left(\frac{c'}{c}\right)^2 - 0.25\, C_L \left(\frac{c'}{c}\right)\left(\frac{c'}{c} - 1\right) + C_m \left[\left(\frac{c'}{c}\right)^2 - 1\right] \right\} \qquad 6.1.5.1\text{-b}$$

where

K_p is the flap-span factor as a function of taper ratio and flap location, obtained from Figure 6.1.5.1-61 as illustrated in Sketch (a). Note: η is the span station, $\eta = \dfrac{\text{control span ordinate}}{b/2}$



SKETCH (a)

$\dfrac{\Delta C'_m}{\Delta C_L}$ is the ratio of the pitching-moment increment to lift increment for a full-span flap on a rectangular wing, obtained from Figure 6.1.5.1-60 as a function of wing thickness and flap-chord-to-extended-wing-chord ratio.

ΔC_L is the lift increment due to flap deflection, obtained from the appropriate equation (determined by the particular flap type) of Section 6.1.4.1 using the following assumptions:

1. full-span flap
2. wing aspect ratio of 6
3. no sweep, $\Lambda_{c/2} = 0$

(Note: the above assumptions are to be used for all calculations involved in calculating ΔC_L.)

$\frac{c'}{c}$ is the ratio of the extended wing chord to the retracted wing chord (see Figures 6.1.1.1-44 through -46 for a graphical illustration).

C_L is the wing-body lift coefficient with the flap retracted. This value should be obtained from test data if available, or from Sections 4.1.3.1* and 4.3.1.2.

C_m is the wing-body pitching-moment coefficient with the flap retracted. This value should be obtained from test data if available, or from Section 4.3.2.2 supplemented with a test-data value for $\left(C_{m_0}\right)_{WB}$

K_Λ is the conversion factor for a partial-span flap on a sweptback wing obtained from Figure 6.1.5.1-57 in a similar manner as K_p; i.e., see the illustration in Sketch (a).

A is the wing aspect ratio.

$\Lambda_{c/4}$ is the sweep of the wing quarter-chord.

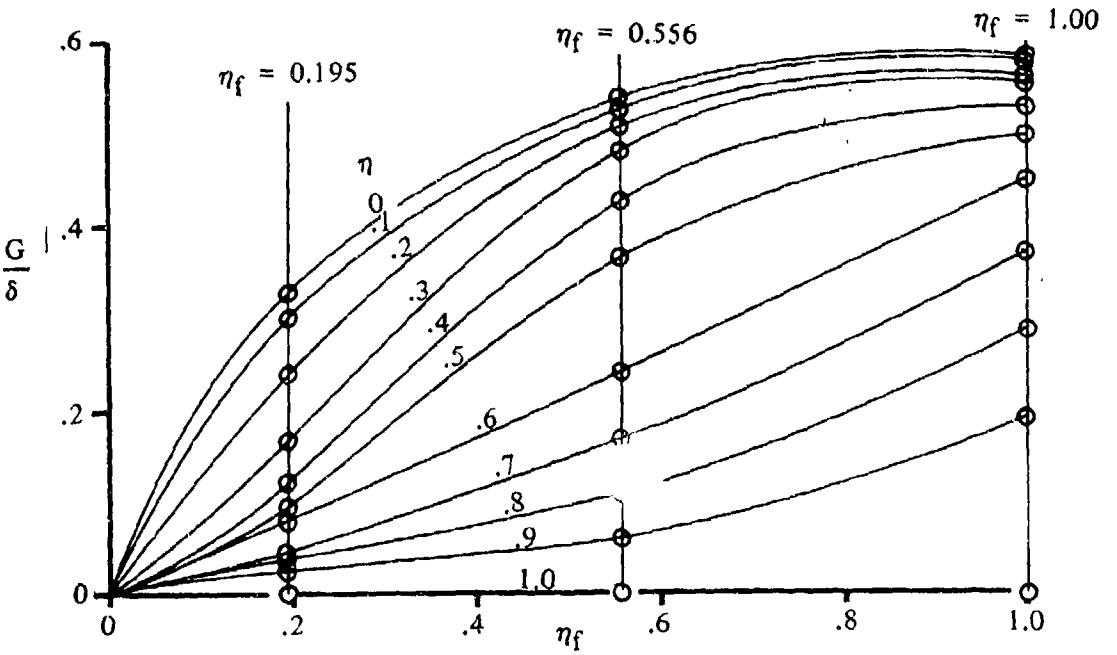
Method 2

This method requires the determination of the span loading due to flap deflection (Reference 5) and the chordwise center-of-pressure location for stations across the span. Once these quantities are determined, the incremental pitching moment can be calculated by an integration process. The pitching-moment increment ΔC_{m_f} is obtained by using the procedure outlined in the following steps:

Step 1. Determine the spanwise loading coefficient G/δ of full wing-chord flaps. The spanwise loading coefficient G/δ of full wing-chord flaps is obtained as a function of span station, $\eta = \frac{\text{span ordinate}}{b/2}$, from Figures 6.1.5.1-62a through 6.1.5.1-62d for appropriate values of $\beta A/\kappa$, Λ_β, and λ, where $\kappa = c_{\ell_{\alpha_M}}/(2\pi/\beta)$ and $\Lambda_\beta = \tan^{-1}\ (\tan \Lambda_{c/4}/\beta)$.

It should be noted that Figures 6.1.5.1-62a through 6.1.5.1-62d present the spanwise loading coefficients for full wing-chord flaps that extend from the plane of symmetry out to span stations of $\eta_o = 0.195$, $\eta_o = 0.556$, and $\eta_o = 1.0$ (Figure 6.1.5.1-62a also includes $\eta_o = 0.831$). The results for other flap spans are obtained by interpolating the results of the particular flap spans presented in Figures 6.1.5.1-62a through 6.1.5.1-62d. The final step in the interpolation procedure is to cross-plot the results of the variation of the loading parameter at given stations as a function of flap span η_f for desired values of the parameters $\beta A/\kappa$, Λ_β, and λ (see Sketch (b)).

*The wing-body zero-lift angle of attack is obtained from the wing-alone data of Section 4.1.3.1. Test data from a similar configuration should be used if available. Wing surface velocity is increased by the presence of the fuselage; therefore, when the fuselage is below the wing, the lift is reduced, and with the fuselage above the wing, the lift will be increased. This effect is generally small, unless wing-mounted bodies, such as stores or nacelles, are close to the fuselage or to each other.

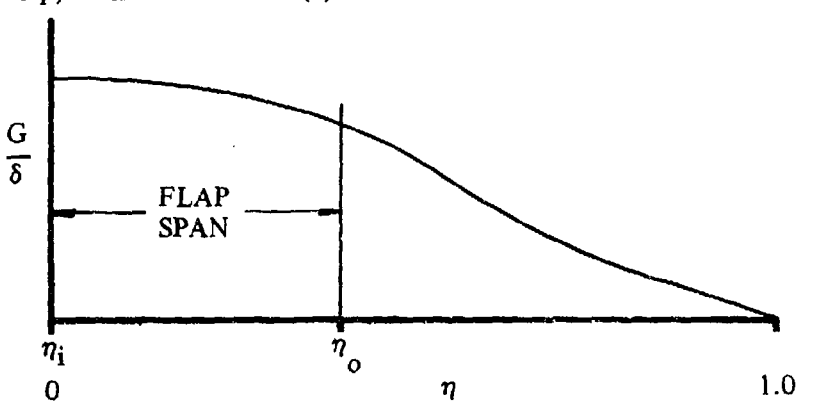


SKETCH (b)

The spanwise loading is then read from this cross plot at the desired values of η_f (η_i and η_o). Note that for cases where Figure 6.1.5.1-62a applies, i.e., where $\beta A/\kappa = 0$, the cross plot represented by Sketch (b) is obtained directly, since no intermediate steps are required to interpolate for λ or Λ_β.

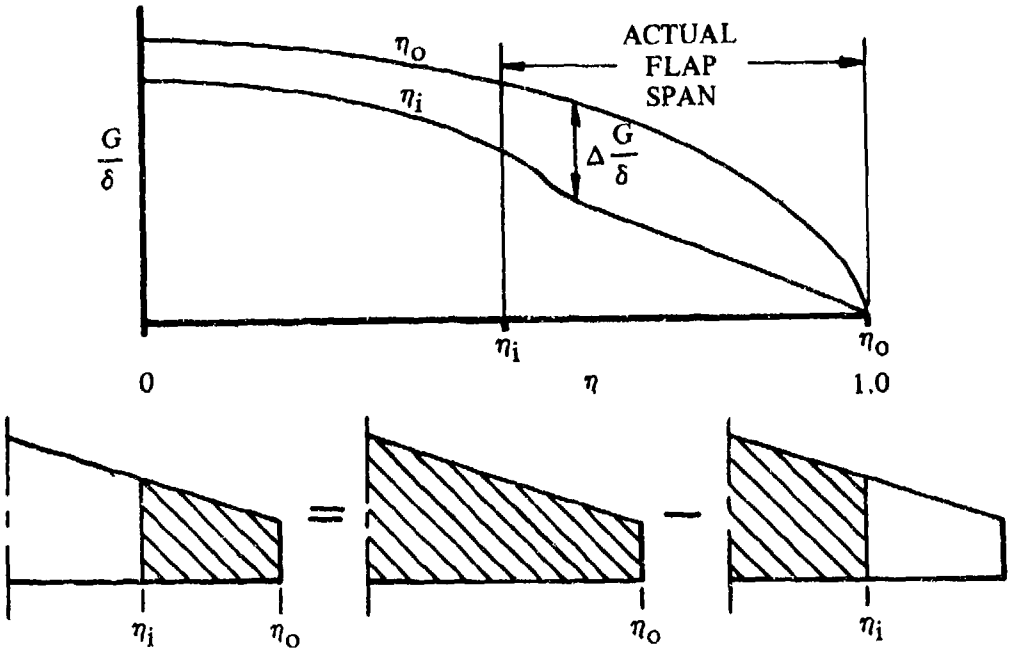
The following procedure is used to determine the spanwise loading of the actual flap:

a. For flaps that extend from the plane of symmetry outboard, tabulate the loading for an inboard flap extending from the plane of symmetry to the outboard station of the actual flap, as shown in Sketch (c).



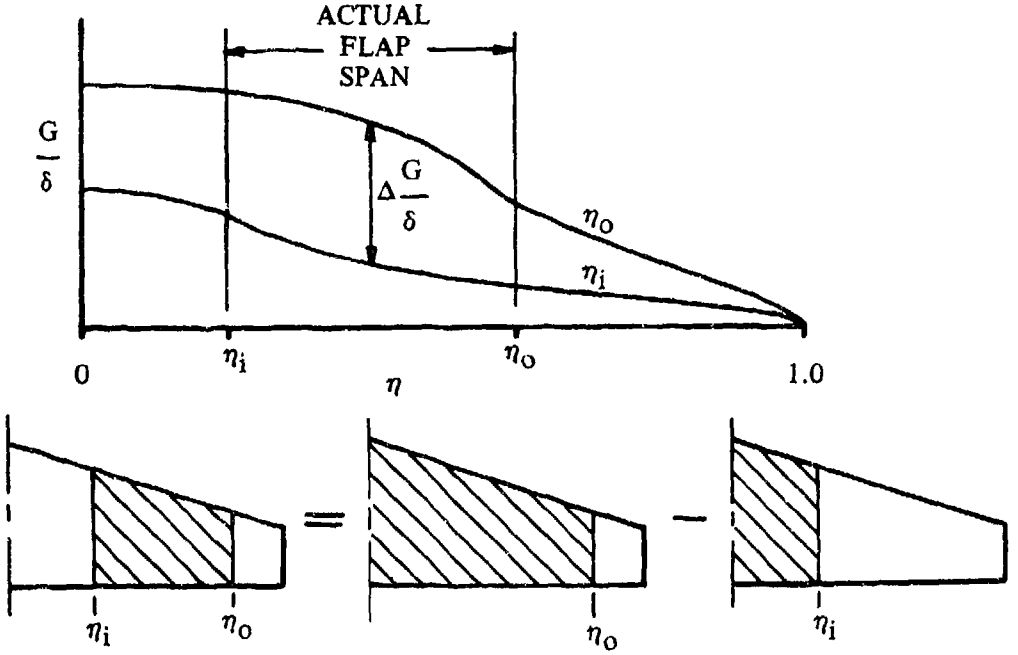
SKETCH (c)

b. For partial-span flaps that extend from the wing tip inboard, the charts are used as follows: Tabulate the loading G/δ for a full-span flap. Tabulate the loading G/δ for an inboard flap extending from the plane of symmetry to the inboard station of the actual flap. Subtract the loadings of the above tabulations at each span station to obtain the loading of the actual flap (see Sketch (d)).



SKETCH (d)

c. For partial-span flaps that have outboard ends inboard of the wing tip and inboard ends outboard of the plane of symmetry, the charts are used as follows: Tabulate the loading function G/δ for flaps extending from the plane of symmetry to the outboard station of the actual flap. Tabulate the loading function G/δ for a flap extending from the plane of symmetry to the inboard end of the actual flap. Subtract the loadings of the above tabulations at each span station to obtain the loading of the actual flap (see Sketch (e)).



SKETCH (e)

Step 2. Determine the incremental section lift coefficient as a function of span station η by*

$$c_{\ell_\Lambda} = -\frac{2b}{c}\frac{G}{\delta}\alpha_\delta \delta \qquad 6.1.5.1\text{-c}$$

where

c_{ℓ_Λ} is the incremental section lift coefficient due to flap deflection.

b is the total wing span.

c is the local chord at the span station in question.

$\frac{G}{\delta}$ is the loading coefficient of a full wing-chord flap at the span station in question, obtained from Step 1.

α_δ is the two-dimensional lift-effectiveness parameter expressed as

$$\alpha_\delta = -\frac{\left(c_{\ell_\delta}\right)_\alpha}{\left(c_{\ell_\alpha}\right)_\delta} \quad \text{(Equation 6.1.1.1-b)}$$

where

c_{ℓ_δ} is the lift effectiveness of the flapped airfoil from the appropriate method of Section 6.1.1.1.

c_{ℓ_α} is the airfoil section lift-curve slope (including the effects of compressibility) from Section 4.1.1.2.

For area-suction and blowing-type flaps the theoretical value of α_δ is presented as a function of c_f/c in the inset of Figure 6.1.4.1-14.

When experimental values of the section lift increment Δc_ℓ are available for plain, split, or slotted flaps, the lift-effectiveness parameter should be calculated using

$$\alpha_\delta = -\frac{(\Delta c_\ell)_{\text{experiment}}}{(c_{\ell_\alpha})_\delta}$$

δ is the streamwise flap deflection in radians. This value may be obtained from

$$\delta = \tan^{-1}(\cos \Lambda_{HL} \tan \delta_{\perp HL}) \qquad 6.1.5.1\text{-d}$$

*In the theory, sections of a yawed infinite wing are dealt with. See Reference 2 for details of the theoretical treatment of sweep and taper.

where

Λ_{HL} is the sweep angle of the flap hinge line.

$\delta_{\perp HL}$ is the flap deflection measured normal to the flap hinge line.

The product $(G/\delta)\alpha_\delta$ in Equation 6.1.5.1-c converts the spanwise loading distribution of full wing-chord flaps, $c_f/c = 1.0$, to the spanwise loading distribution of partial wing-chord flaps. For the case of arbitrary spanwise distribution of flap chord (constant-chord flaps on tapered wings or tapered flaps on untapered wings), the flap can be divided into spanwise steps and a new value for α_δ for each segment determined. The load distribution due to each spanwise step is then determined by the product of G/δ and the average value of α_δ over that spanwise step.

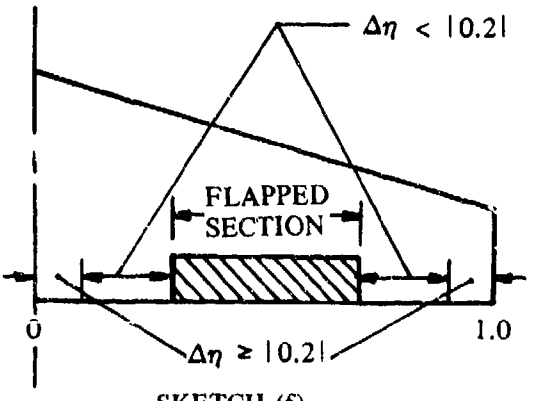
Step 3. Determine the chordwise center-of-pressure location $x_{c.p.}$ for stations across the span.

For this calculation the wing span is divided into not more than three types of regions. These regions are illustrated schematically in Sketch (f), and consist of:

a. Span stations included in the flapped section.

b. Span stations adjacent to the flap ends where the distance from the ends of the flap $\Delta\eta$ is less than $|0.20|$.

c. Span stations not influenced by the flap span, $\Delta\eta \geq |0.20|$.



SKETCH (f)

The chordwise center-of-pressure location in each region is obtained as follows:

a. For the span stations included in the flapped section

$$x_{c.p.} = 0.25 - \frac{\Delta c_m}{c_{\ell_{\Lambda=0}}} \qquad 6.1.5.1\text{-e}$$

where

Δc_m is the section incremental pitching moment obtained from Section 6.1.2.1 by the appropriate trailing-edge mechanical-flap method using c_f/c and δ', where δ' is the flap deflection in the plane normal to the constant-percent chord line through $x_{c.p._b}$, given by

$$\delta' = \tan^{-1} \frac{\tan \delta}{\cos \Lambda_b} \qquad 6.1.5.1\text{-f}$$

where Λ_b is the sweepback of the constant-percent chord line through the center of pressure of the basic loading, given by

$$\tan \Lambda_b = \tan \Lambda_{c/4} - \frac{4}{A}(x_{c.p._b} - 0.25) \frac{1-\lambda}{1+\lambda} \qquad 6.1.5.1\text{-g}$$

where $x_{c.p._b}$ is the chordwise center-of-pressure position (basic loading) for a plain flap from Figure 6.1.5.1-67b.

$c_{\ell_{\Lambda=0}}$ is the incremental section lift coefficient as a function of span station, referred to the basic load line, by

$$c_{\ell_{\Lambda=0}} = \frac{c_{\ell_\Lambda}}{\cos^2 \Lambda_b} \qquad 6.1.5.1\text{-h}$$

where c_{ℓ_Λ} is obtained from Step 2.

b. For the span stations adjacent to the flap ends where the distance from the ends of the flap $\Delta\eta$ is less than |0.20|,

$$x_{c.p.} = 0.25 - K\left(\frac{\Delta c_m}{c_{\ell_{\Lambda=0}}}\right)_{\substack{\text{edge of} \\ \text{flap}}} \qquad 6.1.5.1\text{-i}$$

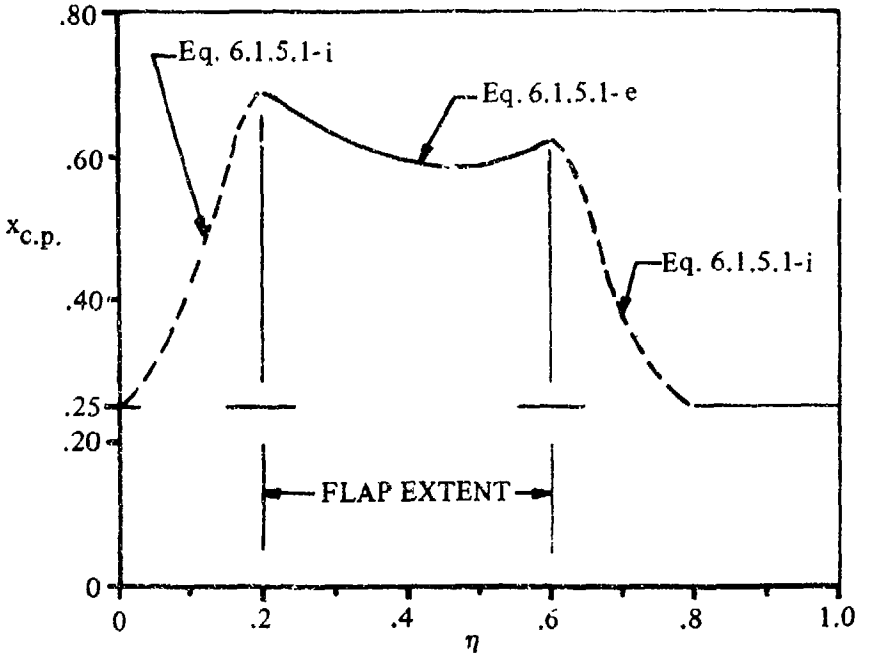
where

K is obtained from Figure 6.1.5.1-67a as a function of distance from the end of the flap.

$\left(\frac{\Delta c_m}{c_{\ell_{\Lambda=0}}}\right)_{\substack{\text{edge}\\ \text{of}\\ \text{flap}}}$ is the value determined in Step 3a at the span station corresponding to the edge of the flap.

c. For span stations not influenced by the flap span, i.e., $\Delta\eta \geq |0.20|$, the theoretical chordwise center-of-pressure position is assumed to be the quarter-chord point.

A typical variation of chordwise center-of-pressure location for stations across the span is illustrated in Sketch (g).



SKETCH (g)

Step 4. For wings with swept quarter-chord, the chordwise center-of-pressure position at each span station must be referred to the quarter-chord of the MAC by

$$\frac{x}{\bar{c}} = (\eta - \bar{\eta})\frac{b/2}{\bar{c}}\tan\Lambda_{c/4} + \frac{c\,(x_{c.p.} - 0.25)}{\bar{c}} \qquad 6.1.5.1\text{-j}$$

where

$\bar{\eta}$ is the lateral distance of the wing MAC from the body center line in semispans.

x is the distance of the local center of pressure aft of the quarter-chord of the MAC.

Step 5. With the local centers of pressure and the span loading known, determine the change in pitching moment due to flap deflection, based on $S_W \bar{c}_W$ taken about the quarter-chord of the wing MAC, by integrating across the span as follows:

$$\Delta C_{m_f} = \int_0^{1.0} - \left[c_{\ell_\Lambda} \frac{c}{c_{av}} \left(\frac{x}{\bar{c}} \right) \right] d\eta \qquad 6.1.5.1\text{-k}$$

where c_{ℓ_Λ} is from Step 2, $(x/\bar{c})$ is from Steps 3 and 4, and c/c_{av} is the ratio of the local chord at a given span station to the average chord ($c_{av} = S_W/b_W$).

2. Leading-Edge Devices

This method assumes a constant flap-chord-to-wing-chord ratio. In the case of an arbitrary spanwise distribution of leading-edge flap chord, the flaps should be divided into spanwise steps. The pitching-moment contributions from each spanwise step are then calculated and added to obtain the total increment for the leading-edge device.

The pitching-moment increment due to mechanical leading-edge devices, based on $S_W \bar{c}_W$, is given by

$$\Delta C_m = \left[c'_{m_{\delta_{LE}}} \left(\frac{\bar{c}'}{\bar{c}} \right) + \left(\frac{x_m}{\bar{c}} - \frac{x_{LE}}{\bar{c}} \right) c'_{\ell_\delta} \right] \frac{S_{W_f}}{S_W} \delta_f$$

$$+ \left\{ C_m \left[\left(\frac{\bar{c}'}{c} \right)^2 - 1 \right] + 0.75\, C_L \left(\frac{\bar{c}'}{c} \right) \left(\frac{\bar{c}' - c}{c} \right) \right\} \Delta\eta \qquad 6.1.5.1\text{-}\ell$$

where

$c'_{m_{\delta_{LE}}}$ is the theoretical two-dimensional, flap pitching-moment effectiveness about the leading edge, obtained from Figure 6.1.2.1-36 as a function of the ratio of flap chord to the extended airfoil chord c_f/c'. (See Figures 6.1.1.1-51 for the definition of flap chord c_f.)

$\bar{c}'$ is the mean aerodynamic chord of the wing segment affected by the leading-edge device (see Sketch (h)). The wing chord is the extended-wing chord due to an extension of the leading-edge device. The trailing-edge flaps, if any, are considered retracted.

$\bar{c}$ is the wing mean aerodynamic chord (MAC).

c is the retracted or basic-airfoil chord at the spanwise station of the MAC of the wing segment affected by the leading-edge device (see Sketch (h)).

$\frac{x_m}{\bar{c}}$ is the moment-reference-center location in fractions of the wing MAC, measured positive aft from the aircraft reference-axis origin (usually the aircraft nose or wing apex) parallel to the longitudinal axis.

$\frac{x_{LE}}{\bar{c}}$ is the location of the leading edge of the mean aerodynamic chord of the wing segment affected by the leading edge device, in fractions of the wing MAC. This parameter is measured positive aft from the aircraft reference-axis origin (see Sketch (h)).

c'_{ℓ_δ} is the two-dimensional leading-edge flap effectiveness parameter obtained from Figure 6.1.1.1-50 as a function of the flap-chord ratio $c_f/\bar{c}'$, instead of c_f/c.

Sw_f is the area of the wing segment affected by the leading-edge device (see Sketch (h)).

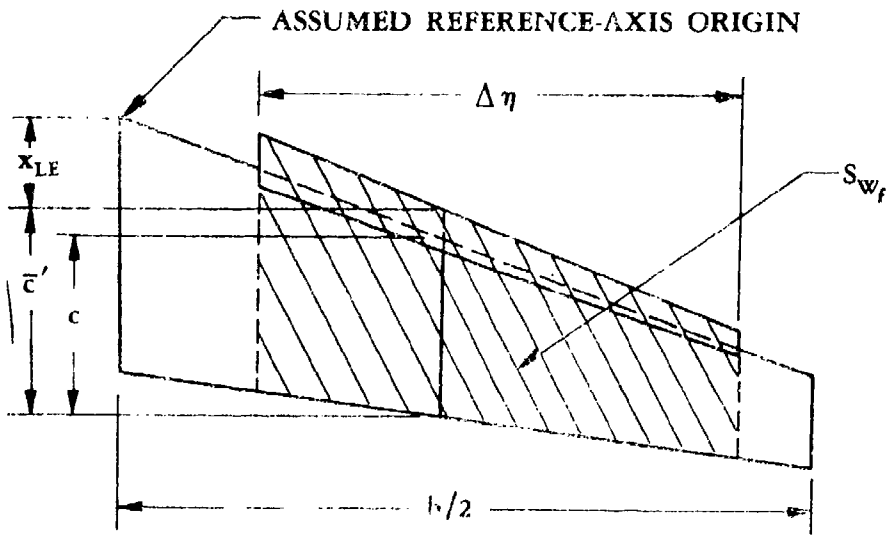
S_W is the wing reference area.

δ_f is the leading-edge-device deflection, measured parallel to the free stream in degrees (see Figure 6.1.1.1-51).

C_m is the wing-body pitching-moment coefficient at a given angle of attack, with the leading- and trailing-edge flaps retracted. This parameter should be obtained from test data, if available, or by using Section 4.3.2.2 supplemented with a test-data value for $(C_{m_0})_{WB}$.

C_L is the wing-body lift coefficient at a given angle of attack, with the leading-edge and trailing-edge flaps retracted. This parameter should be obtained from test data, if available, or from Sections 4.1.3.1*, 4.1.3.2, and 4.3.1.2.

$\Delta\eta$ is the flap span in fractions of the wing semispan (see Sketch (h)).



SKETCH (h)

*The wing-body zero-lift angle of attack is obtained from the ... tion should be used if available.

3. Jet Flaps

The method presented herein pertains to the same concepts as noted in Section 6.1.1.1; i.e., the pure jet-flap concept and the IBF and EBF concepts with a plain trailing-edge flap. For an IBF or EBF concept with a single-slotted or multislotted flap configuration, this method should be used only as a first approximation.

Because of the complexity of calculating the pitching moment due to a trailing-edge jet flap, the method is presented in a stepwise procedure. This procedure assumes that the wing employs a leading-edge device; however, it will also handle configurations without leading-edge devices. In using the method, all flap-chord lengths and flap deflections are measured in a streamwise direction.

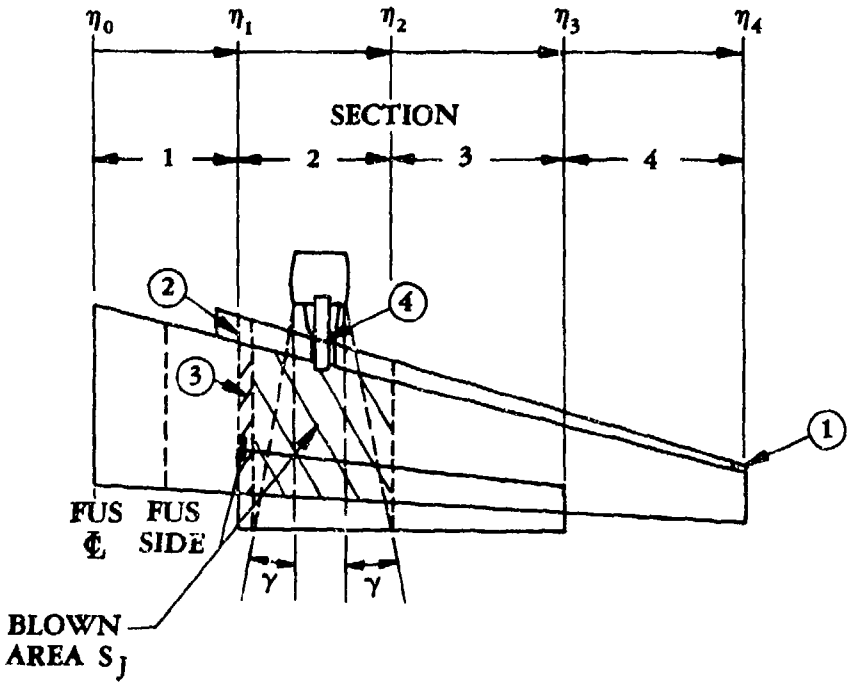
The computation of the pitching moment is broken down into components due to the leading-edge device, the angle of attack, the mechanical flap, and the jet flap. This division can be somewhat misleading because in each term there appears the parameter $c_{\delta\delta}/c$, which is the ratio of the airfoil chord with all flaps extended to the basic airfoil chord. Thus each term is actually dependent upon the total extended airfoil chord $c_{\delta\delta}$. For example, a change in $c_{\delta\delta}$ due to a deflection of the leading-edge device will affect the contribution of each component, not just the component due to the leading-edge device.

No substantiation of the method is presented herein because of the scarcity of data for which enough information is available to make a meaningful comparison. The available data indicate an average error of approximately ±20 percent. For those configurations that have been analyzed by using this method, the results indicate that this method is more accurate in estimating the pitching-moment increment due to flap deflection than in estimating the variation of pitching moment with angle of attack. This may be accounted for by the tendency of wings developing very high lift coefficients to have significant flow separation even at low angles of attack. The variation in the amount of separated flow with angle of attack may be affecting C_{m_α} significantly.

The wing pitching-moment increment (omitting the zero-lift pitching moment at $C_\mu = 0$) due to a trailing-edge jet flap with or without a leading-edge device is obtained from the following procedure. All of the area terms are assumed to be total values, not semispan values, i.e., to include both the left- and right-wing contributions.

Step 1. Divide the wing into spanwise sections that exhibit the same geometric and flow characteristics, i.e., no geometric discontinuities.

a. The blown wing area will determine one or more spanwise sections. The blown wing area is defined as the basic wing area that is affected by the jet flap, excluding any increase in wing area due to Fowler motion of the leading- and/or trailing-edge devices. For a pure jet-flap configuration with the efflux at the trailing edge, S_J is defined as the streamwise basic wing area ahead of the jet flap. For EBF configurations, the jet spreading angle γ must be considered before S_J can be determined. Therefore, it is suggested that the user determine the spreading angle for his particular configuration from test data on a similar configuration. However, if no such test data are available, the Datcom recommends that a value of 12^o be used for the spreading angle γ. An example for determining S_J for an EBF configuration is presented in Sketch (i). In this example the value of S_J has been increased slightly so as to include that portion of the wing ahead of the inboard tip of the flap. The reason for this adjustment is explained in part (b).



SKETCH (i)

b. The basic criterion for dividing the wing is the avoidance of discontinuities. The sections are determined such that the ratio of the extended wing chord (including both leading- and trailing-edge devices) to the basic wing chord is constant or approximately constant, and the ratio of the flap chord to the basic wing chord is constant or approximately constant; i.e., $c_{\delta\delta}/c$ is constant and c_f/c is constant. A schematic illustration for determining these spanwise sections for an EBF configuration is presented in Sketch (i). In order to minimize the number of spanwise sections, it is suggested that small changes are assumed to be made to the actual configuration. In Sketch (i) some of the assumptions made were: 1) the outboard wing slat station was assumed to be at the wing tip, 2) the inboard tip of the slat was neglected, 3) the jet spreading was assumed to extend to the inboard station of the flap, and 4) no discontinuity was assumed in the slat due to the engine pylon.

Step 2. The pitching-moment increment of each spanwise section is now calculated by treating each wing section as a two-dimensional airfoil. The calculation of the pitching-moment increments is performed by strictly applying the jet-flap method of Section 6.1.2.1 (not the mechanical leading- or trailing-edge methods) to evaluate each section individually. To prevent a duplication of effort, the material of Section 6.1.2.1 is not repeated here. It is therefore advised that the reader become familiar with the jet-flap method of Section 6.1.2.1 before proceeding further. However, before the jet-flap method of Section 6.1.2.1 can be applied to the three-dimensional wing sections, the following terms x_m/c, C_μ, K, $x_{f_i}/c_{\delta\delta}$, $x_j/c_{\delta\delta}$, and α_L (for α) must be redefined as follows:

$\frac{x_m}{c}$ redefined as the ratio of the distance from the wing leading edge to the unique unswept reference line (which may lie on or aft of a conventional wing configuration) to the local chord, such that x_m/c has a constant value for straight-tapered wings. (This reference location eliminates the need for calculating the spanwise center-of-pressure location for each wing section.) For non-straight-tapered wings there can be more than one value. Sketch (j) presents an example of a non-straight-tapered wing where two values of x_m/c are required. The determination of x_m/c is defined by

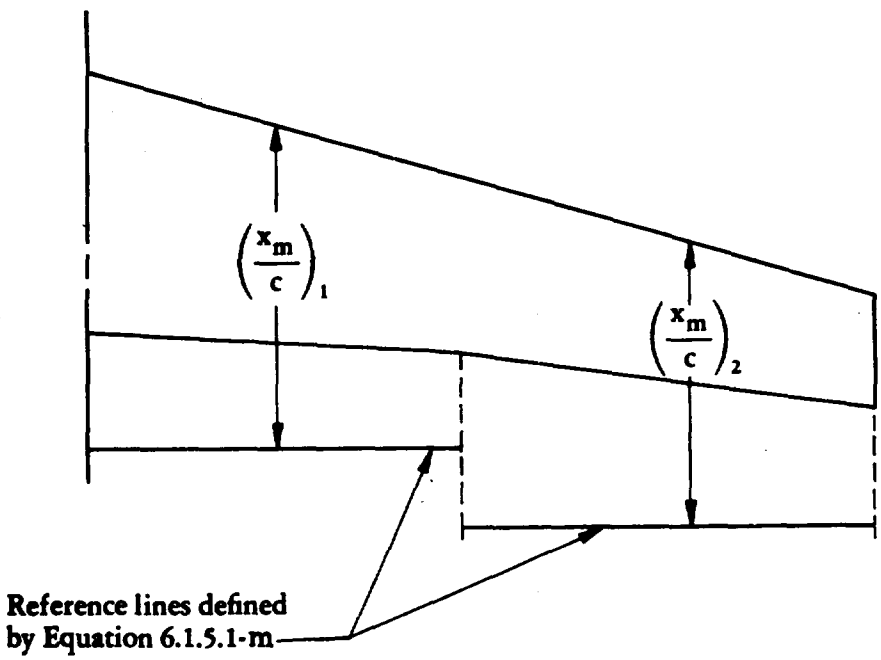
$$\frac{x_m}{c} = \frac{1+\lambda}{1-\lambda}\left(\frac{A_s}{4}\right)\tan \Lambda_{LE} \qquad 6.1.5.1\text{-m}$$

where

λ is the taper ratio of the particular spanwise wing section.

A_s is the aspect ratio of the particular spanwise wing section.

Λ_{LE} is the sweep of the leading-edge angle of the particular spanwise wing section.



SKETCH (j)

However, a problem arises in the case of untapered wings ($\lambda = 1$), since x_m/c in Equation 6.1.5.1-m becomes indeterminate. Therefore, for an untapered wing or wing section, Equation 6.1.5.1-m is modified to the following:

$$\frac{x_m}{c} = \frac{\Delta x_r}{c} \qquad 6.1.5.1\text{-n}$$

where

Δx_f is the distance between the wing apex and the desired moment reference center, measured positive aft.

c is the basic wing chord.

C_μ is the section nondimensional trailing-edge jet momentum coefficient. For those sections that are outside of the blown area, $C_\mu = 0$. For those sections within the blown area, the following approximation is used to determine the relationship between C_μ and C_J:

$$C_\mu = C_J \eta_t \frac{S_W}{S_J} \qquad 6.1.5.1\text{-o}$$

where

C_J is the nondimensional trailing-edge jet momentum coefficient based on the gross engine thrust and the wing reference area. (See Section 6.1.4.1 for an exact definition.)

η_t is the static turning efficiency defined as the resultant force divided by the gross thrust (see Section 6.1.4.3, Sketch (a)). This value should be obtained from test data if possible, or from Figure 6.1.4.3-11 for slotted flaps. Although Figure 6.1.4.3-11 represents a reasonable average of the available data, the data scatter is large. Since this method cannot be expected to yield good results if the error in η_t is large, it is imperative that test data be used if available.

$\frac{S_W}{S_J}$ is the ratio of the wing reference area to the blown wing area.

K redefined here to apply to each wing section individually, based on the following expression

$$K = \left[\frac{A_t + 2\,C'_\mu/\pi}{A_t + 2 + 0.604\,(C'_\mu)^{1/2} + 0.876\,C'_\mu} \right] \frac{c_{\delta\delta}}{c} \qquad 6.1.5.1\text{-p}$$

where

$\frac{c_{\delta\delta}}{c}$ is the ratio of the extended wing chord, including the extensions of both the leading- and trailing-edge devices, to the basic wing chord of the particular spanwise wing section.

A_t is the aspect ratio of the total wing based on the extended wing chord, i.e., $A_t = A(c/c_{\delta\delta})$, using the particular section value for $c/c_{\delta\delta}$.

C'_μ is the section nondimensional trailing-edge jet momentum coefficient based on the extended wing chord $c_{\delta\delta}$, i.e., $C'_\mu = C_\mu (c/c_{\delta\delta})$.

$\frac{x_{f_i}}{c_{\delta\delta}}, \frac{x_j}{c_{\delta\delta}}$ are the center-of-lift location of the incremental load due to the deflection of the i^{th} flap segment and the center-of-lift location of the incremental load due to the jet deflection, respectively. In this section these terms are applied to each spanwise wing section and are corrected for three-dimensional effects by

$$\frac{x_{f_i}}{c_{\delta\delta}} = \left(\frac{x_{f_i}}{c_{\delta\delta}}\right)_{2D} \left[\frac{(x_{c.p.})_{3D}}{(x_{c.p.})_{2D}}\right]_i \qquad 6.1.5.1\text{-q}$$

$$\frac{x_j}{c_{\delta\delta}} = \left(\frac{x_j}{c_{\delta\delta}}\right)_{2D} \left[\frac{(x_{c.p.})_{3D}}{(x_{c.p.})_{2D}}\right]_j \qquad 6.1.5.1\text{-r}$$

where

$\left(\frac{x_{f_i}}{c_{\delta\delta}}\right)_{2D}$ is the two-dimensional center-of-lift location of the incremental load due to deflection of the i^{th} trailing-edge flap segment. This parameter is obtained, as defined in Section 6.1.2.1, from Figure 6.1.2.1-37 as a function of the ratio of the flap chord to the extended airfoil chord $c_{f_i}/c_{\delta\delta}$ and C'_μ.

$\left[\frac{(x_{c.p.})_{3D}}{(x_{c.p.})_{2D}}\right]_i$ is the ratio of the center-of-lift location for a finite-aspect-ratio wing to the center-of-lift location for an infinite-aspect-ratio wing for the incremental load due to deflection of the i^{th} trailing-edge flap segment. This parameter is obtained from Figure 6.1.5.1-68 as a function of $c_{f_i}/c_{\delta\delta}$ and $1/A_t$.

$\left(\frac{x_j}{c_{\delta\delta}}\right)_{2D}$ is the two-dimensional center-of-lift location of the incremental load due to the jet momentum acting at some angle to the trailing-edge camber line. This parameter is obtained from Figure 6.1.2.1-37 at $c_f/c_{\delta\delta} = 0$, as a function of the trailing-edge jet momentum C'_μ.

$\left[\frac{(x_{c.p.})_{3D}}{(x_{c.p.})_{2D}}\right]_j$ is the ratio of the center-of-lift location for a finite-aspect-ratio wing to the center-of-lift location for an infinite-aspect-ratio wing for the incremental load due to the jet momentum acting at some angle to the trailing-edge camber line. This parameter is obtained from Figure 6.1.5.1-68 at $c_f/c_{\delta\delta} = 0$, as a function of $1/A_t$.

α_L is the local angle of attack for the particular spanwise wing section under consideration. For wings with twist, this value will change from section to section. It is suggested that the change be approximated by using the average twist incidence for each section.

Step 3. Compute the sum of the wing section pitching-moment increments from Step 2 according to the following:

$$C_{m_m} = \sum_{k=1}^{p} \Delta c_m \, (K_{b_k} - K_{b_{k-1}}) \qquad 6.1.5.1\text{-s}$$

where

k is the number of the wing section (numbered from the fuselage center line outboard).

p is the total number of wing sections.

Δc_m is the section pitching-moment increment for the particular spanwise section, obtained from the jet-flap procedure of Section 6.1.2.1.

$K_{b_k}, K_{b_{k-1}}$ are the values of the span factor for the outboard and inboard ends, respectively, of the k^{th} wing section. This parameter is obtained from Figure 6.1.4.1-15 as a function of basic-wing taper ratio λ and the span stations η_k and η_{k-1} of the streamwise cuts defining the k^{th} wing section nondimensionalized by the wing semispan (see Sketch (i)).

Step 4. Calculate the lift contribution to the pitching-moment increment for each wing section according to

$$C_{\lambda_k} = \left[\Delta c_1 - \Delta c_2 + \Delta c_4 + \sum_{i=1}^{n} (\Delta c_5)_i + \Delta c_6\right](K_{b_k} - K_{b_{k-1}}) \qquad 6.1.5.1\text{-t}$$

where

$\Delta c_1, \Delta c_2, \Delta c_4, (\Delta c_5)_i$, and Δc_6 are the terms analogous to lift generated during the execution of the jet-flap procedure of Section 6.1.2.1.

$K_{b_k}, K_{b_{k-1}}$ are defined in Step 3 above.

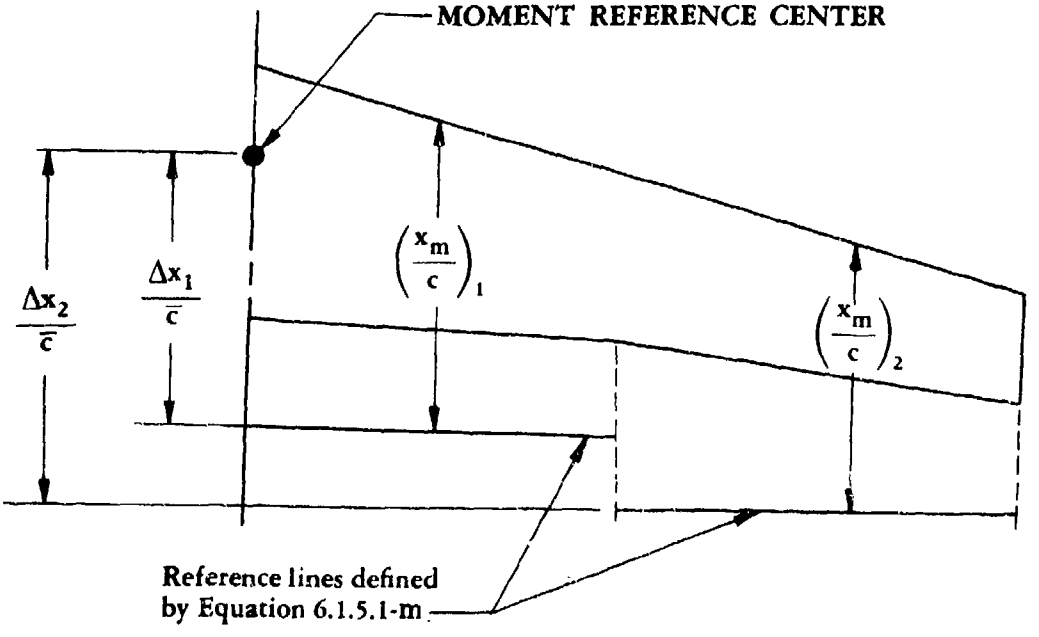
Step 5. The total wing pitching-moment increment due to a jet flap at some angle of attack is calculated by using one of two equations presented below. For a tapered wing, Equation 6.1.5.1-u is used; while for an untapered wing, Equation 6.1.5.1-v should be used. Both equations convert the pitching moments for each wing panel about $x_m/c_{\delta\delta}$ to the desired moment-reference-center location, based on $S_W \bar{c}_W$.

$$\Delta C_m = C_{m_m} + \eta_t C_J \frac{\Delta z}{\bar{c}} + \sum_{k=1}^{p} \left\{ \left[C_\mu \frac{\alpha_L}{57.3} \frac{S_k}{S_W} - C_{\lambda_k} \right] \frac{\Delta x_k}{\bar{c}} \right\} \qquad 6.1.5.1\text{-u}$$

where

$\frac{\Delta z}{\bar{c}}$ is the vertical distance between the desired moment-reference-center location and the quarter-chord of the MAC, positive for the wing below the desired location. (This is an approximation because an exact solution would require accounting for the vertical distance for each blown wing section.)

$\frac{\Delta x_k}{\bar{c}}$ is the longitudinal distance between the moment-reference-center location and the location of the chord station for zero sweep. This parameter is measured positive aft from the moment reference center as illustrated in Sketch (k).



SKETCH (k)

For an untapered wing this distance can be found by using

$$\frac{\Delta x_k}{\bar{c}} = \frac{\eta_k - \eta_{k-1}}{2} \frac{b}{2} \frac{\tan \Lambda}{c} \qquad 6.1.5.1\text{-v}$$

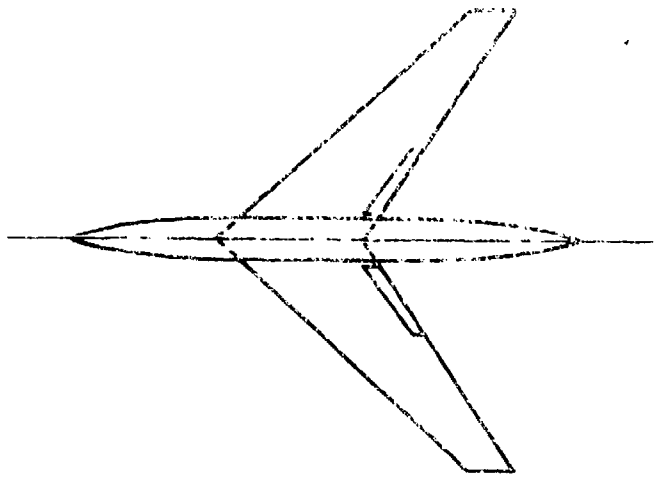
S_k is the area of the k^{th} wing section with all flaps retracted.

All remaining terms have been defined in the previous steps.

Sample Problems

1. Single-Slotted Trailing-Edge Flap (Method 1)

Given: The sweptback wing-body configuration of Reference 32 with a single-slotted flap.



Wing Characteristics:

$A = 5.1$ $\quad b/2 = 74.75$ in. $\quad \lambda = 0.383$ $\quad \Lambda_{c/4} = 44.6°$

$c_r = 42.36$ in. $\quad c_t = 16.24$ in. $\quad S_W = 30.35$ ft^2 $\quad \bar{c} = 31.22$ in.

NACA 64-210 $\downarrow$ 0.286 c $\quad \frac{t}{c} = 0.075$ (streamwise) $\quad \frac{Y_{90}}{2} = 0.671\%$ c

$\frac{Y_{99}}{2} = 0.04\%$ c $\quad a = 0$ $\quad C_m = -0.034$ (test data)

$C_L = 0.025$ (test data)

Flap Characteristics:

Single-slotted flap $\quad \frac{c_f}{c} = 0.286$ (streamwise) $\quad \frac{c'}{c} = 1.05$

$\eta_i = 0.144 \quad \eta_o = 0.45 \quad \delta_f = 30.68°$ (streamwise)

Additional Characteristics:

$M = 0.14; \beta = 0.99 \quad R_\ell = 6 \times 10^6$

Compute:

$$\tan \frac{1}{2} \phi'_{TE} = \frac{\frac{Y_{90}}{2} - \frac{Y_{99}}{2}}{9}$$

$$= \frac{0.671 - 0.04}{9} = 0.07$$

$$\frac{c_{\ell_\alpha}}{\left(c_{\ell_\alpha}\right)_{theory}} = 0.873 \quad \text{(Figure 4.1.1.2-8a)}$$

$\left(c_{\ell_\alpha}\right)_{theory} = 6.66$ per rad (Figure 4.1.1.2-8a)

$$c_{\ell_\alpha} = \frac{1.05}{\beta}\left[\frac{c_{\ell_\alpha}}{\left(c_{\ell_\alpha}\right)_{theory}}\right]\left(c_{\ell_\alpha}\right)_{theory} \quad \text{(equation 4.1.1.2-a)}$$

$$= \frac{1.05}{0.99}(0.873)(6.66)$$

$= 6.167$ per rad

$\alpha_\delta = -0.483$ (Figure 6.1.1.1-4l)

$\Delta c_\ell = -c_{\ell_\alpha} \alpha_\delta \delta_f$ (equation 6.1.1.1-c)

$= -(6.167)(-0.483)\frac{30.68}{57.3}$

$= 1.595$

$$\left.\begin{aligned} A &= 6.0 \\ \Lambda_{c/2} &= 0 \end{aligned}\right\}$$ Method 1 assumptions for calculating ΔC_L

$$\kappa = \frac{c_{\ell_\alpha}}{\beta} \Big/ \frac{2\pi}{\beta} = \frac{6.167}{2\pi} = 0.9815$$

$$\frac{A}{\kappa}\left[\beta^2 + \tan^2 \Lambda_{c/2}\right]^{1/2} = \frac{6}{0.9815}\,(0.99) = 6.05$$

$$\frac{C_{L_\alpha}}{A} = 0.747 \text{ per rad} \quad \text{(Figure 4.1.3.2-49)}$$

$$C_{L_\alpha} = 6(0.747) = 4.48 \text{ per rad}$$

$$\left(\alpha_\delta\right)_{c_\ell} = -0.655 \quad \text{(Figure 6.1.4.1-14 insert)}$$

$$\frac{\left(\alpha_\delta\right)_{C_L}}{\left(\alpha_\delta\right)_{c_\ell}} = 1.04 \quad \text{(Figure 6.1.4.1-14)}$$

$K_b = 1.0$ (assume full-span flaps for calculating ΔC_L)

$$\Delta C_L = \Delta c_\ell \left(\frac{C_{L_\alpha}}{c_{\ell_\alpha}}\right)\left[\frac{\left(\alpha_\delta\right)_{C_L}}{\left(\alpha_\delta\right)_{c_\ell}}\right] K_b \quad \text{(Equation 6.1.4.1-a)}$$

$$= (1.595)\left(\frac{4.48}{6.167}\right)(1.04)(1.0)$$

$$= 1.205$$

$$\frac{c_f}{c'} = \frac{c_f}{c}\,\frac{c}{c'}$$

$$= \frac{0.286}{1.05} = 0.272$$

$$\frac{\Delta C'_m}{\Delta C_L} = -0.271 \quad \text{(Figure 6.1.5.1-60)}$$

$$\left(K_p\right)_{\eta=0.144} = 0.27 \quad \text{(Figure 6.1.5.1-61)}$$

$$\left(K_p\right)_{\eta=0.45} = 0.72 \quad \text{(Figure 6.1.5.1-61)}$$

$$K_p = \left(K_p\right)_{\eta_o} - \left(K_p\right)_{\eta_i}$$

$$= 0.72 - 0.27 = 0.45$$

$$\Delta C_m = K_p\left\{\left(\frac{\Delta C'_m}{\Delta C_L}\right)\Delta C_L\left(\frac{c'}{c}\right)^2 - 0.25\, C_L\left(\frac{c'}{c}\right)\left(\frac{c'}{c} - 1\right) + C_m\left[\left(\frac{c'}{c}\right)^2 - 1\right]\right\}$$

(Equation 6.1.5.1-b)

$$= 0.45\left\{(-0.271)\,(1.205)\,(1.05)^2 - 0.25(0.025)\,(1.05)\,(0.05) - 0.034\left[(1.05)^2 - 1\right]\right\}$$

$$= 0.45\left\{-0.36 - 0.0003 - 0.0035\right\}$$

$$= -0.164$$

$$\left(K_\Lambda\right)_{\eta=0.144} = 0.0365 \quad \text{(Figure 6.1.5.1-57a through -57d, interpolated)}$$

$$\left(K_\Lambda\right)_{\eta=0.45} = 0.0615 \quad \text{(Figure 6.1.5.1-57a through -57d, interpolated)}$$

$$K_\Lambda = \left(K_\Lambda\right)_{\eta_o} - \left(K_\Lambda\right)_{\eta_i}$$

$$= 0.0615 - 0.0365 = 0.025$$

Solution:

$$\Delta C_{m_f} = \Delta C_m + K_\Lambda\left(\frac{A}{1.5}\right)\Delta C_L \tan \Lambda_{c/4} \quad \text{(Equation 6.1.5.1-a)}$$

$$= -0.164 + (0.025)\left(\frac{5.1}{1.5}\right)(1.205)\,(0.9874)$$

$$= -0.164 + 0.101$$

$$= -0.063 \text{ (based on the product of wing area and wing mean aerodynamic chord and referred to a moment center at } \bar{c}/4)$$

This compares with a test value of $\Delta C_{m_f} = -0.074$ from Reference 32.

2. Plain Trailing-Edge Flap (Method 2)

Given: The sweptback wing of Reference 13 with a partial-span plain trailing-edge flap. This is the same configuration as Sample Problem 1 of Paragraph A of Section 6.1.4.1.

Wing Characteristics:

$A = 3.78$ $\quad b/2 = 16.97$ ft $\quad \lambda = 0.586$ $\quad \Lambda_{c/4} = 47.35^{o}$

$c_r = 11.315$ ft $\quad \bar{\eta} = 0.456$ $\quad \bar{c} = 9.09$ ft $\quad c_{av} = 8.98$ ft

NACA 65A006 airfoil (streamwise)

Flap Characteristics:

Plain trailing-edge flap $\quad \Lambda_{HL} = 43^{o}$ $\quad c_f/c = 0.224$ (streamwise)

$\eta_i = 0.10$ $\quad \eta_o = 0.58$ $\quad \delta_{\perp HL} = 30^{o}$ $\quad \delta = 22.1^{o}$ (streamwise)

Additional Characteristics:

Low speed; $\beta = 1.0$ $\quad R_\ell = 6.1 \times 10^{6}$

Compute:

Step 1. Determine the spanwise loading coefficient G/δ (see Step 1c of Datcom Method 2)

$c_{\ell_\alpha} = 6.13$ per rad (Sample Problem 1, Paragraph A, Section 6.1.4.1)

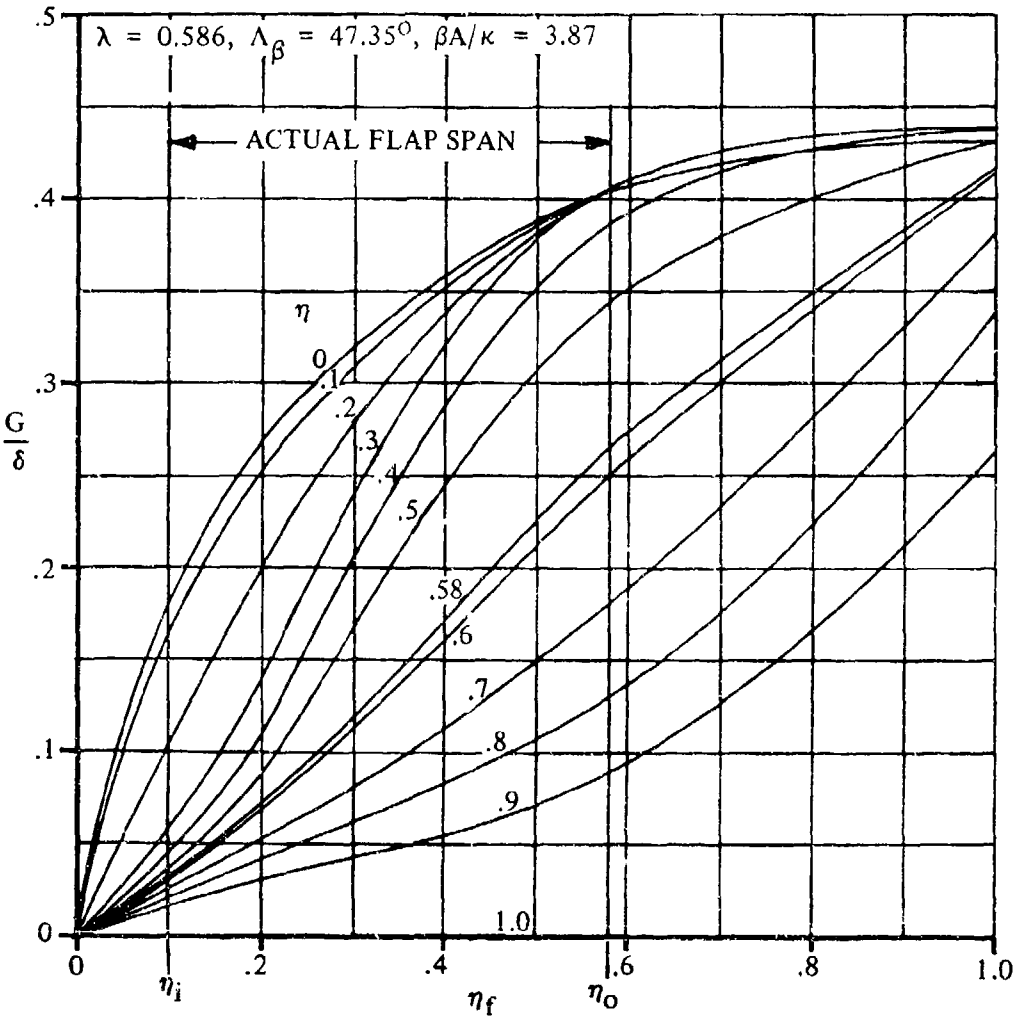
$$\kappa = \frac{c_{\ell_\alpha}}{2\pi} = \frac{6.13}{2\pi} = 0.976$$

$$\frac{\beta A}{\kappa} = \frac{(1.0)(3.78)}{0.976} = 3.87$$

$$\Lambda_\beta = \tan^{-1}\left(\frac{\tan \Lambda_{c/4}}{\beta}\right) = \tan^{-1}\left(\frac{\tan 47.35^{o}}{1.0}\right) = 47.35^{o}$$

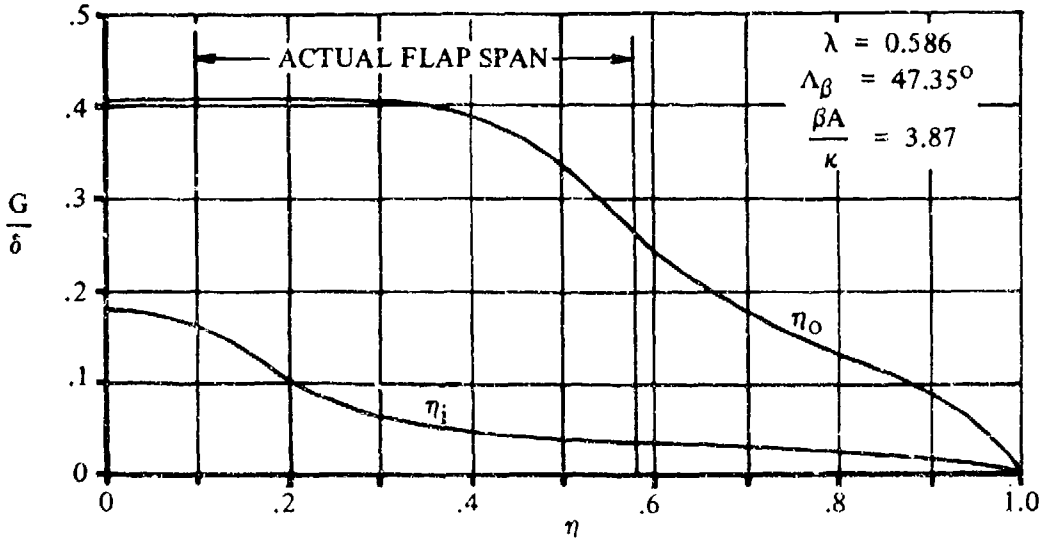
Obtain the spanwise loading coefficient G/δ for a full wing-chord flap extending from the plane of symmetry to the inboard station of the actual flap ($\eta_i = 0.10$), and for a full wing-chord flap extending from the plane of symmetry to the outboard end of the actual flap ($\eta_o = 0.58$). Since the span loadings for these particular flap spans are not presented in Figures 6.1.5.1-62a through 6.1.5.1-62d, the interpolation procedure described in Step 1 of Datcom Method 2 must be applied. The cross-plotted results of the variation of the loading parameter at given span stations as a function of flap span for the desired values of $\beta A/\kappa$, Λ_β, and λ are presented in Sketch (h).

The spanwise loading coefficients for a full wing-chord flap that extends from the plane of symmetry to the inboard station $\eta_i = 0.100$ and for a full wing-chord flap that extends from the plane of symmetry to the outboard station $\eta_o = 0.58$ are read from Sketch (h) at η_i and η_o. These spanwise loading coefficients are presented in Sketch (i).



VARIATION OF LOADING COEFFICIENT WITH FLAP SPAN

SKETCH (h)



VARIATION OF SPANWISE LOADING COEFFICIENT

SKETCH (i)

Step 2. Determine the incremental section lift coefficient as a function of span station η.

$$c_{\ell_\Lambda} = -\frac{2b}{c}\frac{G}{\delta}\alpha_\delta\delta \quad \text{(Equation 6.1.5.1-c)}$$

$$\Delta c_\ell = 0.927 \quad \text{(Sample Problem 1, Paragraph A, Section 6.1.4.1)}$$

$$\alpha_\delta = -\frac{\left(c_{\ell_\delta}\right)_\alpha}{\left(c_{\ell_\alpha}\right)_\delta} \quad \text{(Equation 6.1.1.1-b)}$$

$$= -\frac{\Delta c_\ell}{\left(c_{\ell_\alpha}\right)_\delta \delta} = -\frac{0.927}{(6.13)\,\frac{22.1}{57.3}} = -0.392$$

INCREMENTAL SECTION LIFT COEFFICIENT

① η	② $\left(\frac{G}{\delta}\right)_{\eta_o}$ = 0.58	③ $\left(\frac{G}{\delta}\right)_{\eta_i}$ = 0.10	④ $\frac{G}{\delta}$ ② − ③	⑤ $\alpha_\delta\delta$ (rad)	⑥ c Local Chord (ft)	⑦ c_{ℓ_Λ} -2b ④ ⑤ / ⑥ Eq. 6.1.5.1-c

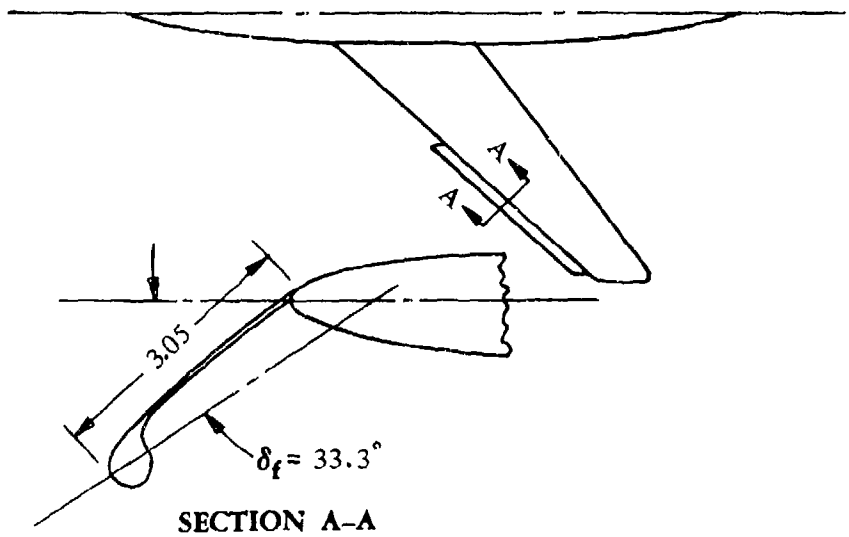
					$\Delta c_{m_f} = \Sigma =$	−0.0473

This compares with a test value of $\Delta C_{m_f} = -0.040$ from Reference 13.

3. Krueger Leading-Edge Flap

Given: The sweptback wing-body configuration of Reference 35 with a leading-edge Krueger flap.



SECTION A–A

Wing Characteristics:

$A = 5.1$ $b/2 = 74.75$ in. $\lambda = 0.383$ $\Lambda_{c/4} = 45.35^{o}$ $\Lambda_{LE} = 47.72^{o}$

$c_r = 42.36$ in. $c_t = 16.24$ in. $S_W = 30.35$ ft^2 $\bar{c} = 31.22$ in.

$y_{\bar{c}} = 31.81$ in. $\alpha = 2^{o}$

Flap Characteristics:

Krueger leading-edge flap $c_{f_{1_{LE}}} = 3.05$ in. $\delta^{*}_{f_{1_{LF}}} = 33.3^{o}$

Constant flap chord $\eta_i = 0.50$ $\eta_o = 0.975$

Additional Characteristics:

$M = 0.14$; $\beta = 0.99$ $R_\ell = 6 \times 10^6$ $C_L = 0.17$

$x_m = 42.79$ in. (aft of wing apex) $C_m = -0.040$ (flaps retracted)

*δ_f is defined according to Figure 6.1.1.1-51, not as defined in Reference 35.

Compute:

Determine $\bar{c}'$

$$c_{f_{LE}} = \frac{c_{f_{LE}}}{\cos \Lambda_{LE}} = \frac{3.05}{0.6727} = 4.53 \text{ in.}$$

$c = c_r - \eta (c_r - c_t)$ (see Section 2.2.2)

At η_i, $c = 42.36 - (0.50)(42.36 - 16.24) = 29.30$ in.

$c' = c + c_f = 29.30 + 4.53 = 33.83$ in.

At η_o, $c = 42.36 - (0.975)(42.36 - 16.24) = 16.89$ in.

$c' = 16.89 + 4.53 = 21.42$ in.

$$\lambda_f = \frac{(c')_{\eta_o}}{(c')_{\eta_i}} = \frac{21.42}{33.83} = 0.633$$

$$\bar{c}' = \frac{2}{3}(c')_{\eta_i}\left(\frac{1 + \lambda_f + \lambda_f^2}{1 + \lambda_f}\right) \quad \text{(Section 2.2.2)}$$

$$= \frac{2}{3}(33.83)\left(\frac{1 + 0.633 + 0.633^2}{1 + 0.633}\right)$$

$= 28.09$ in.

Determine $c_{m'_{\delta_{LE}}}$ and $c_{\ell'_\delta}$ (assuming constant flap-to-chord ratio)

$$\frac{c_{f_{LE}}}{\bar{c}'} = \frac{4.53}{28.09} = 0.161$$

$c_{m'_{\delta_{LE}}} = -0.00127$ per deg (Figure 6.1.2.1-36)

$c_{\ell'_\delta} = -0.00320$ per deg (Figure 6.1.1.1-50)

Determine x_{LE}

$$y_{\bar{c}'} = \frac{1}{3}(\Delta\eta)(b/2)\left(\frac{1 + 2\lambda_f}{1 + \lambda_f}\right) + (\eta_i)(b/2) \quad \text{(Section 2.2.2)}$$

$$= \frac{1}{3}(0.975 - 0.50)(74.75)\left(\frac{1 + 2(0.633)}{1 + 0.633}\right) + 0.5(74.75)$$

$= 16.42 + 37.375 = 53.80$ in.

$$x_{LE} = y_{\bar{c}'} \tan \Lambda_{LE} - c_f$$

$$= 53.80\,(1.0998) - 4.53$$

$$= 54.64 \text{ in.}$$

Determine S_{W_f}

$$S_{W_f} = [(c')_{\eta_i} + (c')_{\eta_o}]\,(\Delta\eta)(b/2)$$

$$= (33.83 + 21.42)(0.975 - 0.50)(74.75)$$

$$= 1961.72 \text{ in.}^2 = 13.62 \text{ ft}^2$$

Determine δ_f (streamwise)

$$\delta_f = \tan^{-1}(\tan \delta_{f_{\perp LE}} \cos \Lambda_{LE}) \quad \text{(Equation 6.1.5.1-d)}$$

$$= \tan^{-1}[(0.6569)(0.6727)]$$

$$= 23.84^{\circ} \text{ (streamwise)}$$

Determine c

$$\text{At } \eta_{\bar{c}'},\ c = c_r - \frac{y_{\bar{c}'}}{b/2}(c_r - c_t) \quad \text{(Section 2.2.2)}$$

$$= 42.36 - \frac{53.80}{74.75}(42.36 - 16.24) = 23.56 \text{ in.}$$

Solution:

$$\Delta C_m = \left[c_{m'_{\delta_{LE}}} \left(\frac{\bar{c}'}{\bar{c}}\right) + \left(\frac{x_m}{\bar{c}} - \frac{x_{LE}}{\bar{c}}\right) c_{\ell'_\delta} \right] \frac{S_{W_f}}{S_W} \delta_f$$

$$+ \left\{ C_m \left[\left(\frac{\bar{c}'}{c}\right)^2 - 1 \right] + 0.75\, C_L \left(\frac{\bar{c}'}{c}\right) \left(\frac{\bar{c}'}{c} - 1\right) \right\} \Delta\eta \quad \text{(Equation 6.1.5.1-}\ell\text{)}$$

$$= \left[(-0.00127)\left(\frac{28.09}{31.22}\right) + \left(\frac{42.79}{31.22} - \frac{54.64}{31.22}\right)(-0.00320) \right] \frac{13.62}{30.35}(23.84)$$

$$+ \left\{ (-0.040)\left[\left(\frac{28.09}{23.56}\right)^2 - 1 \right] + 0.75\,(0.17) \left(\frac{28.09}{23.56}\right) \left(\frac{28.09}{23.56} - 1\right) \right\} (0.975 - 0.50)$$

$$= (-0.00114 + 0.00121)(10.70) + (-0.0169 + 0.0293)(0.475)$$

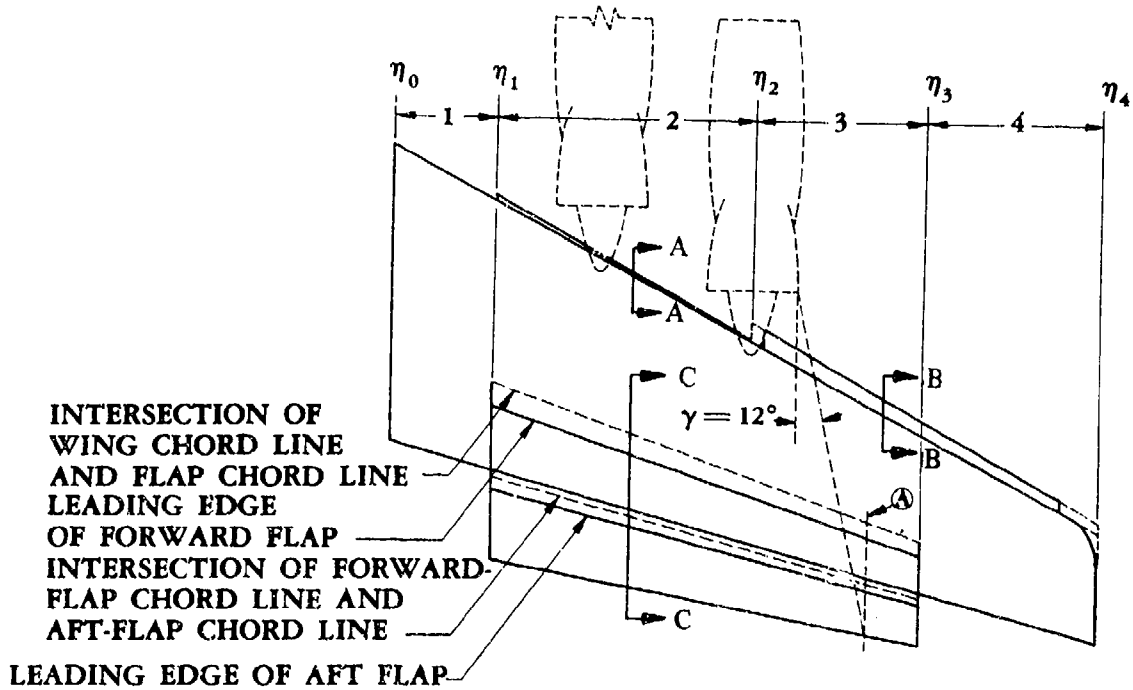
$$= 0.00075 + 0.00589$$

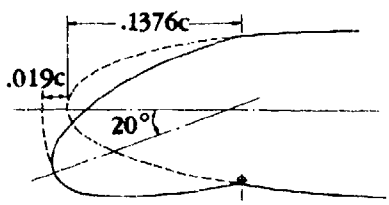
$$= 0.00664$$

This compares with a test value of $\Delta C_m = 0.003$ from Reference 35.

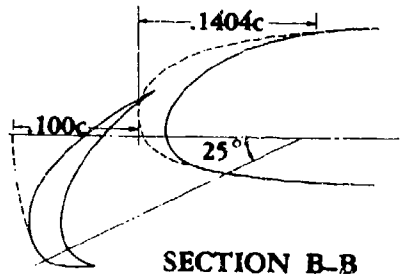
4. Trailing-Edge Jet Flap

Given: The wing with the EBF system shown below.

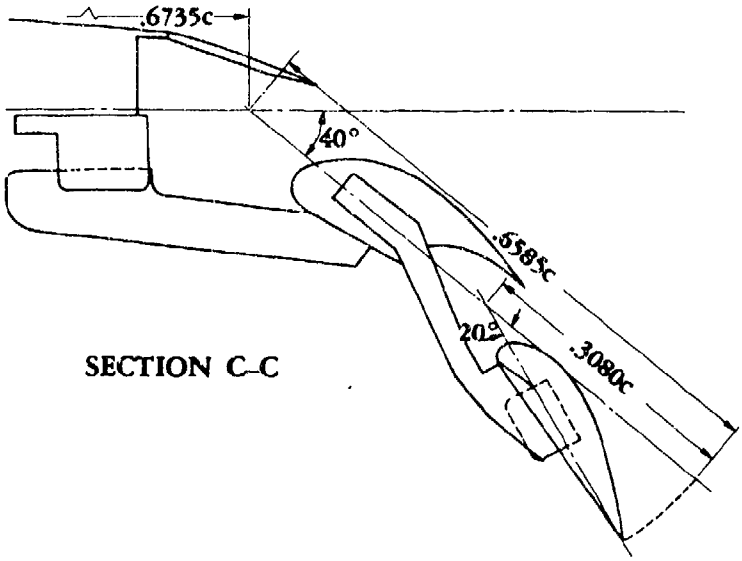




SECTION A–A



SECTION B–B



SECTION C–C

$A = 7.0$ $\lambda = 0.3714$ $b = 5.9360$ ft $\Lambda_{c/4} = 25^{O}$

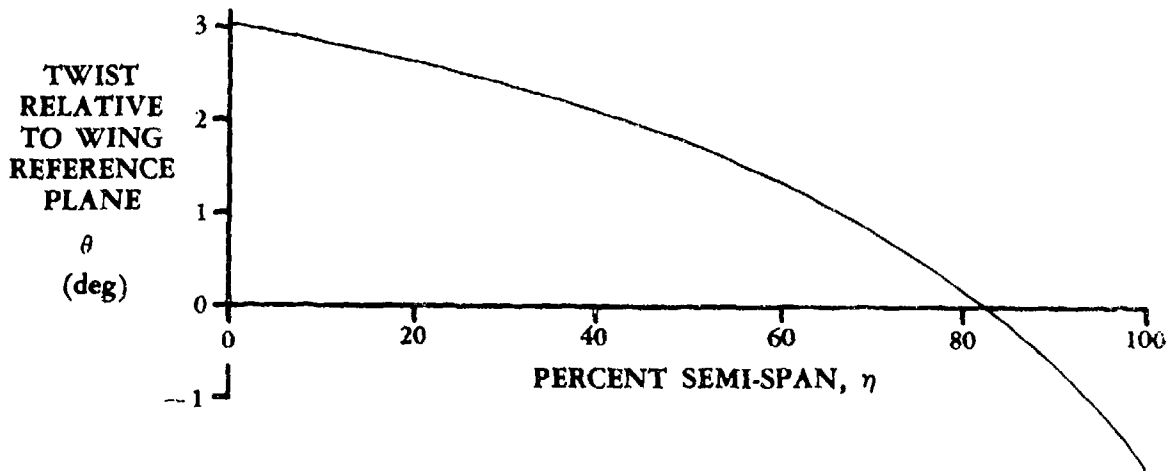
$c_r = 14.84$ in. $\bar{c} = 10.8886$ in. $S_W = 5.0337$ ft^2

$x_{c.g.} = 10.72$ in. aft of wing apex $\Delta z_{c.g.} = -1.922$ in. (below MAC quarter-chord)

$\alpha_W = 0$ $C_J = 3.0$ $\eta_t = 0.81$

$\delta_{j_{eff}} = 57.5^{O}$ } (from static force-test data)

$\delta_{f_1} = 40^{O}$ $\delta_{f_2} = 20^{O}$



Wing section, k	1	2	3	4
Span station of outboard streamwise cut, η_k	0.1443	0.5076	0.7515	1.0
Span station of inboard streamwise cut, η_{k-1}	0	0.1443	0.5076	0.7515
Leading-edge device	None	Drooped leading edge	Slat	Slat
$\delta_{f_{LE}}$	0	20^{O}	25^{O}	25^{O}
Trailing-edge device	None	Double-slot Fowler flap	Double-slot Fowler flap	None
$c_{f_{LE}}/c$	0	0.1376	0.1404	0.1404
c'_{LE}/c	1.0	1.019	1.100	1.100
c_1/c	0	0.3505	0.3505	0
c_2/c	0	0.3080	0.3080	0
$c_{\delta\delta}/c$	1.0	1.351	1.432	1.100

Compute:

Step 1. Divide the wing into four sections as indicated in the drawing. The wing-tip is squared off and the slats extended to avoid definition of additional small wing sections. It was assumed that blowing affects the entire trailing-edge flap.*

Find $S_J = S_2 + S_3$ (the area ahead of the flap)

$$c_t = \lambda c_r = (0.3714)(14.84) = 5.512 \text{ in.}$$

$$c = c_r - \eta_k(c_r - c_t)$$

At η_1, $c = 14.84 - 0.1443(14.84 - 5.51) = 13.49$ in.

At η_2, $c = 14.84 - 0.5076(14.84 - 5.51) = 10.10$ in.

At η_3, $c = 14.84 - 0.7515(14.84 - 5.51) = 7.83$ in.

$$S_2 = \frac{1}{2}\frac{(13.49 + 10.10)}{12}(0.5076 - 0.1443)(5.9360) = 2.120 \text{ ft}^2$$

$$S_3 = \frac{1}{2}\frac{(10.10 + 7.83)}{12}(0.7515 - 0.5076)(5.9360) = 1.082 \text{ ft}^2$$

$$S_J = 2.120 + 1.082 = 3.202 \text{ ft}^2$$

Because of the lengthiness of the calculations for various parameters in Steps 2 through 5, the calculations for only wing section 2 will be presented in detail. However, the calculated components for each wing section are listed in summary tables with the detailed calculations for wing section 2.

*For purposes of illustration only, an additional division, Ⓐ in the sketch, is shown. It is made at the intersection of the jet and the extended flap trailing edge, by assuming that the jet spreading is 12 degrees. If the wing had been equipped with a full-span trailing-edge flap, division A would have been used as η_3 instead of $\eta_3 = 0.7515$.

Step 2. Δc_m (Section 6.1.2.1. Note, however, that several terms have been redefined in Section 6.1.5.1; e.g., C_μ, K, $\frac{x_m}{c}$, α_L, $\frac{x_{f_i}}{c_{\delta\delta}}$, and $\frac{x_j}{c_{\delta\delta}}$)

Find $(\Delta c_m)_{\delta f_{LE}}$ (Wing Section 2)

$$\left.\begin{aligned} \delta_{f_{LE}} &= 20^o \\ \frac{c_{f_{LE}}}{c} &= 0.1376 \end{aligned}\right\} \text{ (given)}$$

$$c_a = c_{\delta\delta} - c_{f_{LE}} \quad \text{(Equation 6.1.2.1-g)}$$

$$\frac{c_a}{c_{\delta\delta}} = 1 - \frac{c_{f_{LE}}}{c} \Big/ \frac{c_{\delta\delta}}{c}$$

$$= 1 - \frac{0.1376}{1.351}$$

$$= 0.8981$$

$$C_\mu = C_J \eta_t \frac{S_W}{S_J} \quad \text{(Equation 6.1.5.1-o)}$$

$$= (3.0)(0.81)\frac{5.0337}{3.202}$$

$$= 3.820$$

$$C_\mu' = C_\mu \frac{c}{c_{\delta\delta}} \quad \text{(defined in Section 6.1.2.1 Step 1a)}$$

$$= 3.820/1.351$$

$$= 2.828$$

$$c_{\ell_{\delta_a}} = 11.6 \text{ per rad} \quad \text{(Figure 6.1.1.1-49)}$$

$$c_{\ell_\alpha} = 11.8 \text{ per rad} \quad \text{(Figure 6.1.1.1-49)}$$

$$A_t = A\frac{c}{c_{\delta\delta}} = \frac{7.0}{1.351} = 5.181$$

$$K = \left[\frac{A_t + 2 C'_\mu/\pi}{A_t + 2 + 0.604(C'_\mu)^{1/2} + 0.876\, C'_\mu} \right] \frac{c_{\delta\delta}}{c} \quad \text{(Equation 6.1.5.1-p)}$$

$$= \left[\frac{5.181 + 2(2.828)/\pi}{5.181 + 2 + 0.604(2.828)^{1/2} + 0.876(2.828)} \right] (1.351)$$

$$= \frac{6.981(1.351)}{10.674}$$

$$= 0.8836$$

$$\Delta c_1 = \frac{\delta_{f_{LE}}}{57.3} K\, c_{\ell_{\delta_a}} \quad \text{(Equation 6.1.2.1-e)}$$

$$= \frac{20}{57.3}(0.8836)(11.6)$$

$$= 3.5776$$

$$\Delta c_2 = \frac{\delta_{f_{LE}}}{57.3} K\, c_{\ell_\alpha} \quad \text{(Equation 6.1.2.1-f)}$$

$$= \frac{20}{57.3}(0.8836)(11.8)$$

$$= 3.6393$$

$$\tan \Lambda_{LE} = \tan \Lambda_{c/4} - \frac{4}{A}\left(-\frac{1}{4}\right)\frac{1-\lambda}{1+\lambda} \quad \text{(Section 2.2.2)}$$

$$= 0.4663 - \frac{4}{7}\left(-\frac{1}{4}\right)\frac{1-0.3714}{1.3714}$$

$$= 0.5318$$

$$\frac{x_m}{c} = \left(\frac{1+\lambda}{1-\lambda}\right)\frac{A_s}{4}\tan\Lambda_{LE} \quad \text{(Equation 6.1.5.1-m)}$$

$$= \left(\frac{1.3714}{1-0.3714}\right)\frac{7}{4}(0.5318)$$

$$= 2.0304$$

$$\frac{x_a}{c_{\delta\delta}} = 0.245 \quad \text{(Figure 6.1.2.1-37)}$$

$$\frac{x_{a.c.}}{c_{\delta\delta}} = 0.215 \quad \text{(Figure 6.1.2.1-37)}$$

$$x_1 = \frac{x_m}{c} + \left(\frac{c'_{LE}}{c} - 1\right) - \frac{x_a}{c_{\delta\delta}}\frac{c_{\delta\delta}}{c} \quad \text{(Equation 6.1.2.1-h)}$$

$$= 2.0304 + (1.019 - 1) - 0.245\,(1.351)$$

$$= 1.718$$

$$x_2 = \frac{x_m}{c} + \left(\frac{c'_{LE}}{c} - 1\right) - \frac{x_{a.c.}}{c_{\delta\delta}}\frac{c_{\delta\delta}}{c} \quad \text{(Equation 6.1.2.1-i)}$$

$$= 2.0304 + (1.019 - 1) - 0.215(1.351)$$

$$= 1.759$$

$$\Delta c_{m_3} = C_\mu \frac{c_{f_{LE}}}{c}\sin\delta_{f_{LE}} \quad \text{(Equation 6.1.2.1-j)}$$

$$= 3.820\,(0.1376)(0.3420)$$

$$= 0.1798$$

$$(\Delta c_m)_{\delta f_{LE}} = \Delta c_1\, x_1 - \Delta c_2\, x_2 + \Delta c_{m_3} \quad \text{(Equation 6.1.2.1-d)}$$

$$= (3.5776)(1.718) - (3.6393)(1.759) + 0.1798$$

$$= -0.0754 \quad \text{(for Wing Section 2)}$$

$(\Delta c_m)_{\delta f_{LE}}$ Summary

Wing Section	1	2	3	4

B. TRANSONIC

The following method for the estimation of C_{m_δ} at transonic speeds is based on a procedure similar to that of Reference 6 and is developed empirically from test data of References 7 through 10. The only readily available test data for pitching-moment effectiveness at transonic speeds are those of References 7 through 10. Therefore, the method has not been substantiated independently of these test data.

DATCOM METHOD

A first-order approximation to the pitching-moment effectiveness at transonic speeds is given by

$$C_{m_\delta} = -C_{L_\delta} \frac{x}{\bar{c}} \qquad 6.1.5.1\text{-w}$$

where

C_{L_δ} is the lift effectiveness of the control surfaces from the method of Paragraph B of Section 6.1.4.1.

$\frac{x}{\bar{c}}$ is the distance, in percent of MAC, of the chordwise center-of-pressure location aft of the wing moment reference point.

$$\frac{x}{\bar{c}} = -\frac{b}{\bar{c}} \tan \Lambda_{LE} \left[\frac{1 + 2\lambda}{6(1 + \lambda)} - 2 \frac{\left(C_{l_\delta}\right)_{M = 0.6}}{\left(C_{L_\delta}\right)_{M = 0.6}} \right] + \left(\frac{x_{c.p.}}{c_{c.p.}}\right) \frac{c_{c.p.}}{\bar{c}} - \frac{x_{MRP}}{\bar{c}} \qquad 6.1.5.1\text{-x}$$

where

$\left(C_{l_\delta}\right)_{M = 0.6}$ is the roll effectiveness of the control surface at M = 0.6, based on the total wing span with one control deflected. This parameter is one-half the value of C_{l_δ} obtained by the method of Paragraph A of Section 6.2.1.1.

$\left(C_{L_\delta}\right)_{M = 0.6}$ is the lift effectiveness of the control surfaces at M = 0.6 from Paragraph A of Section 6.1.4.1.

$\frac{x_{MRP}}{\bar{c}}$ is the distance, in percent of MAC, from the leading edge of the MAC to the moment reference point, positive for the moment reference point aft of the leading edge of the MAC.

$\frac{x_{c.p.}}{c_{c.p.}}$ is the empirically derived chordwise center-of-pressure location of the incremental load due to surface deflection, determined by

$$\frac{x_{c.p.}}{c_{c.p.}} = \left(\frac{x_{c.p.}}{c_{c.p.}}\right)_1 + K\left(\frac{c_f}{c} - 0.2\right) \qquad 6.1.5.1\text{-y}$$

where $\left(x_{c.p.}/c_{c.p.}\right)_1$ and K are empirically derived factors presented as functions of Mach number and $\Lambda_{c/4}$ in Figures 6.1.5.1-69a and 6.1.5.1-69b, respectively. The flap-chord ratio c_f/c is measured in the streamwise direction.

$\frac{c_{c.p.}}{\bar{c}}$ is the wing chord at the spanwise center-of-pressure location, in percent of MAC given by

$$\frac{c_{c.p.}}{\bar{c}} = \frac{c_r}{\bar{c}}\left[1 - 4(1-\lambda)\frac{\left(C_{l_\delta}\right)_{M=0.6}}{\left(C_{L_\delta}\right)_{M=0.6}}\right] \qquad 6.1.5.1\text{-}z$$

where $\left(C_{l_\delta}\right)_{M=0.6}$ and $\left(C_{L_\delta}\right)_{M=0.6}$ are defined above.

The planform parameters of the empirical data used to derive Figures 6.1.5.1-69a and 6.1.5.1-69b are: A = 4.0, λ = 0.6, t/c = 0.06, $0 \leq \Lambda_{c/4} \leq 60^o$, and a 0.30c plain sealed flap.

Sample Problem

Given: The configuration of Reference 8 with a partial-span plain trailing-edge flap.

Wing Characteristics:

A = 4.0 b/2 = 4.243 in. λ = 0.60 $\Lambda_{c/4} = 35^o$ $\Lambda_{LE} = 37.33^o$

NACA 65A006 airfoil (streamwise) $x_{MRP} = \frac{\bar{c}}{4}$ $c_r/\bar{c}$ = 1.183 $\frac{b}{\bar{c}}$ = 3.918

Flap Characteristics:

Plain trailing-edge flap c_f/c = 0.30 $\Lambda_{HL} = 30.44^o$

η_i = 0.57 η_o = 1.0 $\delta = 16^o$ (streamwise)

Additional Characteristics:

M = 0.90 $\left(C_{l_\delta}\right)_{M=0.6}$ = 0.0014 per deg (test value for semispan model, based on S_W and b_W)

$\left(C_{l_\delta}\right)_{M=0.9}$ = 0.00135 per deg (test value for semispan model, based on S_W and b_W)

$\left(C_{L_\delta}\right)_{M=0.6}$ = 0.0105 per deg (test value for full-span model, based on S_W)

Compute:

Chordwise center-of-pressure location

$$\frac{c_{c.p.}}{\bar{c}} = \frac{c_r}{\bar{c}}\left[1 - 4(1-\lambda)\frac{\left(C_{l_\delta}\right)_{M=0.6}}{\left(C_{L_\delta}\right)_{M=0.6}}\right] \qquad \text{(Equation 6.1.5.1-z)}$$

$$= 1.183\left[1 - 4(0.4)\ \frac{0.0014}{0.0105}\right]$$

$$= 0.931$$

$$\left(\frac{x_{c.p.}}{c_{c.p.}}\right)_1 = 0.880 \quad \text{(Figure 6.1.5.1-69 a)}$$

$K = -0.690$ (Figure 6.1.5.1-69b)

$$\frac{x_{c.p.}}{c_{c.p.}} = \left(\frac{x_{c.p.}}{c_{c.p.}}\right)_1 + K\left(\frac{c_f}{c} - 0.2\right) \qquad \text{(Equation 6.1.5.1-y)}$$

$$= (0.880) + (-0.690)(0.30 - 0.20)$$

$$= 0.811$$

$$\frac{x}{\bar{c}} = -\frac{b}{\bar{c}}\tan\Lambda_{LE}\left[\frac{1+2\lambda}{6(1+\lambda)} - 2\,\frac{\left(C_{l_\delta}\right)_{M=0.6}}{\left(C_{L_\delta}\right)_{M=0.6}}\right] + \left(\frac{x_{c.p.}}{c_{c.p.}}\right)\frac{c_{c.p.}}{\bar{c}} - \frac{x_{MRP}}{\bar{c}} \qquad \text{(Equation 6.1.5.1-x)}$$

$$= (-3.918)(0.7626)\left[\frac{2.20}{9.60} - 2\left(\frac{0.0014}{0.0105}\right)\right] + (0.811)(0.931) - 0.25$$

$$= 0.112 + 0.755 - 0.25$$

$$= 0.617$$

Lift effectiveness at M = 0.9 (Section 6.1.4.1)

$$C_{L_\delta} = \left(C_{L_\delta}\right)_{M=0.6}\left(\frac{C_{l_\delta}}{C_{l_{\delta_{M=0.6}}}}\right) \qquad \text{(Equation 6.1.4.1-e)}$$

$$= 0.0105\left(\frac{0.00135}{0.0014}\right)$$

$$= 0.0101 \text{ per deg}$$

Solution:

$$C_{m_\delta} = - C_{L_\delta} \frac{x}{\bar{c}} \quad \text{(Equation 6.1.5.1-w)}$$

$$= - (0.0101)(0.617)$$

$$= - 0.00623 \text{ per deg}$$

The test value at M = 0.90 from Reference 8 is – 0.0065 per degree.

C. SUPERSONIC

The procedure for estimating trailing-edge control effectiveness at supersonic speeds is based on the method presented in Reference 11. The restrictions used in the derivation of the method are listed below.

1. Leading and trailing edges of the control surface are swept ahead of the Mach lines from the deflected controls.
2. Control root and tip chords are parallel to the plane of symmetry.
3. Controls are located either at the wing tip or far enough inboard so that the outermost Mach lines from the deflected controls do not cross the wing tip.
4. Innermost Mach lines from the deflected controls do not cross the wing root chord.
5. Wing planform has leading edges swept ahead of the Mach lines and has streamwise tips.
6. Controls are not influenced by the tip conical flow from the opposite wing panel or by the interaction of the wing-root Mach cone with the wing tip.

DATCOM METHOD

The pitching-moment effectiveness C_{m_δ} at supersonic speeds for symmetric, straight-sided controls, based on total wing area and $\bar{c}$, is given by

$$C_{m_\delta} = K_1 \frac{1}{3} \frac{b_f}{\bar{c}} \frac{c_{r_f}}{S_W} C'_{m_\delta} - K_2 \frac{1}{2} \frac{b_f}{\bar{c}} \frac{S_f}{S_W} C'_{l_\delta} - K_3 \frac{x_f}{\bar{c}} \frac{S_f}{S_W} C'_{L_\delta} \quad \text{6.1.5.1-aa}$$

where

$$K_1 = \left(1 - \frac{C_2}{C_1} \phi_{TE}\right) (1 + \lambda_f + \lambda_f^2)$$

$$K_2 = \left(1 - \frac{C_2}{C_1} \phi_{TE}\right) \tan \Lambda_{HL}$$

$$K_3 = \left(1 - \frac{C_2}{C_1} \phi_{TE}\right)$$

where $\left(1 - \frac{C_2}{C_1}\phi_{TE}\right)$ is a thickness correction factor to the supersonic flat-plate derivative.

$$C_1 = \frac{2}{\sqrt{M^2 - 1}} \text{ per radian}$$

$$C_2 = \frac{(\gamma + 1)M^4 - 4(M^2 - 1)}{2(M^2 - 1)^2} \text{ per radian}$$

ϕ_{TE} is the trailing-edge angle in radians, measured normal to the control hinge line.

γ is the ratio of specific heats, $\gamma = 1.4$.

b_f is the control span (both sides of wing).

S_f is the control area (both sides of wing).

λ_f is the taper ratio of the control.

Λ_{HL} is the sweep of the control hinge line.

c_{r_f} is the root chord of the control.

x_f is the distance of the leading edge of the control root chord behind the wing axis of pitch.

C'_{m_δ} is the pitching-moment effectiveness of one symmetric, straight-sided control, based on twice its moment area about the hinge line, from Figures 6.1.5.1-70 through 6.1.5.1-73b, according to the control planform as follows:

(a) Tapered controls with outboard edge coincident with wing tip, use Figure 6.1.5.1-70.

(b) Tapered controls with outboard edge not coincident with wing tip, use Figure 6.1.5.1-73a.

(c) Untapered controls with outboard edge coincident with wing tip, use Figure 6.1.5.1-73b.

(d) Untapered controls with outboard edge not coincident with wing tip, use Figure 6.1.5.1-73a.

C'_{L_δ} is the lift effectiveness of one symmetric, straight-sided control, based on the area of the control, obtained from Paragraph C of Section 6.1.4.1.

C'_{l_δ} is the rolling-moment effectiveness of one symmetric, straight-sided control about its root chord line, based on the area and span of one control, obtained from Paragraph C of Section 6.2.1.1.

It should be noted that control deflection angles are measured streamwise.

For swept-forward wings and controls with inverse taper, see Reference 11 for the proper values of C'_{m_δ}, C'_{L_δ} and C'_{l_δ}.

Thickness correction factors for other than symmetrical, straight-sided controls can be determined from Reference 11.

The computation of pitching-moment effectiveness for leading-edge controls and trailing-edge controls with subsonic leading edges can be accomplished with the aid of Reference 12.

Not enough test data are available to allow substantiation of the method.

Sample Problem

Given: A wing-control configuration with the following characteristics:

Wing Characteristics:

S_W = 46.5 sq ft $\quad \bar{c}$ = 4.0 ft $\quad b$ = 12.0 ft $\quad \Lambda_{LE} = 42^\circ$

$\Lambda_{TE} = 27.7^\circ$

Control Characteristics:

Symmetric, straight-sided inboard flap

S_f = 4.71 sq ft (both sides of wing) $\quad b_f$ = 6.5 ft (both sides of wing)

λ_f = 0.715 $\quad c_{r_f}$ = 0.85 ft $\quad x_f$ = 1.768 ft $\quad \phi_{TE} = 3^\circ$

$\Lambda_{HL} = 30.8^\circ$

Additional Characteristics:

$M = 1.90$; $\beta = 1.62$

Compute:

$$C_1 = \frac{2}{\sqrt{M^2 - 1}} = 1.235$$

$$C_2 = \frac{(\gamma + 1) M^4 - 4 (M^2 - 1)}{2 (M^2 - 1)^2} = \frac{(2.4) (1.90)^4 - 4 \left[(1.90)^2 - 1\right]}{2 \left[(1.90)^2 - 1\right]^2} = \frac{20.84}{13.62} = 1.53$$

$$K_1 = \left(1 - \frac{C_2}{C_1} \phi_{TE}\right) \left(1 + \lambda_f + \lambda_f^2\right)$$

$$= \left[1 - \left(\frac{1.53}{1.235}\right)\left(\frac{3.0}{57.3}\right)\right]\left[1 + 0.715 + (0.715)^2\right] = (0.935)(2.226) = 2.08$$

$$K_2 = \left(1 - \frac{C_2}{C_1}\phi_{TE}\right)(\tan \Lambda_{HL}) = (0.935)(0.5961) = 0.557$$

$$K_3 = \left(1 - \frac{C_2}{C_1}\phi_{TE}\right) = 0.935$$

$$\frac{\tan \Lambda_{TE}}{\beta} = \frac{0.5250}{1.62} = 0.324$$

$$\frac{\tan \Lambda_{HL}}{\beta} = \frac{0.5961}{1.62} = 0.368$$

$\beta C'_{m_\delta}$ = -0.0360 per deg (Figure 6.1.5.1-73a)

C'_{m_δ} = -0.0222 per deg

$\beta C'_{L_\delta}$ = 0.0750 per deg (Figure 6.1.4.1-25)

C'_{L_δ} = 0.0463 per deg

$\beta C'_{l_\delta}$ = 0.0340 per deg (Figure 6.2.1.1-28, interpolated)

C'_{l_δ} = 0.0210 per deg

Solution:

$$C_{m_\delta} = K_1 \frac{1}{3}\frac{b_f}{\bar{c}}\frac{c_{r_f}}{S_W} C'_{m_\delta} - K_2 \frac{1}{2}\frac{b_f}{\bar{c}}\frac{S_f}{S_W} C'_{l_\delta} - K_3 \frac{x_f}{\bar{c}}\frac{S_f}{S_W} C'_{L_\delta}$$ (Equation 6.1.5.1-aa)

$$= (2.08)\frac{1}{3}\left(\frac{6.5}{4.0}\right)\left(\frac{0.85}{46.5}\right)(-0.0222) - (0.557)\frac{1}{2}\left(\frac{6.5}{4.0}\right)\left(\frac{4.71}{46.5}\right)(0.0210)$$

$$-(0.935)\left(\frac{1.768}{4.0}\right)\left(\frac{4.71}{46.5}\right)(0.0463)$$

$$= (-0.000457) - (0.000963) - (0.00194)$$

$$= -0.00336 \text{ per deg}$$

6.1.5.2 WING DERIVATIVE C_{m_α} WITH HIGH-LIFT AND CONTROL DEVICES

Mechanical Flaps

According to lifting-line or lifting-surface theory, camber, such as that due to flaps, does not affect the variation of pitching moment with angle of attack over the region where there is no flow separation. The theory is substantiated by experiment over the linear angle-of-attack and flap-deflection ranges (References 1 and 2).

Theoretically, the pitching-moment-curve slope of both wings and airfoils is affected by leading- and/or trailing-edge flaps that extend beyond the basic airfoil chord. However, the changes in C_{m_α} for airfoils (as predicted by linear theory) cannot be substantiated with test data (see Section 6.1.2.2). In addition, the effect of extended flaps on C_{m_α} for a wing of finite aspect ratio is not treated in detail in any of the literature surveyed for Datcom. Therefore, no method is presented to account for the effects of extended flaps on C_{m_α}.

Jet Flaps

The aerodynamic-center location for a wing with a jet flap is dependent upon the trailing-edge jet momentum coefficient C_μ and upon the extent to which leading- and trailing-edge flaps extend beyond the basic wing.

Considerations of clarity and simplicity of presentation dictated a deviation from normal Datcom practice in that the effect of jet flaps on C_{m_α} was included in Section 6.1.5.1, which deals with the pitching-moment increment ΔC_m.

DATCOM METHOD

1. Mechanical Flaps

The variation of wing pitching moment with angle of attack for various flap deflections is assumed to be the same as that for zero flap deflection over the linear-lift range (see Section 6.1.3, particularly Figure 6.1.3-2).

2. Jet Flaps

The variation of pitching moment with angle of attack for wings equipped with jet flaps is covered in the jet-flap method of Section 6.1.5.1. The range of applicability and the limitations of the method are discussed there and in Sections 6.1.1.1 and 6.1.2.1.

6.1.6 HINGE MOMENTS OF HIGH-LIFT AND CONTROL DEVICES

This section presents approximate methods for determining hinge-moment derivatives at subsonic and supersonic speeds. At subsonic speeds the method, based on lifting-line theory, is believed to be of sufficient accuracy to be used for preliminary-design work. This method is best suited for higher-aspect-ratio wings.

The methods presented for supersonic speeds have one stringent restriction: the leading edges of the wing planform must be swept ahead of the Mach lines. The methods are based on conical-flow solutions. Since hinge-moment variation with Mach number at transonic speeds becomes somewhat erratic, no method is presented for calculating transonic hinge moments. However, some trends in the transonic range can be noted from References 1 through 4. As the critical Mach number is passed, a shock forms on the upper surface of the airfoil and moves rearward with increasing Mach number. The airfoil pressure distribution changes from one that is approximately triangular, with a peak negative pressure forward, to one more nearly rectangular, with lower pressures at the trailing edge. In general, this causes hinge moments to become more negative. Sketch (a) presents some typical hinge-moment-derivative variations with Mach number.

It should be noted that in the more normal or stable case, where C_{h_α} and C_{h_δ} are negative at subsonic speeds, hinge-moment derivatives decrease in a somewhat regular fashion through the transonic range and then increase slightly to their supersonic value. Most of the very erratic variations of C_{h_α} and C_{h_δ} occur when these values are near zero or positive at subsonic speeds. It can also be seen that in the transonic region some hinge-moment derivatives can change sign.

6.1.6.1 HINGE-MOMENT DERIVATIVE C_{h_α} OF HIGH-LIFT AND CONTROL DEVICES

A. SUBSONIC

The hinge-moment derivative due to angle of attack can be approximated from the method of Reference 1. The method is based on lifting-line theory, with additional lifting-surface corrections to account for sweep.

The method is based on equations in terms of section parameters; therefore, the accuracy of the method is dependent upon the accuracy with which the section characteristics can be estimated. Test data on the particular airfoil-flap combination under consideration or one closely resembling it should always be preferred to characteristics obtained from generalized methods. Calculated values and test data for several different configurations are presented in Table 6.1.6.1-A to illustrate the accuracy of the method and summarize available test data.

The method is directly applicable to control surfaces having constant chord ratios and constant airfoil contours across the span. For configurations with variable chord ratios or variable airfoil contours across the span, it is suggested that average values of the section characteristics be used. Furthermore, the accuracy of the method in predicting the effects of finite-wing parameters decreases as the wing aspect ratio decreases. Application of the method to wings with aspect ratios of three or less should be avoided.

Experimental data have shown that for sweptback wings the shape of the ends of the control surface can have a critical effect on the hinge-moment parameters. The Datcom method is applicable to controls with the control-surface ends cut parallel to the plane of symmetry. For configurations with wing cutouts, or with control surfaces that do not have ends parallel to the plane of symmetry, it is suggested that empirical procedures be used to estimate C_{h_α}.

The effect of subcritical Mach-number corrections on hinge moments appears to be small for control surfaces having trailing-edge angles less than approximately 12°. Therefore the Datcom method, which neglects subcritical Mach-number effects, may be applied over a large portion of the subcritical Mach-number range.

DATCOM METHOD

The hinge-moment derivative due to angle of attack of a sealed, plain trailing-edge control at subsonic speeds, based on the product of the control-surface area and the control-surface chord $S_c c_c$ (area and chord aft of the hinge line), is approximated by

$$C_{h_\alpha} = \frac{A \cos \Lambda_{c/4}}{A + 2 \cos \Lambda_{c/4}} \left(c_{h_\alpha}\right)_{\text{balance}} + \Delta C_{h_\alpha} \qquad \text{6.1.6.1-a}$$

where

$\left(c_{h_\alpha}\right)_{\text{balance}}$ is the section hinge-moment derivative due to angle of attack. Test data on the particular flapped airfoil are preferred, but the derivative can be approximated by the method of Paragraph A of Section 6.1.3.1. (This term could be c'_{h_α} or c''_{h_α} from Section 6.1.3.1.)

ΔC_{h_α} is an approximate lifting-surface correction which accounts for induced-camber effects. It is obtained by multiplying the quantity $\frac{\Delta C_{h_\alpha}}{c_{\ell_\alpha} B_2 K_\alpha \cos\Lambda_{c/4}}$, from Figure 6.1.6.1-19a, by its denominator

where

c_{ℓ_α} is the airfoil section lift-curve slope obtained by using the method of Section 4.1.1.2.

B_2 accounts for the effect of control-surface and balance chord ratios. This parameter is obtained from Figure 6.1.6.1-19c. The primed values of the control-surface and balance chord ratios used in reading Figure 6.1.6.1-19c, refer to measurements normal to the wing quarter-chord line.

K_α accounts for the effect of control-surface span. This parameter is defined by

$$K_\alpha = \frac{(K_\alpha)_{\eta_i}(1-\eta_i) - (K_\alpha)_{\eta_o}(1-\eta_o)}{\eta_o - \eta_i} \qquad 6.1.6.1\text{-b}$$

where

η_i is the inboard span station of the control,
$\eta_i = \frac{\text{inboard span ordinate}}{b/2}$

$(K_\alpha)_{\eta_i}$ is obtained from Figure 6.1.6.1-19b as a function of the inboard spanwise location (η_i) of the control panel.

η_o is the outboard span station of the control,
$\eta_o = \frac{\text{outboard span ordinate}}{b/2}$

$(K_\alpha)_{\eta_o}$ is obtained from Figure 6.1.6.1-19b as a function of the outboard spanwise location (η_o) of the control panel.

Sample Problem

Given: The flapped wing configuration of Reference 8

Wing Characteristics:

$A = 3.43$ $\lambda = 0.44$ $\Lambda_{c/4} = 48.7^o$

$t/c = 0.086$ (streamwise) $\tan\frac{\phi'_{TE}}{2} = 0.0697$ (streamwise)

$\tan \frac{\phi''_{TE}}{2}$ = 0.0523 (streamwise)

NACA 65-012 airfoil (normal to .50c of unswept wing)

Flap Characteristics:

Plain trailing-edge flap | Sealed gap | Λ_{HL} = 41°

c_f/c = 0.167 (streamwise) | c'_f/c' = 0.20 (normal to .25c)

c_b/c_f = 0.090 (streamwise) | c'_b/c'_f = 0.115 (normal to .25c)

$t_c/(2c_f)$ = 0.090 (streamwise) | Round-nosed control

η_i = 0.586 | η_o = 0.99

Additional Characteristics:

Low speed | R_{ℓ} = 2.2 x 10^6

Compute:

Section hinge-moment derivative c_{h_α} (Section 6.1.3.1)

$\left(c_{h_\alpha}\right)_{theory}$ = -0.384 per rad (Figure 6.1.3.1-11b)

$\frac{c_{\ell_\alpha}}{\left(c_{\ell_\alpha}\right)_{theory}}$ = 0.855 (Figure 4.1.1.2-8a)

$\frac{c'_{h_\alpha}}{\left(c_{h_\alpha}\right)_{theory}}$ = 0.600 (Figure 6.1.3.1-11a)

$c'_{h_\alpha} = \left[\frac{c'_{h_\alpha}}{\left(c_{h_\alpha}\right)_{theory}}\right] \left(c_{h_\alpha}\right)_{theory}$ (Equation 6.1.3.1-a)

= (0.600) (-0.384) = -0.230 per rad

$\left(c_{\ell_\alpha}\right)_{theory}$ = 6.715 per rad (Figure 4.1.1.2-8b)

Balance ratio = $\sqrt{\left(\frac{c_b}{c_f}\right)^2 - \left(\frac{t_c}{2c_f}\right)^2}$ = 0 (Equation 6.1.3.1-d)

$\left(c_{h_\alpha}\right)_{balance} / c''_{h_\alpha}$ = 1.0 (Figure 6.1.3.1-12a)

$$c''_{h_\alpha} = c'_{h_\alpha} + 2\left(c_{\ell_\alpha}\right)_{\text{theory}} \left[1 - \frac{c_{\ell_\alpha}}{\left(c_{\ell_\alpha}\right)_{\text{theory}}}\right] \left(\tan\frac{\phi''_{TE}}{2} - \frac{t}{c}\right) \quad \text{(Equation 6.1.3.1-b)}$$

$$= -0.230 + 2\,(6.715)\,[1 - 0.855]\quad (0.0523 - 0.086)$$

$$= -0.296 \text{ per rad} = -0.00516 \text{ per deg}$$

$$\left(c_{h_\alpha}\right)_{\text{balance}} = c''_{h_\alpha}\left[\left(c_{h_\alpha}\right)_{\text{balance}} / c''_{h_\alpha}\right] \quad \text{(Equation 6.1.3.1-c)}$$

$$= -0.00516 \text{ per deg}$$

Induced camber effect ΔC_{h_α}

$$c_{\ell_\alpha} = \frac{1.05}{\beta}\left[\frac{c_{\ell_\alpha}}{\left(c_{\ell_\alpha}\right)_{\text{theory}}}\right]\left(c_{\ell_\alpha}\right)_{\text{theory}} \quad \text{(Equation 4.1.1.2-a)}$$

$$= \left(\frac{1.05}{1.0}\right)(0.855)(6.715)$$

$$= 6.03 \text{ per rad}$$

$$= 0.105 \text{ per deg}$$

$B_2 = 0.885$ (Figure 6.1.6.1-19c)

$\left.\begin{aligned}(K_\alpha)_{\eta_i} &= 2.18\\ (K_\alpha)_{\eta_o} &= 4.20\end{aligned}\right\}$ (Figure 6.1.6.1-19b)

$$K_\alpha = \frac{(K_\alpha)_{\eta_i}(1-\eta_i) - (K_\alpha)_{\eta_o}(1-\eta_o)}{\eta_o - \eta_i} \quad \text{(Equation 6.1.6.1-b)}$$

$$= \frac{(2.18)(1-0.586) - (4.20)(1-0.99)}{0.99 - 0.586}$$

$$= 2.13$$

$$c_{\ell_\alpha} B_2 K_\alpha \cos\Lambda_{c/4} = (0.105)(0.885)(2.13)(0.66) = 0.1306 \text{ per deg}$$

$$\frac{\Delta C_{h_\alpha}}{c_{\ell_\alpha} B_2 K_\alpha \cos\Lambda_{c/4}} = 0.0125 \quad \text{(Figure 6.1.6.1-19a)}$$

$$\Delta C_{h_\alpha} = (0.0125)(0.1306) = 0.00163 \text{ per deg}$$

Solution:

$$C_{h_\alpha} = \frac{A \cos \Lambda_{c/4}}{A + 2 \cos \Lambda_{c/4}} \left(c_{h_\alpha}\right)_{\text{balance}} + \Delta C_{h_\alpha} \qquad \text{(Equation 6.1.6.1-a)}$$

$$= \frac{(3.43)(0.6600)}{(3.43) + (2)(0.6600)} (-0.00516) + 0.00163$$

$$= -0.00083 \text{ per deg}$$

This compares with a test value of −0.0014 per degree from Reference 8.

B. TRANSONIC

No method is available for the prediction of the hinge-moment derivative C_{h_α} at transonic speeds. Because of the mixed-flow conditions and interrelated shock-wave and boundary-layer-separation effects encountered at transonic speeds, the prediction of C_{h_α} by theoretical means is extremely difficult. Experimental results for C_{h_α} at transonic speeds are presented in References 2 through 5.

C. SUPERSONIC

The supersonic three-dimensional hinge moment due to angle of attack can be computed for trailing-edge control surfaces by the method presented in Reference 6. The method is based on linearized theory and applies to tapered and untapered trailing-edge control surfaces, with the following restrictions:

1. Control root and tip chords are parallel to the plane of symmetry.
2. Wing planform has leading edges swept ahead of the Mach lines and has streamwise tips.
3. Controls are not influenced by the tip conical flow from the opposite wing panel or by the interaction of the wing-root Mach cone with the wing tip.

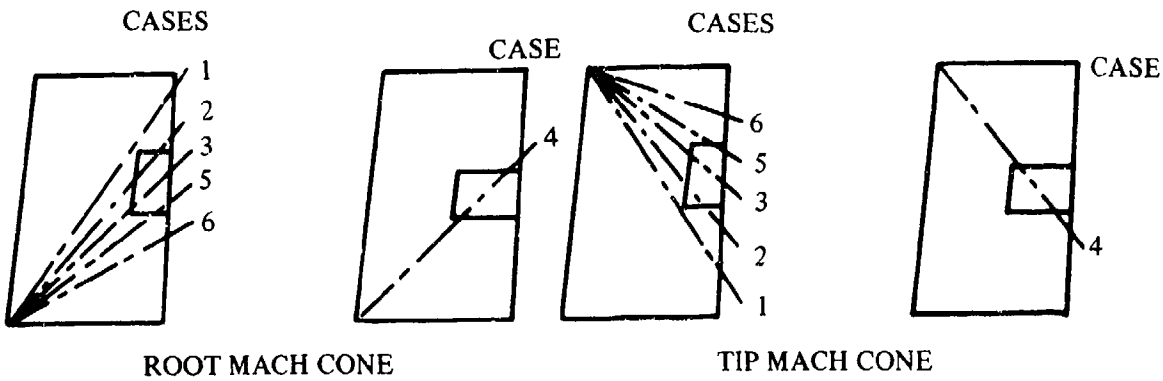
Calculated values and test data for several different configurations are presented in Table 6.1.6.1-B to illustrate the accuracy of the method and summarize available test data.

For leading-edge control surfaces or for trailing-edge control surfaces with subsonic leading edges, reverse-flow techniques (see Reference 7) can be used.

DATCOM METHOD

The method consists of determining the pressure-area-moment for an infinitely thin flat-plate control by assuming two-dimensional loading and then subtracting the losses in loading resulting from the interference of the wing-root and wing-tip conical flows.

Combinations of wing-root and wing-tip conical-flow cases for a typical wing-planform-control configuration are illustrated by the relative positions of the Mach lines in Sketch (a).



SKETCH (a)

For a given Mach number and wing-control combination (which determines the wing-root and wing-tip conical-flow case), the conical-flow losses are obtained by dividing the conical regions into a series of triangular segments, each having its origin at the apex of the Mach cone, and summing the loss in pressure-area-moment $P'S_L x$ for those segments. The procedure to be followed in summing $P'S_L x$ for the triangular segments is illustrated for the most general wing-root and wing-tip conical-flow case (Case 1) in Figure 6.1.6.1-21. Table 6.1.6.1-C is a general computing form for summing a pressure-area-moment parameter representing a loss in loading from the two-dimensional loading of the triangular segments of the conical-flow region defined by Case 1.

Figure 6.1.6.1-21 and Table 6.1.6.1-C can be adapted to compute the pressure-area-moment parameter for wing-root and wing-tip conical-flow Cases 2 through 5 by determining the proper regions that will be affected by the Mach cones. For wing-root and wing-tip conical-flow Case 6, there is no loss in loading from the two-dimensional loading value.

The hinge-moment derivative C_{h_α} at supersonic speeds for a symmetric, straight-sided control, based on the product of the control-surface area and the control-surface chord $S_c c_c$ (area and chord aft of hinge line), is given by

$$\left(C_{h_\alpha}\right)_{t/c} = \left(1 - \frac{C_2}{C_1}\phi_{TE}\right)\left(C_{h_\alpha}\right)_{t/c\,=\,0} \qquad 6.1.6.1\text{-c}$$

where

$\left(1 - \frac{C_2}{C_1}\phi_{TE}\right)$ is a thickness correction factor to the supersonic flat-plate derivative.

$C_1 = \frac{2}{\sqrt{M^2 - 1}}$ per radian

$$C_2 = \frac{(\gamma + 1)\, M^4 - 4\,(M^2 - 1)}{2\,(M^2 - 1)^2} \quad \text{per radian}$$

ϕ_{TE} is the trailing-edge angle in radians, measured normal to the control hinge line.

γ is the ratio of specific heats, $\gamma = 1.4$.

For a symmetrical biconvex airfoil the thickness correction factor in Equation 6.1.6.1-c is

$$1 - \frac{2\,C_2 \left(\frac{t}{c}\right)'}{3\,C_1\,(1 + k)\cos\left(\Lambda_{LE} - \Lambda_{HL}\right)} \left\{ 2 \left[1 + 2 \left(\frac{x_h}{c}\right)' \right] - k \left[1 - \left(\frac{x_h}{c}\right)' \right]^2 \right\}$$

where

$\left(\frac{t}{c}\right)'$ is the maximum airfoil-thickness ratio, measured in a plane normal to the control hinge axis.

$\left(\frac{x_h}{c}\right)'$ is the chordwise location of the control hinge axis, measured in a plane normal to the control hinge axis.

$$k = \tan\left(\Lambda_{LE} - \Lambda_{HL}\right) \tan\left(\Lambda_{LE} - \Lambda_{TE}\right)$$

Thickness correction factors for other airfoil sections can be determined from Reference 6.

$\left(C_{h_\alpha}\right)_{t/c\,=\,0}$ is the supersonic flat-plate hinge-moment derivative.

The procedure for calculating $\left(C_{h_\alpha}\right)_{t/c\,=\,0}$ is outlined in the following steps:

Step 1. Construct the wing-root and wing-tip Mach lines on a layout of the wing-control configuration, and determine the wing-root and wing-tip conical-flow case by referring to Sketch (a).

If the wing-root and wing-tip conical-flow case is Case 6, there is no loss of loading from the two-dimensional value. For this case calculate β and g as presented in Step 2, then

$$\left(C_{h_\alpha}\right)_{t/c\,=\,0} = \frac{-2}{57.3\,\beta\sqrt{1 - g^2}} \quad \text{(per degree)} \qquad 6.1.6.1\text{-d}$$

Step 2. Compute the following geometric and Mach-number parameters (see Sketch (b)):

$$\beta = \sqrt{M^2 - 1}$$

$$g = \frac{\tan \Lambda_{LE}}{\beta}$$

$$a = \frac{\tan \Lambda_{HL}}{\beta}$$

$$d = \frac{\tan \Lambda_{TE}}{\beta}$$

$$K_1 = \beta y_o$$

$$K_2 = \beta y_i$$

$$K_3 = \beta\left(\frac{b}{2} - y_i\right)$$

$$K_4 = \beta\left(\frac{b}{2} - y_o\right)$$

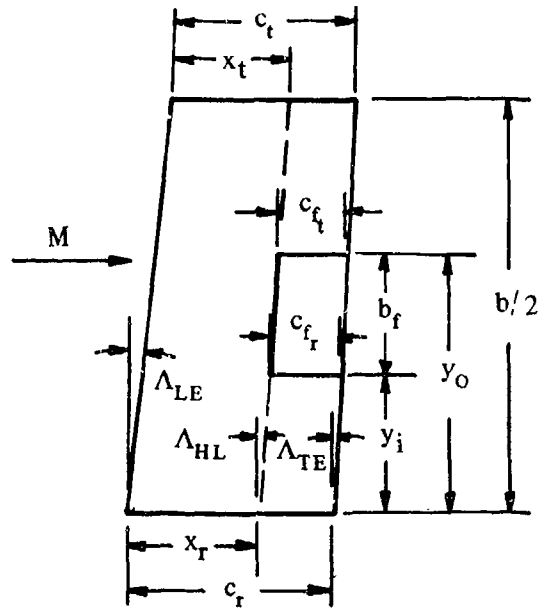
$$K_5 = \beta (y_o)^2$$

$$K_6 = \frac{1}{\beta (1 - d)}$$

$$K_7 = \frac{1}{\beta (1 - a)}$$

$$K_8 = \beta (y_i)^2$$

$$K_9 = \beta\left(\frac{b}{2} - y_i\right)^2$$



SKETCH (b)

$$K_{10} = \frac{1}{\beta (1 + d)}$$

$$K_{11} = \frac{1}{\beta (1 + a)}$$

$$K_{12} = \beta\left(\frac{b}{2} - y_o\right)^2$$

Step 3. Determine the regions (triangular segments numbered (1) through (8) on Figure 6.1.6.1-21) that are affected by the wing-root and wing-tip conical-flow case determined in Step 1.

The regions affected for each case are:

Conical-Flow Case (Sketch (a))	Wing-Root and Wing-Tip Conical Flow Regions Affected
1	1, 2, 3, 4, 5, 6, 7, 8
2	1, 3, 4, 5, 7, 8
3	3, 5, 7, 8
4	1, 3, 4, 7
5	3, 7
6	None

Step 4. Calculate the pressure-area-moment parameter representing a loss in loading from the two-dimensional loading value for each of the wing-root and wing-tip conical-flow regions affected by using the computing procedure presented in Table 6.1.6.1-C.

Step 5. Sum the values of the pressure-area-moment parameter calculated in Step 4 for the affected regions and obtain $\left(C_{h_\alpha}\right)_{t/c = 0}$ by

$$\left(C_{h_\alpha}\right)_{t/c = 0} = \frac{-2}{57.3\,\beta\sqrt{1 - g^2}} \left\{1 - \frac{\Sigma P' \left(3x\sqrt{1 + \beta^2 a^2}\right) 2S_L}{2M_a \left[3\sqrt{1 + \beta^2 a^2}\right]}\right\} \text{(per deg)} \quad 6.1.6.1\text{-e}$$

where

$$2M_a \left[3\sqrt{1 + \beta^2 a^2}\right] = b_f \frac{\left(c_{f_r}\right)^3 - \left(c_{f_t}\right)^3}{c_{f_r} - c_{f_t}} \quad 6.1.6.1\text{-f}$$

for tapered controls, and

$$2M_a \left[3\sqrt{1 + \beta^2 a^2}\right] = 3\, b_f \left(c_{f_r}\right)^2 \quad 6.1.6.1\text{-g}$$

for untapered controls.

SYMBOLS AND DEFINITIONS USED IN COMPUTATION OF $\left(C_{h_\alpha}\right)_{t/c = 0}$

n, r' nondimensional coordinates used in integration of wing-root and wing-tip conical pressures. Equations are given in column (1) of Table 6.1.6.1-C for calculating n and r'. Values of n are required to enter the design charts for P' and $t_{c.p.}$ for conical-flow Regions 3, 4, 5, and 6. Values of r' are required to enter the design charts for P' and $t_{c.p.}$ for conical-flow Regions 1, 2, 7, and 8.

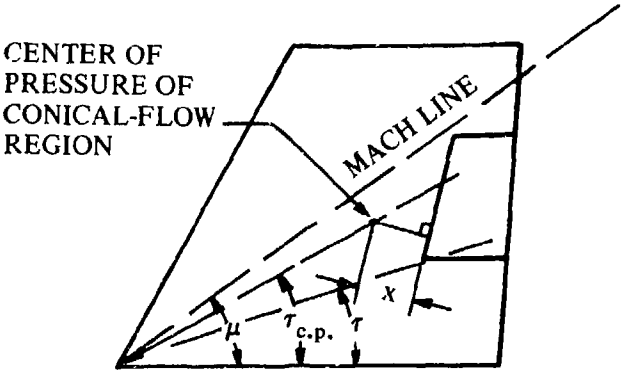
P' the loss of loading of the average value of the local pressure ratio (C_p/C_{p_o}) over the conical-flow region. This parameter is obtained from Figure 6.1.6.1-22 for conical-flow regions intersecting the wing-root Mach cone and from Figure 6.1.6.1-34 for conical-flow regions intersecting the wing-tip Mach cone.

C_p is the pressure coefficient $(\Delta p/q)$ for a three-dimensional wing.

C_{p_o} is the two-dimensional pressure coefficient.

$t_{c.p.}$ nondimensional parameter used in calculating the moment-arm parameter $3x\sqrt{1 + \beta^2 a^2}$. $t_{c.p.}$ is obtained from Figure 6.1.6.1-22 for conical-flow regions intersecting the wing-root Mach cone and from Figure 6.1.6.1-34 for conical-flow regions intersecting the wing-tip Mach cone.

x distance of the center of loading of a conical-flow region from the control hinge axis measured normal to the hinge axis (see Sketch (c)). Equations are given in Column (4) of Table 6.1.6.1-C for calculating the moment-arm parameter $3x\sqrt{1+\beta^2 a^2}$ for the appropriate conical-flow region; hence, explicit values of x are not required.



SKETCH (c)

$\tau_{c.p.}$ angle of a ray in the conical-flow field which passes through the center of pressure.

τ angle denoting an arbitrary position of the ray in the conical-flow field.

S_L area of a loaded region. Equations are given in Column (5) of Table 6.1.6.1-C for determining $2S_L$.

M_a area moment of a control surface about its hinge axis.

$$M_a = \frac{\left(c_{f_r}\right)^2 b_f}{6} \cos \Lambda_{HL} \left(\lambda^2{}_f + \lambda_f + 1\right)$$

where λ_f is the control-surface taper ratio.

η angle of sweep of the line intersecting conical-flow regions of the wing at angle of attack. In reading values of P' and $t_{c.p.}$ from Figures 6.1.6.1-22a through 6.1.6.1-22j, and from Figures 6.1.6.1-34a through 6.1.6.1-34d, $\eta = \Lambda_{HL}$ for conical-flow Regions 5 and 6, and

$\eta = \Lambda_{TE}$ for conical-flow Regions 3 and 4.

The sample problem below illustrates use of the method for obtaining $\left(C_{h_\alpha}\right)_{t/c\,=\,0}$

Sample Problem

Given: A wing-control configuration with the following characteristics:

$A = 6.19$ $\lambda = 0.55$ $b/2 = 6.0$ ft $\Lambda_{LE} = 41.9^{o}$

$\Lambda_{TE} = 27.57^{o}$ $\Lambda_{HL} = 30.85^{o}$ $c_t = 2.75$ ft $c_r = 5.0$ ft

$x_t = 2.20$ ft $x_r = 4.0$ ft $c_{f_t} = 0.606$ ft $c_{f_r} = 0.850$ ft

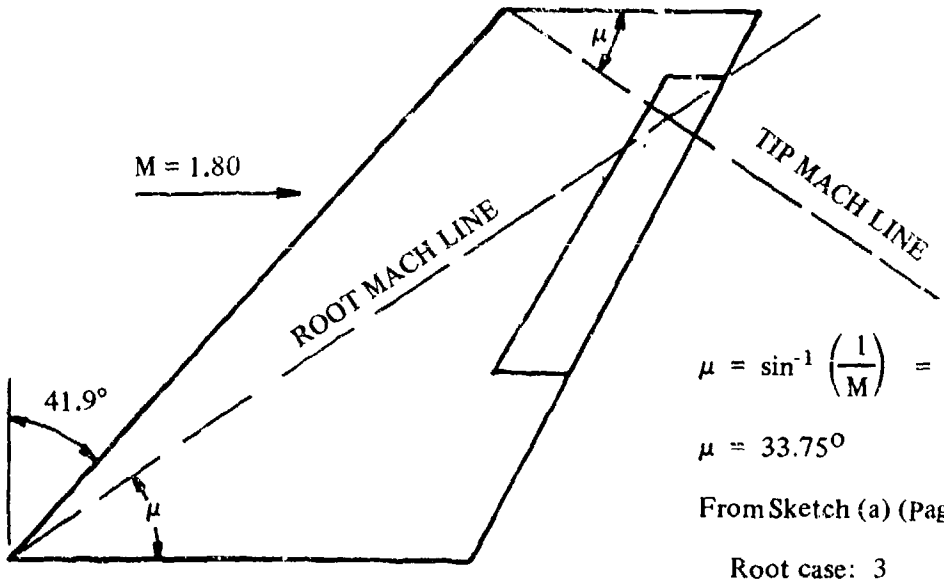
$b_f = 3.25$ ft $y_i = 2.0$ ft $y_o = 5.25$ ft

Additional Characteristics:

$M = 1.80$; $\beta = 1.4967$

Compute:

Step 1. Determine the wing-root and wing-tip conical-flow case.



$$\mu = \sin^{-1}\left(\frac{1}{M}\right) = \sin^{-1}\left(\frac{1}{1.80}\right)$$

$\mu = 33.75^{o}$

From Sketch (a) (Page 6.1.6.1-6):

Root case: 3

Tip case: 3

Step 2. Compute the required geometric and Mach-number parameters.

$$g = \frac{\tan \Lambda_{LE}}{\beta} = \frac{0.8972}{1.4967} = 0.5995$$

$$a = \frac{\tan \Lambda_{HL}}{\beta} = \frac{0.5973}{1.4967} = 0.3991$$

$$d = \frac{\tan \Lambda_{TE}}{\beta} = \frac{0.5221}{1.4967} = 0.3488$$

$$K_1 = \beta y_o = (1.4967)(5.25) = 7.8577 \text{ ft}$$

$$K_2 = \beta y_i = (1.4967)(2.0) = 2.9934 \text{ ft}$$

$$K_3 = \beta\left(\frac{b}{2} - y_i\right) = (1.4967)(6.0 - 2.0) = 5.9868 \text{ ft}$$

$$K_4 = \beta\left(\frac{b}{2} - y_o\right) = (1.4967)(6.0 - 5.25) = 1.1225 \text{ ft}$$

$$K_5 = \beta\left(y_o\right)^2 = (1.4967)(5.25)^2 = 41.2528 \text{ sq ft}$$

$$K_6 = \frac{1}{\beta(1 - d)} = \frac{1}{(1.4967)(1 - 0.3488)} = 1.0260$$

$$K_7 = \frac{1}{\beta(1 - a)} = \frac{1}{(1.4967)(1 - 0.3991)} = 1.1119$$

$$K_8 = \beta\left(y_i\right)^2 = (1.4967)(2.0)^2 = 5.9868 \text{ sq ft}$$

$$K_9 = \beta\left(\frac{b}{2} - y_i\right)^2 = (1.4967)(6.0 - 2.0)^2 = 23.9472 \text{ sq ft}$$

$$K_{10} = \frac{1}{\beta(1 + d)} = \frac{1}{(1.4967)(1 + 0.3488)} = 0.4954$$

$$K_{11} = \frac{1}{\beta(1 + a)} = \frac{1}{(1.4967)(1 + 0.3991)} = 0.4775$$

$$K_{12} = \beta\left(\frac{b}{2} - y_o\right)^2 = (1.4967)(6.0 - 5.25)^2 = 0.8419 \text{ sq ft}$$

Step 3. Determine the wing-root and wing-tip conical-flow regions affected.

From the chart of Step 3 of the Datcom method the affected wing-root and wing-tip conical-flow regions are: 3, 5, 7, and 8.

Step 4. Using the computing form, presented as Table 6.1.6.1-C, calculate the pressure-area-moment parameter representing a loss in loading from the two-dimensional loading value of the affected conical-flow Regions.

6.1.6.2 HINGE-MOMENT DERIVATIVE C_{h_δ} OF HIGH-LIFT AND CONTROL DEVICES

A. SUBSONIC

The hinge-moment derivative due to control deflection can be approximated from the method of Reference 1. The method is based on lifting-line theory, with additional lifting-surface corrections to account for sweep.

The method is based on equations in terms of section parameters; therefore, the accuracy of the method is dependent upon the accuracy with which the section characteristics can be estimated. Test data on the particular airfoil-flap combination under consideration or one closely resembling it should always be preferred to characteristics obtained from generalized methods. Calculated values and test data for several different configurations are presented in Table 6.1.6.2-A to illustrate the accuracy of the method and summarize available test data.

The method is directly applicable to control surfaces having constant chord ratios and constant airfoil contours across the span. For configurations with variable chord ratios or variable airfoil contours across the span, it is suggested that average values of the section characteristics be used. Furthermore, the accuracy of the method in predicting the effects of finite-wing parameters decreases as the wing aspect ratio decreases. Application of the method to wings with aspect ratios of three or less should be avoided.

Experimental data have shown that for sweptback wings the shape of the ends of the control surface can have a critical effect on the hinge-moment parameters. The Datcom method is applicable to controls with the control-surface ends cut parallel to the plane of symmetry. For configurations with wing cutouts, or with control surfaces that do not have ends parallel to the plane of symmetry, it is suggested that empirical procedures be used to estimate C_{h_δ}.

The effect of subcritical Mach-number corrections on hinge moments appears to be small for control surfaces having trailing-edge angles less than approximately 12°. Therefore, the Datcom method, which neglects subcritical Mach-number effects, may be applied over a large portion of the subcritical Mach-number range.

DATCOM METHOD

The hinge-moment derivative due to the deflection of a sealed, plain trailing-edge control at subsonic speeds, based on the product of the control-surface area and the control-surface chord $S_c c_c$ (area and chord aft of the hinge line), is approximated by

$$C_{h_\delta} = \cos\Lambda_{c/4}\,\cos\Lambda_{HL}\left[\left(c_{h_\delta}\right)_{\text{balance}} + \alpha_\delta\left(c_{h_\alpha}\right)_{\text{balance}}\frac{2\cos\Lambda_{c/4}}{A + 2\cos\Lambda_{c/4}}\right] + \Delta C_{h_\delta} \quad 6.1.6.2\text{-a}$$

where

$\left(c_{h_\alpha}\right)_{\text{balance}}$ is the section hinge-moment derivative due to angle of attack. Test data on the particular flapped airfoil are preferred, but the derivative can be approximated by the method of Paragraph A of Section 6.1.3.1. (This term could be c'_{h_α} or c''_{h_α} from Section 6.1.3.1.)

$\left(c_{h_\delta}\right)_{\text{balance}}$ is the section hinge-moment derivative due to control deflection. Test data on the particular flapped airfoil are preferred, but the derivative can be approximated by the method of Paragraph A of Section 6.1.3.2. (This term could be c'_{h_δ} or c''_{h_δ} from Section 6.1.3.2.)

α_δ is the two-dimensional lift-effectiveness parameter expressed as

$$\alpha_\delta = -\frac{\left(c_{\ell_\delta}\right)_\alpha}{\left(c_{\ell_\alpha}\right)_\delta} \qquad \text{(Equation 6.1.1.1-b)}$$

where

c_{ℓ_δ} is the lift effectiveness of the sealed, plain trailing-edge control obtained by using the method of Section 6.1.1.1.

c_{ℓ_α} is the airfoil section lift-curve slope (including the effects of compressibility) from Section 4.1.1.2.

When experimental values of the section lift increment Δc_ℓ are available, the lift effectiveness parameter should be calculated using

$$(\alpha_\delta)_{c_\ell} = -\frac{\left(\Delta c_\ell\right)_{\text{experiment}}}{\left(c_{\ell_\alpha}\right)_\delta \delta}$$

ΔC_{h_δ} is an approximate lifting-surface correction which accounts for induced-camber effects. It is obtained by multiplying the quantity $\dfrac{\Delta C_{h_\delta}}{c_{\ell_\delta} B_2 K_\delta \cos\Lambda_{c/4} \cos\Lambda_{HL}}$, from Figure 6.1.6.2-15a, by its denominator. The primed values of the control-surface and wing chord ratios, used in reading Figure 6.1.6.2-15a, refer to measurements normal to the wing quarter-chord line.

The terms in the denominator are defined below, except for c_{ℓ_δ}, which is defined above.

B_2 accounts for the effect of the control surface and balance chord ratios. This parameter is obtained from Figure 6.1.6.1-19c,where the primed values of the control-surface and balance-chord ratios refer to measurements normal to the quarter-chord line.

K_δ accounts for the effect of control-surface span. This parameter is defined by

$$K_\delta = \frac{(K_\delta)_{\eta_i}(1-\eta_i) - (K_\delta)_{\eta_o}(1-\eta_o)}{\eta_o - \eta_i} \qquad 6.1.6.2\text{-b}$$

where

η_i is the inboard span station of the control,

$$\eta_i = \frac{\text{inboard span ordinate}}{b/2}$$

$(K_\delta)_{\eta_i}$ is obtained from Figure 6.1.6.2-15b as a function of the inboard spanwise location (η_i) of the control panel.

η_o is the outboard span station of the control,

$$\eta_o = \frac{\text{outboard span ordinate}}{b/2}$$

$(K_\delta)_{\eta_o}$ is obtained from Figure 6.1.6.2-15b as a function of the outboard spanwise location (η_o) of the control panel.

Sample Problem

Given: The flapped wing configuration of Reference 8. This is the configuration of the sample problem of Paragraph A, Section 6.1.6.1. The characteristics are repeated.

Wing Characteristics:

$A = 3.43$ $\lambda = 0.44$ $\Lambda_{c/4} = 48.7^o$ NACA 65-012 airfoil (normal to .50c of unswept wing)

$t/c = 0.086$ (streamwise) $\tan\frac{\phi'_{TE}}{2} = 0.0697$ (streamwise)

$$\tan\frac{\phi''_{TE}}{2} = 0.0523 \text{ (streamwise)}$$

Flap Characteristics:

Plain trailing-edge flap Sealed gap $\Lambda_{HL} = 41^{o}$

$c_f/c = 0.167$ (streamwise) $c'_f/c' = 0.20$ (normal to .25c)

$c_b/c_f = 0.090$ (streamwise) $c'_b/c'_f = 0.115$ (normal to .25c)

$t_c/(2c_f) = 0.090$ (streamwise) Round-nosed control

$\eta_i = 0.586$ $\eta_o = 0.99$ $\delta = 0$

Additional Characteristics:

Low speed $R_\ell = 2.2 \times 10^6$

$\left(c_{h_\alpha}\right)_{balance} = -0.00516$ per deg

$c_{\ell_\alpha} = 0.105$ per deg

$\dfrac{c_{\ell_\alpha}}{\left(c_{\ell_\alpha}\right)_{theory}} = 0.855$

} (Sample Problem, Paragraph A, Section 6.1.6.1)

Compute:

Lift effectiveness (Section 6.1.1.1)

$\left(c_{\ell_\delta}\right)_{theory} = 3.29$ per rad (Figure 6.1.1.1-39a)

$\dfrac{c_{\ell_\delta}}{\left(c_{\ell_\delta}\right)_{theory}} = 0.745$ (Figure 6.1.1.1-39b)

$K' = 1.0$ (Figure 6.1.1.1-40)

$$c_{\ell_\delta} = \frac{\Delta c_\ell}{\delta_f} = \left[\frac{c_{\ell_\delta}}{\left(c_{\ell_\delta}\right)_{theory}}\right]\left(c_{\ell_\delta}\right)_{theory} K' \quad \text{(Equation 6.1.1.1-c)}$$

$= (0.745)(3.29)(1.0) = 2.45$ per rad

$$\alpha_\delta = - \frac{\left(c_{\ell_\delta}\right)_\alpha}{\left(c_{\ell_\alpha}\right)_\delta} \qquad \text{(Equation 6.1.1.1-b)}$$

$$= - \frac{2.45}{(0.105)} \frac{1}{57.3} = -0.407$$

Section hinge-moment derivative c_{h_δ} (Section 6.1.3.2)

$$\left(c_{h_\delta}\right)_{\text{theory}} = -0.810 \text{ per rad} \qquad \text{(Figure 6.1.3.2-12b)}$$

$$\frac{c'_{h_\delta}}{\left(c_{h_\delta}\right)_{\text{theory}}} = 0.883 \qquad \text{(Figure 6.1.3.2-12a)}$$

$$c'_{h_\delta} = \left[\frac{c'_{h_\delta}}{\left(c_{h_\delta}\right)_{\text{theory}}} \right] \left(c_{h_\delta}\right)_{\text{theory}} \qquad \text{(Equation 6.1.3.2-a)}$$

$$= (0.883)(-0.810) = -0.715 \text{ per rad}$$

$$\text{Balance ratio} = \sqrt{\left(\frac{c_b}{c_f}\right)^2 - \left(\frac{t_c}{2c_f}\right)^2} = 0 \qquad \text{(Equation 6.1.3.1-d)}$$

$$\frac{\left(c_{h_\delta}\right)_{\text{balance}}}{c''_{h_\delta}} = 1.0 \qquad \text{(Figure 6.1.3.2-13)}$$

$$c''_{h_\delta} = c'_{h_\delta} + 2\left(c_{\ell_\delta}\right)_{\text{theory}} \left[1 - \frac{\left(c_{\ell_\delta}\right)}{\left(c_{\ell_\delta}\right)_{\text{theory}}} \right] \left(\tan \frac{\phi''_{TE}}{2} - \frac{t}{c} \right) \qquad \text{(Equation 6.1.3.2-b)}$$

$$= (-0.715) + 2(3.29)\ [1 - 0.745]\ (0.0523 - 0.086)$$

$$= -0.7715 \text{ per rad} = -0.0135 \text{ per deg}$$

$$\left(c_{h_\delta}\right)_{\text{balance}} = c''_{h_\delta} \left[\frac{\left(c_{h_\delta}\right)_{\text{balance}}}{c''_{h_\delta}} \right] \qquad \text{(Equation 6.1.3.2-c)}$$

$$= -0.0135 \text{ per deg}$$

Induced camber effect ΔC_{h_δ}

$B_2 = 0.885$ (Figure 6.1.6.1-19 c)

$$\left.\begin{aligned}(K_\delta)_{\eta_i} &= 2.0\\ (K_\delta)_{\eta_o} &= 4.25\end{aligned}\right\} \quad \text{Figure 6.1.6.2-15b}$$

$$K_\delta = \frac{(K_\delta)_{\eta_i}(1 - \eta_i) - (K_\delta)_{\eta_o}(1 - \eta_o)}{\eta_o - \eta_i} \qquad \text{(Equation 6.1.6.2-b)}$$

$$= \frac{(2.0)(1 - 0.586) - (4.25)(1 - 0.99)}{0.99 - 0.586}$$

$$= 1.944$$

$$c_{\ell_\delta} B_2 K_\delta \cos \Lambda_{c/4} \cos \Lambda_{HL} = \frac{2.45}{57.3}(0.885)(1.944)(0.660)(0.7547)$$

$$= 0.03665 \text{ per deg}$$

$$\frac{\Delta C_{h_\delta}}{c_{\ell_\delta} B_2 K_\delta \cos \Lambda_{c/4} \cos \Lambda_{HL}} = 0.0218 \qquad \text{(Figure 6.1.6.2-15a)}$$

$$\Delta C_{h_\delta} = (0.0218)(0.03665) = 0.000799 \text{ per deg}$$

Solution:

$$C_{h_\delta} = \cos \Lambda_{c/4} \cos \Lambda_{HL} \left[\left(c_{h_\alpha}\right)_{\text{balance}} + \alpha_\delta \left(c_{h_\alpha}\right)_{\text{balance}} \frac{2 \cos \Lambda_{c/4}}{A + 2 \cos \Lambda_{c/4}} \right] + \Delta C_{h_\delta}$$

(Equation 6.1.6.2-a)

$$= (0.6600)(0.7547)\left[(-0.0135) + (-0.407)(-0.00516) \frac{2(0.6600)}{3.43 + 2(0.6600)} \right] + 0.000799$$

$$= -0.00563 \text{ per deg}$$

The test value from Reference 8 is -0.0031 per degree.

B. TRANSONIC

No method is available for the prediction of the hinge-moment derivative C_{h_δ} at transonic speeds. Because of the mixed-flow conditions and interrelated shock-wave and boundary-layer-separation effects encountered at transonic speeds, the prediction of C_{h_δ} by theoretical means is extremely difficult. Experimental results for C_{h_δ} at transonic speeds are presented in References 2 through 5.

C. SUPERSONIC

The supersonic three-dimensional hinge moment due to control deflection can be computed for trailing-edge surfaces by the method of Reference 6. The method is based on linearized theory and applies to tapered and untapered control surfaces with the following restrictions:

1. Leading and trailing edges of the control surface are swept ahead of the Mach lines from the deflected controls.
2. Control root and tip chords are parallel to the plane of symmetry.
3. Controls are located either at the wing tip or far enough inboard so that the outermost Mach lines from the deflected controls do not cross the wing tip.
4. Innermost Mach lines from the deflected controls do not cross the wing root chord.
5. The wing planform has leading edges swept ahead of the Mach lines and has streamwise tips.
6. Controls are not influenced by the tip conical flow from the opposite wing panel or by the interaction of the wing-root Mach cone with the wing tip.

Calculated values and test data for several different configurations are presented in Table 6.1.6.2-B to illustrate the accuracy of the method and summarize available test data.

For leading-edge control surfaces and for trailing-edge control surfaces with subsonic leading edges, reverse-flow techniques (see Reference 7) can be used.

DATCOM METHOD

The hinge-moment derivative C_{h_δ} at supersonic speeds for a symmetric, straight-sided control, based on the product of the control-surface area and the control-surface chord $S_c c_c$ (area and chord aft of the hinge line), is approximated by

$$C_{h_\delta} = \frac{1}{\beta}\left(1 - \frac{C_2}{C_1}\,\phi_{TE}\right)\beta C'_{h_\delta} \qquad 6.1.6.2\text{-c}$$

where

$\left(1 - \frac{C_2}{C_1}\phi_{TE}\right)$ is a thickness correction factor to the supersonic flat-plate derivative.

$$C_1 = \frac{2}{\sqrt{M^2 - 1}} \text{ per radian}$$

$$C_2 = \frac{(\gamma+1)M^4 - 4(M^2 - 1)}{2(M^2 - 1)^2} \text{ per radian}$$

ϕ_{TE} is the trailing-edge angle in radians, measured normal to the control hinge line.

γ is the ratio of specific heats, $\gamma = 1.4$.

For a symmetrical biconvex airfoil the airfoil thickness correction factor in Equation 6.1.6.2-c is

$$1 - \frac{4}{3}\frac{C_2}{C_1}\left(\frac{t}{c}\right)'\left[1 + 2\left(\frac{x_h}{c}\right)'\right]$$

where

$\left(\frac{t}{c}\right)'$ is the maximum airfoil-thickness ratio, measured in a plane normal to the control hinge axis.

$\left(\frac{x_h}{c}\right)'$ is the chordwise location of the control hinge axis, measured in a plane normal to the control hinge axis.

Thickness correction factors for other airfoil sections can be determined from Reference 6.

$\beta C'_{h_\delta}$ is the supersonic flat-plate hinge-moment parameter obtained from Figure 6.1.6.2-17. For tapered controls this parameter is a function of tan Λ_{HL}/β, tan Λ_{TE}/β, and the control taper ratio λ_f. For untapered controls it is a function of tan Λ_{HL}/β, tan Λ_{TE}/β, and the control aspect-ratio parameter βA_f.

Sample Problem

Given: Wing with a tapered, trailing-edge control.

$\Lambda_{HL} = 31^\circ$ $\Lambda_{TE} = 27.6^\circ$ $\lambda_f = 0.713$ $\phi_{TE} = 3^\circ$

Symmetric, flat-sided section $M = 1.80$; $\beta = 1.50$

Compute:

$$C_1 = \frac{2}{\sqrt{M^2 - 1}} = \frac{2}{1.5} = 1.33 \text{ per rad}$$

$$C_2 = \frac{(\gamma+1) M^4 - 4 (M^2 - 1)}{2(M^2 - 1)^2} = \frac{(2.4) (1.8)^4 - 4(2.24)}{2(2.24)^2} = 1.62 \text{ per rad}$$

$$\left(1 - \frac{C_2}{C_1} \phi_{TE}\right) = \left[1 - \left(\frac{1.62}{1.33}\right)\frac{3.0}{57.3}\right] = 0.936$$

$$\frac{\tan \Lambda_{HL}}{\beta} = \frac{0.6009}{1.5} = 0.401$$

$$\frac{\tan \Lambda_{TE}}{\beta} = \frac{0.5228}{1.5} = 0.349$$

$\beta C'_{h_\delta}$ =−0.0335 per deg (Figure 6.1.6.2-17c)

Solution:

$$C_{h_\delta} = \frac{1}{\beta}\left(1 - \frac{C_2}{C_1} \phi_{TE}\right) \beta C'_{h_\delta} \qquad \text{(Equation 6.1.3.2-c)}$$

$$= \frac{0.936}{1.5} (-0.0335) = -0.0209 \text{ per deg}$$

6.1.7 DRAG OF HIGH-LIFT AND CONTROL DEVICES

There are two types of movable control surfaces. Control surfaces or flaps may exist as movable portions of primary lifting surfaces, such as ailerons on a wing or elevators attached to stabilizers. A control surface may also exist as an independent lifting surface, such as an "all-flying" horizontal tail. The drag due to deflection of the latter type of control is treated simply as the drag of the surface at a different angle of attack. This section of the Datcom is therefore concerned only with the drag due to deflection of flaps or control surfaces that are movable parts of primary lifting surfaces.

The deflection of flaps or control surfaces causes two increments of drag. First, the profile drag of the primary-surface – movable-surface combination is changed. Second, if the two surfaces are producing a force normal to the local flow direction, the deflection of the control surface will produce a different span-loading distribution and may therefore change the induced drag of the surfaces. Both profile-drag and induced-drag effects are considered in the Datcom.

A. SUBSONIC

The changes of both induced drag and profile drag due to control or flap deflection are considered. The change of induced drag is caused by a change in span-loading distribution. The induced drag is calculated first without flap or control surfaces deflected and then with these surfaces deflected. The increment of drag thus obtained is the change of induced drag due to flap or control-surface deflection.

The method of calculating induced drag used in this Section is limited to the flap deflections and angles of attack for which the flow is attached over the control surface. The approximate maximum control deflections for linear control characteristics are given in figure 6.1.3-2. This chart, based on test data for an NACA 0009 airfoil, is intended only to serve as a guide.

DATCOM METHOD

To calculate the induced drag for a spanwise symmetrically loaded wing, the span-loading distribution is determined by the method of Section 6.1.5.1. A finite number m of spanwise stations on the full-span wing is chosen. Each station is indicated by the integers v and n, which are related to span location by the equation

$$\eta = \cos\frac{v\pi}{m+1} = \cos\frac{n\pi}{m+1} \qquad 6.1.7\text{-a}$$

The number of span stations m must be an odd integer. If the span loading is a smooth curve, m may be relatively small, for example, 7, 9, or 11. If the span loading is not smooth, m should be larger, for example, 13, 15, or 17.

For a given flap deflection δ, the span loading is given by

$$G_v = \left(\frac{G}{\delta}\right)_v (\alpha_\delta)\,\delta \qquad 6.1.7\text{-b}$$

where α_δ is obtained from Section 6.1.1.1, δ is the streamwise control deflection, and $(G/\delta)_v$ is determined as outlined in step 1 of Method 2 in paragraph A of Section 6.1.5.1.

The induced drag can be expressed, by the method of reference 1, as

$$C_{D_i} = \frac{\pi A}{m+1}\left[G_k\left\{ b_{kk}\,G_k - \sum_{n=1}^{k}(1-\delta_{kn})\,B_{kn}\,G_n \right\} + 2\sum_{v=1}^{k-1} G_v\left\{ b_{vv}\,G_v - \sum_{n=1}^{k}(1-\delta_{vn})\,B_{vn}\,G_n \right\}\sin\phi_v \right] \qquad 6.1.7\text{-c}$$

where

$$k = \frac{m+1}{2} \qquad 6.1.7\text{-d}$$

$$b_{vv} = \frac{m+1}{4 \sin \phi_v} \quad \text{for } n = v \qquad \text{6.1.7-e}$$

$$= b_{kk} \quad \text{for } v = n = k$$

$$b_{vn} = \frac{\sin \phi_n}{(\cos \phi_n - \cos \phi_v)^2} \left(\frac{1 - (-1)^{n-v}}{2\,(m+1)} \right) \quad \text{for } n \neq v \qquad \text{6.1.7-f}$$

$$\delta_{vn} = 1 \quad \text{for } v = n \qquad \text{6.1.7-g}$$

$$\delta_{vn} = 0 \quad \text{for } v \neq n \qquad \text{6.1.7-h}$$

$$B_{vn} = b_{vn} \quad \text{for } n = \frac{m+1}{2} = k \qquad \text{6.1.7-i}$$

$$B_{vn} = b_{vn} + b_{v,\,m+1-n} \quad \text{for } n \neq \frac{m+1}{2} = k \qquad \text{6.1.7-j}$$

$$\phi = \cos^{-1} \eta \qquad \text{6.1.7-k}$$

$$\phi_v = \frac{v\pi}{m+1} \qquad \text{6.1.7-}\ell$$

$$\phi_n = \frac{n\pi}{m+1} \qquad \text{6.1.7-m}$$

$$G_v = \left(\frac{G}{\delta} \right)_v (\alpha_\delta)\, \delta \quad \text{(equation 6.1.7-b)}$$

$$= G_n \quad \text{for } n = v$$

$$= G_k \quad \text{for } n = k$$

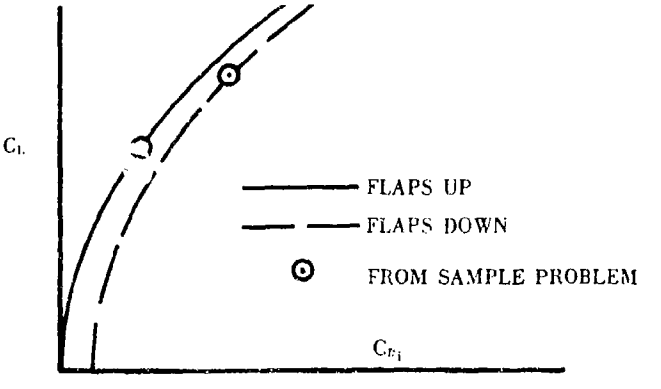
The sample problem at the end of this section demonstrates the use of equation 6.1.7-c. Step 1 of the sample problem is an evaluation of the terms of equation 6.1.7-c that are functions only of m, and hence of n and v. Once calculated for a given number of span locations m, Step 1 need not be repeated. Therefore, when using m = 11 or m = 21, one may utilize the results of Step 1 in the sample problem, and begin the calculations at Step 2.

Equation 6.1.7-c gives the induced drag coefficient at a given angle of attack and a given flap deflection. The corresponding lift coefficient is

$$C_L = \frac{\pi A}{m+1} \left[G_k + 2 \sum_{n=1}^{k-1} G_n \sin \phi_n \right] \qquad \text{6.1.7-n}$$

where the terms of equation 6.1.7-n are defined as in equa' 6.1.7-c.

SKETCH (a)



Equations 6.1.7-c and 6.1.7-n are evaluated at several angles of attack, both with flaps up and with flaps down. The induced drag coefficient C_{D_i} is then plotted versus C_L for flaps up and flaps down, as shown in sketch (a). The increment of C_{D_i} between these curves, at constant C_L, is the induced drag due to flap deflection at a given lift coefficient.

The increment of profile drag due to control or flap deflection can be expressed as a change of the minimum drag coefficient for the polar of the primary surface with undeflected control or flap. The minimum drag coefficient is then

$$(C_D)_{min} = (C_{D_{min}})_{flaps\ up} + \Delta C_{D_{min}} \qquad 6.1.7\text{-o}$$

where

$$\Delta C_{D_{min}} = \Delta c_{d_f} K_b + K' \frac{(\Delta C_{L_f})^2}{\pi A} \qquad 6.1.7\text{-p}$$

Δc_{d_f} is the airfoil section drag coefficient with deflected flap given in figures 6.1.7-22 and 6.1.7-23 as a function of deflection and of $\frac{c_f}{c}$ for plain and for single-slotted flaps.

K_b is given in figure 6.1.4.1-15 as a function of taper ratio and flap span ratio.

K' is the flap span factor given in figures 6.1.7-24(a), (b), and (c), taken from reference 2.

ΔC_{L_f} is determined by the mechanical flap method of Section 6.1.4.1

The shift of the polar without flap or control deflection can now be drawn (figure 6.1.7-27). The increment of induced drag due to flap or control deflection is added to the basic polar. The resulting curve is then translated parallel to the C_D-axis until the minimum C_D agrees with the value given by equation 6.1.7-o.

Sample Problem

Given: The flapped-wing configuration with the following characteristics.

Wing Characteristics:

$A = 6.35 \quad \lambda = 0.50 \quad \Lambda_{c/4} = 40^o \quad S_W = 567$ sq ft

$c_r = 12.6$ ft $\quad \bar{c} = 9.8$ ft $\quad b_W/2 = 30.0$ ft

NACA 63_1012 airfoil (streamwise) $\quad \tan \frac{\phi'_{TE}}{2} = 0.073$

Flap Characteristics:

Plain trailing-edge flap Sealed gap

$\eta_i = 0.195 \quad \eta_o = 0.556 \quad \delta = 11.3^o$ (streamwise)

$c_f/c = 0.20$ (streamwise)

Additional characteristics:

Low speed; $\beta = 1.0$ $\left(C_{D_{min}}\right)_{\delta = 0} = 0.0203$ $\alpha = 10^{o}$

$R_{\ell} = 9.0 \times 10^{6}$

Compute:

Step 1. Parameters that are functions of m are evaluated. These parameters remain constant for any particular value of m. Tables are presented in this section for m = 11 and 21, (tables 6.1.7-A through 6.1.7-F). In case it is desired to use some other value of m, the procedure for calculating these parameters is outlined below. Equations 6.1.7-a through 6.1.7-m are used.

Let $m = 11$

$m + 1 = 12$

$k = \frac{m+1}{2} = 6$

$v = 1$ to k (1 to 6)

$n = 1$ to k (1 to 6)

Step 2. Spanwise loading coefficient G_v.

The following spanwise loading coefficients must be obtained:

1. Basic loading without flaps
2. Incremental loading due to flap deflection
3. Basic loading with flaps

1. Basic loading without flaps:

The variation of G/δ with η_v is determined as outlined in step 1 of Method 2 in paragraph A of Section 6.1.5.1.

$$c_{\ell_\alpha} = 0.116 \text{ per deg} = 6.65 \text{ per rad (table 4.1.1-B)}$$

$$\kappa = \frac{c_{\ell_\alpha}}{2\pi} = \frac{6.65}{2\pi} = 1.06$$

$$\frac{\beta A}{\kappa} = \frac{(1.0)(6.35)}{1.06} = 6.0$$

$$\Lambda_\beta = \tan^{-1}\left(\frac{\tan \Lambda_{c/4}}{\beta}\right) = \tan^{-1}\left(\frac{\tan 40^o}{1.0}\right) = 40^o$$

The variation of G/δ with η_v is then the spanwise loading from figure 6.1.5.1-62c with $\eta_o = 1.0$ (wing treated as a full-span flap). The desired loading coefficient G_v is calculated as follows:

$$G_v = -\left(\frac{G}{\delta}\right)\alpha_\delta \ \delta \quad \text{(equation 6.1.7-b)}$$

$\alpha_\delta = -1.0$ (wing treated as a full wing-chord flap)

$\delta = \sigma$ (radians) = 0.175 rad

Then

$$G_v = \left(\frac{G}{\delta}\right)_v \alpha$$

The calculation is shown below.

η	$\left(\frac{G}{\delta}\right)_v$ per rad	α rad	G_v
0	.32	.175	.0560
.1	.33	.175	.0578
.2	.34	.175	.0595
.3	.34	.175	.0595
.4	.34	.175	.0595
.5	.33	.175	.0578
.6	.32	.175	.0560
.7	.30	.175	.0525
.8	.26	.175	.0455
.9	.21	.175	.0368
1.0	0	.175	0

2. Incremental loading due to flap deflection:

The variation of G/δ with η_v may be read directly from figure 6.1.5.1-62c at $\eta_i = 0.195$ and $\eta_o = 0.556$. Then, the difference in the spanwise loading of those tabluations at each span station is the spanwise loading of the actual full-chord flap. (See sketch (b), Section 6.1.5.1.)

Flap effectiveness α_δ

$$\frac{c_{\ell_\alpha}}{\left(c_{\ell_\alpha}\right)_{theory}} = 0.899 \quad \text{(figure 4.1.1.2-8a)}$$

$$\frac{c_{\ell_\delta}}{\left(c_{\ell_\delta}\right)_{theory}} = 0.836 \quad \text{(figure 6.1.1.1-39b)}$$

$$\left(c_{\ell_\delta}\right)_{theory} = 3.68 \text{ per rad} \quad \text{(figure 6.1.1.1-39a)}$$

$K' = 0.999$ (figure 6.1.1.1-40)

$$\Delta c_\ell = \delta \left[\frac{c_{\ell_\delta}}{\left(c_{\ell_\delta}\right)_{theory}}\right] \left(c_{\ell_\delta}\right)_{theory} K' \quad \text{(equation 6.1.1.1-c)}$$

$$= \frac{11.3}{57.3} (0.836)(3.68)(0.999) = 0.606$$

$$\alpha_\delta = -\frac{\Delta c_\ell}{\left(c_{\ell_\alpha}\right)_\delta \delta} \quad \text{(equation 6.1.1.1-b)}$$

$$= -\frac{0.606}{(0.116)(11.3)} = -0462$$

$$G_v = -\left(\frac{G}{\delta}\right)_v \alpha_\delta \delta \quad \text{(equation 6.1.7-b)}$$

$$= -\left(\frac{G}{\delta}\right)_v (-0.462)(11.3/57.3) = 0.0911 \left(\frac{G}{\delta}\right)_v$$

η	$\left(\frac{G}{\delta}\right)_{\eta_o} = 0.556$ (fig. 6.1.5.1-62c)	$\left(\frac{G}{\delta}\right)_{\eta_i} = 0.195$ (fig. 6.1.5.1-62c)	$\left(\frac{G}{\delta}\right)_v$ $(\ )_{\eta_o} - (\ )_{\eta_i}$	G_v

3. Basic loading with flaps:

The incremental loading due to flap deflection is added to the basic loading without flaps to obtain the basic loading with flaps.

η	G_v basic loading without flaps	G_v incremental loading due to flaps	G_v basic loading with flaps
0	0.0560	0.0073	0.0633
.1	0.0578	0.0091	0.0669
.2	0.0595	0.0155	0.0750

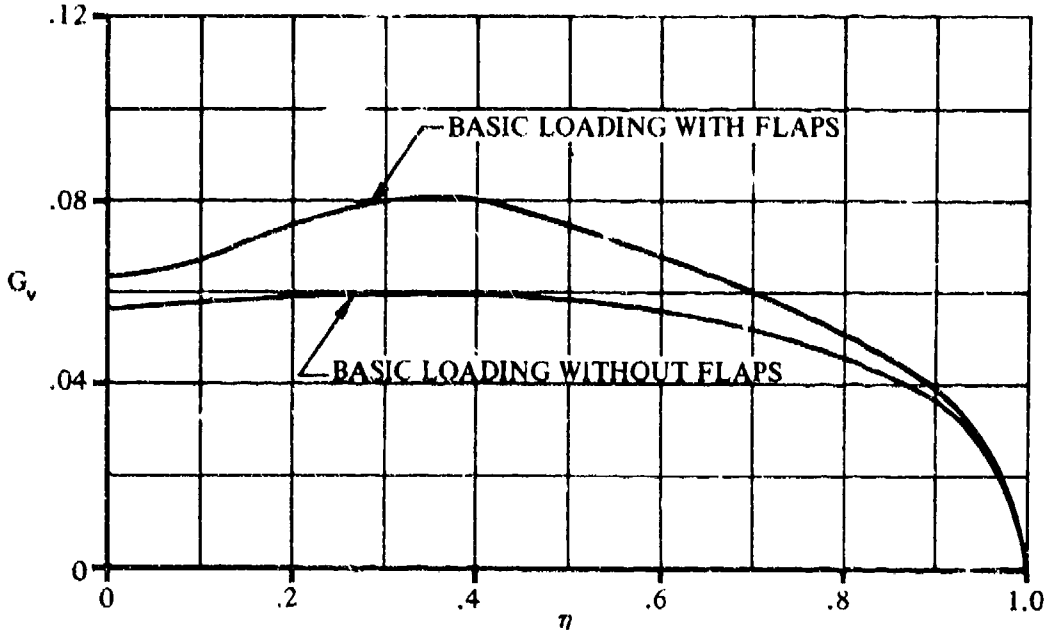
.4	0.0595	0.0210	0.0805
.5	0.0578	0.0164	0.0742
.6	0.0560	0.0118	0.0678
.7	0.0525	0.0073	0.0598
.8	0.0455	0.0046	0.0501
.9	0.0368	0.0027	0.0395
1.0	0	0	0

The above loadings are plotted in sketch (b), in order that values of G_v may be read for any desired η_v.



SKETCH (b)

Step 3 C_{D_i} due to flaps

Let $C_{D_i} = \frac{\pi A}{m+1} \{N_1 + N_2\}$ (equation 6.1.7-c)

where

$$N_1 = G_k \left\{ b_{kk} G_k - \sum_{n=1}^{k} \left[\left(1 - \delta_{vn}\right) B_{kn} G_n \right] \right\}$$

$$N_2 = 2 \sum_{v=1}^{k-1} \left(G_v \left\{ b_{vv} G_v - \sum_{n=1}^{k} \left[\left(1 - \delta_{vn}\right) B_{vn} G_n \right] \right\} \sin \phi_v \right)$$

$m + 1 = 12 \qquad k = 6 \qquad \frac{\pi A}{m+1} = \frac{\pi (6.35)}{12} = 1.662$

C_{D_i} must be calculated for the following loadings:

Case 1. Basic loading without flaps

Case 2. Basic loading with flaps

Case 1. (Calculations for basic loading without flaps)

Tabulate G_v for v = 1 to k

v	η (table 6.1.7-A)	G_v [from sketch (b)]
1	.9659	.0205
2	.8660	.0400
3	.7071	.0520
4	.5000	.0578
5	.2588	.0595
6	0	.0560

Calculate N_1

for v = k = 6, n = k = 6

①	②	③
G_k	b_{kk} table 6.1.7-B	$b_{kk} G_k$ = ① ②
.0560	3.000	.1680

for v = k = 6

①	②	③	④
n	$(1 - \delta_{vn}) B_{kn}$ table 6.1.7-C	G_n	② ③
1	.04622	.0205	.0009
2	0	.0400	0

5	.9659	3.106	.0784	.2435	.1873	.0562	.002456

$$N_2 = 2\sum_{v=1}^{k=1} ⑧ = 0.02127$$

$$C_{D_i} = \frac{\pi A}{m+1}\left[N_1 + N_2\right] = 1.662\ [-0.000819 + 0.02127]$$

$$= 0.0340 \text{ (basic loading with flaps deflected } 11.3^{o} \text{ at } \alpha = 10^{o})$$

Step 4. Determine the lift coefficient C_L for Cases 1 and 2.

Case 1. (Basic Loading without flaps)

Case 2. (Basic Loading with flaps)

$G_k = 0.0635$ for $v = k = 6$

①	②	③	④
n	G_n	$\sin \phi_n$ table 6.1.7-A	$G_n \sin \phi_n$ ② ③
1	.0220	.2588	.00569
2	.0432	.5000	.02160
3	.0590	.7071	.04172
4	.0747	.8660	.06469
5	.0784	.9659	.07573

$$2 \sum_{n=1}^{k-1} \text{④} = 0.4189$$

$$C_L = \frac{\pi A}{m+1} \left[G_k + 2 \sum_{n=1}^{k-1} G_n \sin \phi_n \right] \quad \text{(equation 6.1.7-n)}$$

$= 1.662\,[0.0635 + 0.4189]$

$= 0.8017$ (basic loading with flaps deflected 11.3° at $\alpha = 10^\circ$)

Step 5. Determine the profile drag increment due to flaps $\Delta C_{D_{min}}$

$\Delta c_{d_f} = 0.0050$ (figure 6.1.7-22)

$$\left.\begin{aligned} K_{b_{(\eta_o = 0.556)}} &= 0.688 \\ K_{b_{(\eta_i = 0.195)}} &= 0.265 \end{aligned}\right\} \quad \text{(figure 6.1.4.1-15)}$$

$K_b = K_{b_{(\eta_o)}} - K_{b_{(\eta_i)}} = 0.424$

$K' \doteq 1.01$ (figures 6.1.7-24a through -24c, interpolated)

ΔC_{L_f} (Section 6.1.4.1)

$$\left.\begin{aligned} \Delta c_{\ell} &= 0.606 \\ \alpha_{\delta} &= -0.462 \\ c_{\ell_{\alpha}} &= 6.65 \text{ per rad} \end{aligned}\right\} \quad \text{(Step 2, above)}$$

$$\frac{(\alpha_{\delta})_{C_L}}{(\alpha_{\delta})_{c_{\ell}}} = 1.056 \text{ (figure 6.1.4.1-14) (at } (\alpha_{\delta})_{c_{\ell}} = 0.55 \text{ from inset of figure 6.1.4.1-14)}$$

$$\frac{A}{\kappa}\left[\beta^2 + \tan^2 \Lambda_{c/2}\right]^{1/2} = \frac{6.35}{1.06}\left[1 + (0.7866)^2\right]^{1/2} = 7.62$$

$$C_{L_{\alpha}}/A = 0.640 \text{ per rad (figure 4.1.3.2-49)}$$

$$C_{L_{\alpha}} = (0.640)(6.35) = 4.06 \text{ per rad}$$

$$\Delta C_{L_f} = \Delta c_{\ell}\left(\frac{C_{L_{\alpha}}}{c_{\ell_{\alpha}}}\right)\left[\frac{(\alpha_{\delta})_{C_L}}{(\alpha_{\delta})_{c_{\ell}}}\right] K_b \text{ (equation 6.1.4.1-a)}$$

$$= (0.606)\left(\frac{4.06}{6.65}\right)[1.056]\ (0.424)$$

$$= 0.166$$

$$\Delta C_{D_{min}} = \Delta c_{d_f} K_b + K'\frac{\left(\Delta C_{L_f}\right)^2}{\pi A} \text{ (equation 6.1.7-p)}$$

$$= (0.0050)(0.424) + (1.31)\frac{(0.166)^2}{\pi(6.35)}$$

$$= 0.00212 + 0.00181$$

$$= 0.00393$$

Step 6. Determine the minimum drag coefficient with flaps deflected

$$C_{D_{min}} = \left(C_{D_{min}}\right)_{\delta=0} + \Delta C_{D_{min}} \text{ (equation 6.1.7-o)}$$

$$= 0.0203 + 0.0039$$

$$= 0.0242$$

At this point, the lift coefficients and induced-drag coefficients are known at $\alpha = 10^{o}$ for flaps deflected 11.3^{o}. The minimum drag coefficient with flaps deflected is also known. Steps 2 through 4 must now be repeated at several angles of attack to determine the variation of C_{D_f} with C_L, as shown in sketch (a)

on page 6.1.7-2 for flaps undeflected and flaps deflected 11.3°. These values are plotted in the form of figure 6.1.7-27 to give a flap-deflected drag polar.

B. TRANSONIC

At transonic Mach numbers, the drag increment due to control deflection is extremely difficult to estimate. The transonic flow about an airfoil, which has locally subsonic and supersonic regions, is very sensitive to changes in airfoil section. The supersonic flow regions frequently terminate with a nearly normal shock wave, causing an abrupt increase in pressure at that point. The location of this shock wave can be greatly influenced by control deflection, which results in changes to the pressure distribution, and hence causes an unpredictable drag increment. The complexity of the mixed flows prevents the use of either simple theory or empirical analysis for general treatment of the problem.

DATCOM METHOD

Because of the extreme sensitivity of the mixed flows at transonic Mach numbers, no Datcom Method is given to estimate the drag increment due to control deflection.

C. SUPERSONIC

At supersonic speeds, the drag due to control-surface deflection can be considered in two parts – a change of wave or pressure drag, and a change of skin-friction drag.

DATCOM METHOD

The increment of wave drag of the primary surface with control surface deflected is

$$\Delta(C_{D_{wave}}) = \left[\frac{(C_{D_{wave}})}{(C_{D_{wave}})_{\delta=0}} - 1\right](C_{D_{wave}})_{\delta=0} \qquad 6.1.7\text{-q}$$

where $(C_{D_{wave}})_{\delta=0}$ is determined by the method of Section 4.1.5.1.

The ratio $\dfrac{(C_{D_{wave}})}{(C_{D_{wave}})_{\delta=0}}$ can be estimated by linear theory and is approximated by

$$\frac{(C_{D_{wave}})}{(C_{D_{wave}})_{\delta=0}} = \left[1 - \frac{\bar{c}_f}{c}\right] + \left[\frac{\bar{c}_f}{c}\right]\left[\frac{\alpha+\delta}{\alpha}\right]^2\left[\frac{S_{n1} + \frac{1}{2}S_1}{S} + 1 - \frac{S_{n1} + S_1}{S}\right] \qquad 6.1.7\text{-r}$$

where

$\dfrac{\bar{c}_f}{c}$ is the ratio of mean flap chord to primary-surface chord

α is the angle of attack of the primary surface with $\delta=0$

δ is the deflection of the control surface relative to the primary surface, positive for trailing edge down

S_{n1} is the part of the primary-surface planform area forward of and including the flap area that is not influenced by the primary-surface tip [see figure 6.1.7-28 (b)]

S_1 is the part of the primary-surface planform area forward of and including the flap area that is influenced by the primary-surface tip [see figure 6.1.7-28 (b)]

The effect of control surface or flap deflection on drag is

$$(C_D)_\delta = (C_D)_{\delta=0} + \Delta(C_{D_{wave}}) + \Delta(C_{D_f}) \qquad 6.1.7\text{-s}$$

Although procedures can be devised for estimating the change of skin-friction drag due to control surface or flap deflection, the estimated changes are so small as to be of the order of the reading accuracy of the charts of reference 3 that are used in the calculations. Therefore the change of skin-friction drag due to control deflection will be assumed to be zero.

Sample Problem

Given:

Configuration of sample problem 1, Method 1, paragraph C, Section 4.1.5.1.

$\Lambda_{c/4} = 35°$ $A = 4.0$ $t/c = 0.06$

Smooth surface Stabilized flight

$R_\ell = 10^7$ Round-nose airfoil

$M = 2.0$ $(C_{D_f})_{\delta=0} = 0.00521$ $(C_{D_{wave}})_{\delta=0} = (\Delta C_{D_o})_{\delta=0} = 0.0171$

Additional characteristics:

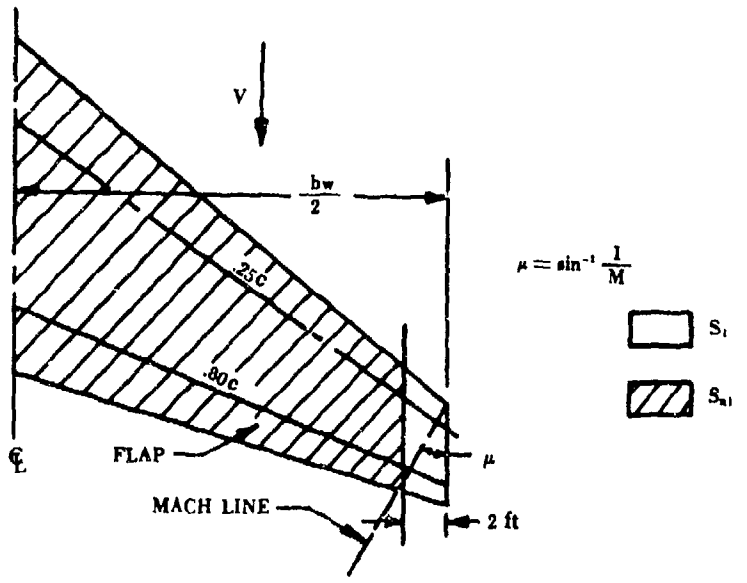
$\frac{S_w}{2} = 200$ sq ft $\frac{b_w}{2} = 20$ ft

$\lambda = 0.3$ $c_r = 15.40$ ft

full-span flap $\frac{\delta_f}{c} = 0.20$

$\alpha = 5°$ $\delta = -8°$ $(C_D)_{\delta=0} = 0.0395$ (at $\alpha = 5°$)

The pertinent Mach line is shown below.



$S_l = 10$ sq ft

$S_{al} = 190$ sq ft

Compute:

$\Delta C_{D_{wave}}$ calculation:

$$\left[1 - \frac{\delta_f}{c}\right] = 0.8$$

$$\left[\frac{\alpha+\delta}{\alpha}\right]^2 = 0.36$$

$$\left[\frac{S_{n1}+\frac{1}{2}S_l}{S}\right] = \frac{195}{200} = 0.975$$

$$\left[\frac{S_{n1}+S_l}{S}\right] = 1.0$$

$$\frac{C_{D_{wave}}}{(C_{D_{wave}})_{\delta=0}} = \left[1-\frac{\bar{c}_f}{c}\right]+\left[\frac{\bar{c}_f}{c}\right]\left[\frac{\alpha+\delta}{\alpha}\right]^2\left[\frac{S_{n1}+\frac{1}{2}S_l}{S}+1-\frac{S_{n1}+S_l}{S}\right] \quad \text{(equation 6.1.7-r)}$$

$$= 0.8 + 0.2\,(0.36)\,(0.975)$$

$$= 0.8702$$

$$\Delta C_{D_{wave}} = \left[\frac{C_{D_{wave}}}{(C_{D_{wave}})_{\delta=0}} - 1\right](C_{D_{wave}})_{\delta=0} \quad \text{(equation 6.1.7-q)}$$

$$= [0.8702 - 1]\,(0.0171)$$

$$= -0.00222$$

Solution for drag with flap deflection:

For $\alpha = 5°$

$$(C_D)_{\delta=-8°} = (C_D)_{\delta=0} + \Delta C_{D_{wave}} + \Delta C_{D_f} \quad \text{(equation 6.1.7-s)}$$

$$= 0.0395 + (-0.00222) + 0$$

$$= 0.03728$$

6.2 ASYMMETRICALLY DEFLECTED CONTROLS ON WING-BODY AND TAIL-BODY CONTROL COMBINATIONS

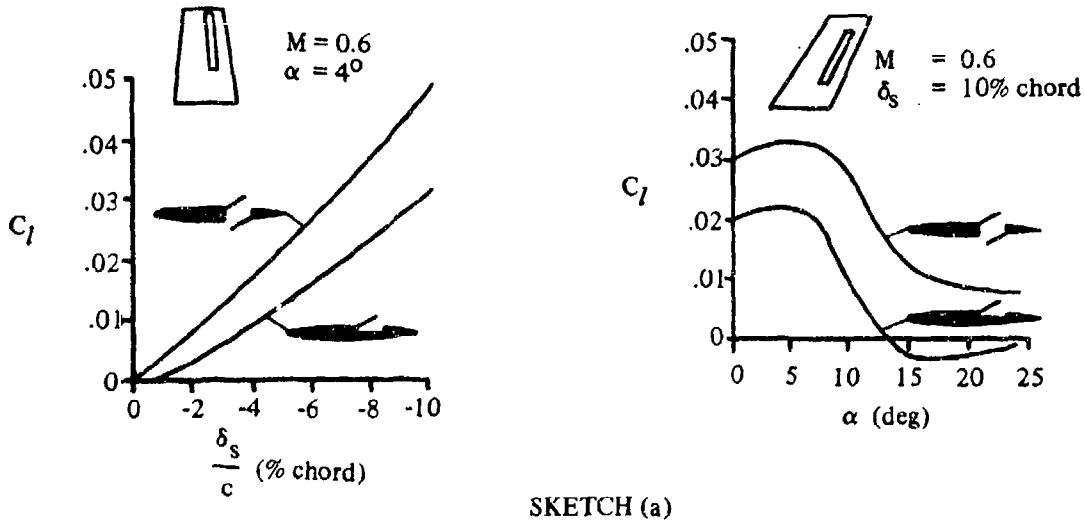
6.2.1 ROLLING MOMENT DUE TO ASYMMETRIC DEFLECTION OF CONTROL DEVICES

6.2.1.1 ROLLING MOMENT DUE TO CONTROL DEFLECTION

Methods are presented in this section for estimating the rolling moment due to control deflection at subsonic, transonic, and supersonic speeds. Plain trailing-edge flap-type controls and spoilers are included. The fundamental means by which each of these devices changes the lift of a wing, and hence the rolling moment, is discussed in Section 6.1.1.1.

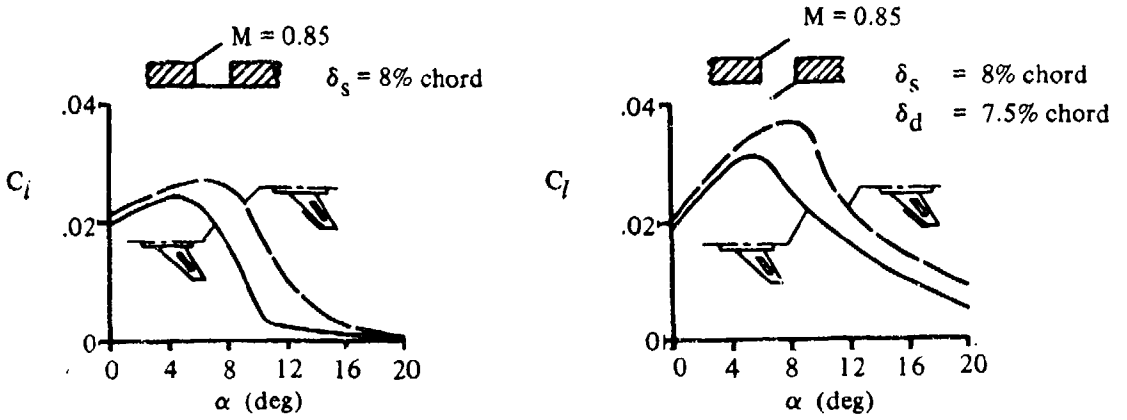
A discussion of the aerodynamic aspects of spoilers on three-dimensional wings is given in reference 1. This reference also contains an extensive bibliography of spoiler tests. The following discussion summarizes the conclusions of this reference.

At subsonic and transonic speeds, spoilers do not, in general, provide linear variation of effectiveness with spoiler projection, particularly at small deflections (see sketch (a)). This deficiency can be corrected by the use of a slot or slot-deflector behind the spoiler.



SKETCH (a)

For thin wings at high angles of attack plain spoilers are ineffective. This ineffectiveness can be partially overcome by the use of a slot behind the spoiler and by the use of leading-edge devices. Sketch (b) shows the effect of a drooped leading-edge extension on the rolling effectiveness of a plain and of a slotted spoiler.



EFFECT OF DROOPED WING LEADING-EDGE EXTENSION ON SPOILER EFFECTIVENESS

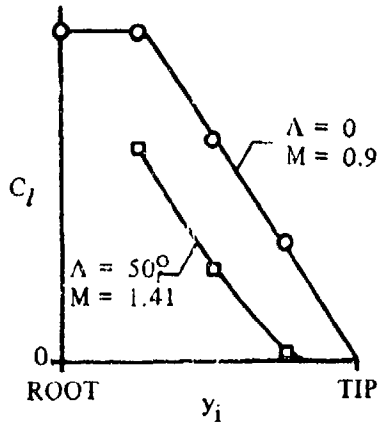
SKETCH (b)

In order to achieve maximum effectiveness, spoilers should be located toward the rear portion of the wing for the following reasons:

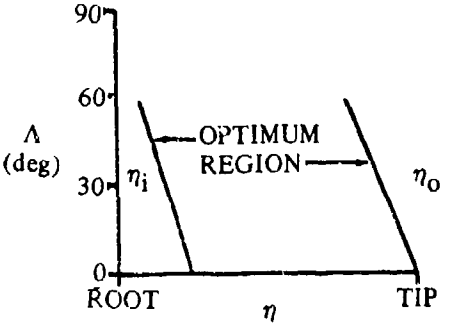
1. The ineffectiveness of spoilers at small deflections increases with distance from the trailing edge.

2. The lag time at low speeds becomes excessively long for forward-mounted spoilers.

The optimum spanwise extent and position of spoilers are determined primarily by wing sweep. The higher the sweep angle, the farther inboard the spoilers should be placed. Sketch (c) shows the spoiler rolling moment for a spoiler extending from the wing tip to any inboard station y_i. The ineffectiveness of tip-located spoilers on swept wings is apparent.



SKETCH (c)



SKETCH (d)

The optimum spanwise location of spoilers as a function of wing sweep is shown in sketch (d).

A. SUBSONIC

Plain Trailing-Edge Flaps

A simplified lifting-surface theory is used in reference 2 to obtain the rolling-moment effectiveness C_{l_δ} for plain trailing-edge controls at subcritical Mach numbers. The theory is applicable to wings for which $\beta A \geq 2$ and $\Lambda_\beta < 60^o$, where $\Lambda_\beta = \tan^{-1}(\tan \Lambda_{c/4}/\beta)$. The Prandtl-Glauert compressibility correction is used to account for subcritical compressibility effects. In this section the theory of reference 2 is used up to M = 0.6. Since the theory is based on potential flow, the results are valid for attached-flow conditions only, i.e., wing angle of attack and surface deflection where no flow separation exists.

Two-dimensional lift-curve slopes for specific wing sections are used to adjust the wing lift distribution. It should be noted that the design charts from reference 2 give results for two full-chord controls antisymmetrically deflected. Then, absolute values of the section-lift effectiveness $|\alpha_\delta|$ for a specific configuration are used to adjust the theory to realistic values. This results in positive values of C_{l_δ} for antisymmetric control deflections. The proper sign of the rolling-moment coefficient will result from the expression $C_l = C_{l_\delta} \dfrac{(\delta_L - \delta_R)}{2}$ *

Spoilers

The method for predicting the effectiveness of plug and flap type spoilers is taken from reference 3. The method is based on the simplified lifting-surface theory developed for flap-type controls in reference 2, used with section spoiler data and an empirical correction for the effective spanwise location on swept wings. The results are valid for attached flow conditions only.

A design chart based on the empirical results of reference 4 is presented for the prediction of the subsonic rolling effectiveness of spoiler-slot-deflector controls.

DATCOM METHODS

Plain Trailing-Edge Flaps

The wing trailing-edge control derivative C_{l_δ} at subcritical Mach numbers, based on the total wing area and wing span, is obtained from the procedure outlined in the following steps:

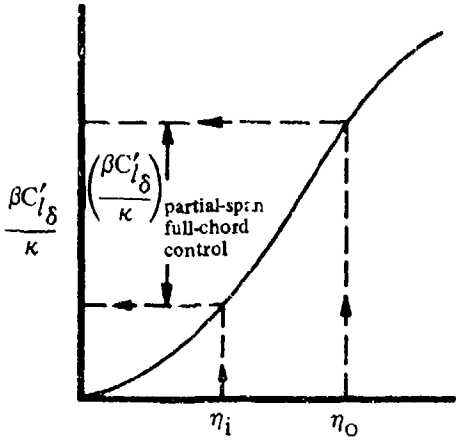
Step 1. Obtain the rolling-moment effectiveness parameter $\beta C'_{l_\delta}/\kappa$ of two full-chord controls ($c_f/c = 1.0$) antisymmetrically deflected, as a function of $\beta A/\kappa$ and Λ_β, from figure 6.2.1.1-23.

The parameter κ is the ratio of the two-dimensional lift-curve slope at the appropriate Mach number to $2\pi/\beta$, i.e., $(c_{\ell_\alpha})_M / 2\pi/\beta$. The two-dimensional lift-curve slope is obtained from Section 4.1.1.2. For wings with airfoil sections varying in a reasonably linear manner with span, the lift-curve slope of the section at the MAC of the flapped portion of the wing is adequate.

The parameter Λ_β is the compressible sweep parameter, given as $\Lambda_\beta = \tan^{-1}(\tan \Lambda_{c/4}/\beta)$.

*The usual convention is implied. Positive rolling moment is right wing down. Positive control deflection is trailing edge down.

Figure 6.2.1.1-23 gives directly the effectiveness parameter for control spans measured from the plane of symmetry outboard. For partial-span controls having the inboard edge of the control at spanwise station η_i and the outboard edge at η_o, the effectiveness parameter is obtained as illustrated in sketch (e).



SKETCH (e)

Step 2. Determine the rolling effectiveness of two full-chord controls antisymmetrically deflected by

$$C'_{l_\delta} = \frac{\kappa}{\beta}\left(\frac{\beta C'_{l_\delta}}{\kappa}\right) \qquad 6.2.1.1\text{-a}$$

Step 3. Determine the rolling effectiveness of the partial-chord controls (c_f/c < 1.0) of constant-percent-chord (c_f/c = constant) antisymmetrically deflected by

$$C_{l_\delta} = |\alpha_\delta| C'_{l_\delta} \qquad 6.2.1.1\text{-b}$$

where C'_{l_δ} is obtained from equation 6.2.1.1-a and $|\alpha_\delta|$ is the absolute value of the section lift effectiveness. α_δ is obtained from Section 6.1.1.1 for the particular control under consideration. For antisymmetric control deflections the value of α_δ is based on the deflection of one surface.

The effect of a differential control deflection is taken into account by considering C_{l_δ} of each control as one-half the antisymmetric value (equation 6.2.1.1-b) where $|\alpha_\delta|$ is considered separately for each control and based on its respective deflection. Then, the total rolling-moment coefficient for differential-control deflection is obtained by

$$C_l = \left(\frac{C_{l_\delta}}{2}\right)_L \delta_L - \left(\frac{C_{l_\delta}}{2}\right)_R \delta_R$$

For arbitrary spanwise distribution of control chord (constant-chord controls on tapered wings or tapered controls on untapered wings), the control is divided into spanwise steps, and the total C_{l_δ} value is found by summing the C_{l_δ} values due to each spanwise step, based on the average $|\alpha_\delta|$ values over that spanwise step.

It should be noted that in applying this method the control deflection angles and all dimensions are measured in planes parallel and perpendicular to the plane of symmetry.

The relationship between streamwise control deflection δ, control deflection measured normal to the control hinge line $\delta_{\perp_{HL}}$, and sweep of the flap hinge line Λ_{HL} is

$$\tan \delta = \cos \Lambda_{HL} \tan \delta_{\perp_{HL}}$$

The relationship between a C_{l_δ} value defined for a streamwise deflection and the corresponding value defined normal to the hinge line is

$$C_{l_\delta} = C_{l_{\delta_{\perp_{HL}}}} \cos \Lambda_{HL}$$

Sample problem 1 on page 6.2.1.1-7 illustrates the use of this method.

There are not enough experimental data available to substantiate this method. However, for configurations within the limitations of the method it is expected that the accuracy of the calculated results will be within ±10 percent.

Spoilers

Plug or Flap-Type Spoilers

The rolling-moment coefficient of a plug or a flap-type spoiler deflected on one wing panel only, based on the total wing area and wing span, is given by

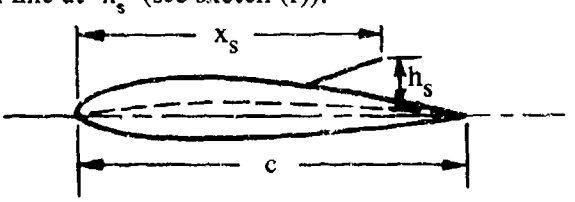
$$C_l = \frac{C'_{l_\delta}}{2} \Delta\alpha'_s \qquad \text{6.2.1.1-c}$$

where

C'_{l_δ} is the rolling-moment effectiveness of two full-chord controls antisymmetrically deflected, obtained as outlined in the above method for plain-trailing-edge controls, but with effective locations of the inboard and outboard ends of the control used in place of their geometric locations in reading figure 6.2.1.1-23.

$\Delta\alpha'_s$ is the spoiler lift effectiveness expressed in terms of the change in zero-lift angle of attack. This parameter is presented as a function of effective spoiler height for four spoiler chordwise locations in figure 6.1.1.1-52. In using this figure, x_s is the distance from the nose of the airfoil to the spoiler lip, and h_s is the height of the spoiler measured from and normal to the airfoil mean line at x_s (see sketch (f)).

SKETCH (f)



The effective locations of the inboard and outboard ends of the spoiler, used in reading figure 6.2.1.1-23, are given by

$$\left.\begin{aligned} \eta_{i_{eff}} &= \eta_i + \Delta\eta_i \\ \eta_{o_{eff}} &= \eta_o + \Delta\eta_o \end{aligned}\right\} \qquad 6.2.1.1.\text{-d}$$

where η_i and η_o are the spanwise locations of the inboard and outboard ends of the spoiler, respectively, and $\Delta\eta_i$ and $\Delta\eta_o$ are effective increments in the spoiler spanwise locations due to the spanwise flow of the spoiler wake for partial-span spoilers. These increments in spoiler spanwise locations are given by

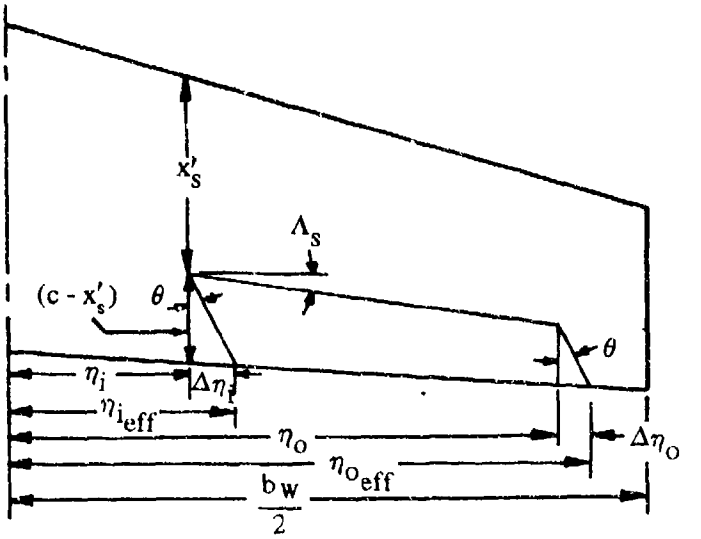
$$\left.\begin{aligned} \Delta\eta_i &= \frac{4\left(1 - \frac{x'_s}{c}\right)}{A(1+\lambda)}\left[1 - (1-\lambda)\,\eta_i\right]\frac{\cos\Lambda_{TE}\,\sin\theta}{\cos(\Lambda_{TE}+\theta)} \\ \Delta\eta_o &= \frac{4\left(1 - \frac{x'_s}{c}\right)}{A(1+\lambda)}\left[1 - (1-\lambda)\,\eta_o\right]\frac{\cos\Lambda_{TE}\,\sin\theta}{\cos(\Lambda_{TE}+\theta)} \end{aligned}\right\} \qquad 6.2.1.1.\text{-e}$$

where θ is an empirically determined angle obtained from figure 6.2.1.1-26a as a function of the spoiler sweepback. The spoiler sweepback is determined from the expression

$$\tan\Lambda_s = \tan\Lambda_{c/4} - \frac{4\left[0.75 - \left(1 - \frac{x'_s}{c}\right)\right]}{A}\left(\frac{1-\lambda}{1+\lambda}\right)$$

In using this method, if $\eta_{o_{eff}}$ exceeds 1.0, which would be the case for the spoiler extending almost to the wing tip on a highly swept wing, the value of C'_{l_δ} at $\eta_o = 1.0$ is used.

The effective spanwise extent of an arbitrarily located spoiler as used in this method is illustrated in sketch (g).



SKETCH (g)

Sample problem 2 on page 6.2.1.1-9 illustrates the use of this method.

Comparisons of test data with results calculated by using this method are presented as table 6.2.1.1-A. Additional comparisons between test and calculated values are given in reference 3.

Only spoilers of constant-percent-chord height (h_s/c = constant) were included in the analysis of reference 3; however, it is implied therein that the method should give acceptable results for arbitrary spanwise distribution of spoiler control chord.

Spoiler-Slot-Deflector

The rolling-moment coefficient of a spoiler-slot-deflector on one wing panel, based on the total wing area and wing span, is given by

$$(C_l)_{\text{spoiler-slot-deflector}} = K(C_l)_{\text{plain spoiler}} \qquad 6.2.1.1\text{-f}$$

where

$(C_l)_{\text{plain spoiler}}$ is the rolling-moment coefficient of a plain flap-type spoiler deflected on one wing panel, based on the total wing area and wing span, determined by using equation 6.2.1.1-c.

K is the ratio of the rolling-moment coefficient of a spoiler-slot-deflector to that of a plain spoiler, obtained from figure 6.2.1.1-26b, as a function of the ratio of spoiler deflection to deflector deflection δ_s/δ_d. The spoiler and deflector deflections are illustrated in figure 6.2.1.1-26b. Note the difference between the spoiler-height measurement h_s used in determining C_l of the plain spoiler and the δ_s and δ_d measurements for the spoiler-slot-deflector control.

Figure 6.2.1.1-26b is based on the empirical results of reference 4. The wing planform of the test configuration is a straight-tapered wing with $A = 4.0$, $\lambda = 0.6$, $\Lambda_{c/4} = 32.6^\circ$, and with an NACA 65006 airfoil section in the streamwise direction. The method has not been verified by comparison with other test results. Nevertheless, the method is expected to give acceptable results over the linear-lift range for configurations with $\beta A \geq 2$ and $\Lambda_\beta < 60^\circ$, and at Mach numbers up to 0.6.

The use of this method is illustrated in sample problem 3 on page 6.2.1.1-12.

Sample Problems

1. Plain Trailing-Edge-Flap Ailerons

Given: The following wing-aileron configuration:

Wing Characteristics:

$A_W = 3.78$ $\lambda_W = 0.586$ $\Lambda_{c/4} = 47.35^\circ$

NACA 65009 airfoil (streamwise) $\tan \phi'_{TE}/2 = 0.0776$ (streamwise airfoil section geometry)

Aileron Characteristics:

Plain trailing-edge flap $c_f/c = 0.30$ $\eta_i = 0.75$ $\eta_o = 0.95$

$\delta_L = 15^o$ $\delta_R = -15^o$

Additional Characteristics:

$M = 0.40$; $\beta = 0.917$ $R_\ell = 9 \times 10^6$

Compute:

C'_{l_δ}

$$\frac{c_{\ell_\alpha}}{\left(c_{\ell_\alpha}\right)_{theory}} = 0.893 \quad \text{(figure 4.1.1.2-8a)}$$

$$\left(c_{\ell_\alpha}\right)_{theory} = 6.58 \text{ per rad} \quad \text{(figure 4.1.1.2-8b)}$$

$$\left(c_{\ell_\alpha}\right)_M = \frac{1.05}{\beta}\left[\frac{c_{\ell_\alpha}}{\left(c_{\ell_\alpha}\right)_{theory}}\right]\left(c_{\ell_\alpha}\right)_{theory} \quad \text{(equation 4.1.1.2-a)}$$

$$= \frac{1.05}{0.917}\,(0.893)\,(6.58) = 6.73 \text{ per rad}$$

$$\kappa = \frac{\left(c_{\ell_\alpha}\right)_M}{2\pi/\beta} = \frac{6.73}{2\pi/\beta} = 0.981$$

$$\frac{\beta A}{\kappa} = \frac{(0.917)\,(3.78)}{0.981} = 3.53$$

$$\Lambda_\beta = \tan^{-1}\frac{\tan \Lambda_{c/4}}{\beta} = \tan^{-1}\left(\frac{1.0856}{0.917}\right) = 49.8^o$$

$$\left.\begin{aligned}\left(\frac{\beta C'_{l_\delta}}{\kappa}\right)_{\eta_i = 0.75} &= 0.320 \text{ per rad}\\ \left(\frac{\beta C'_{l_\delta}}{\kappa}\right)_{\eta_o = 0.95} &= 0.420 \text{ per rad}\end{aligned}\right\} \quad \text{(figures 6.2.1.1-23a through -23c, interpolated)}$$

$$C'_{l_\delta} = \frac{\kappa}{\beta}\left[\left(\frac{\beta C'_{l_\delta}}{\kappa}\right)_{\eta_o} - \left(\frac{\beta C'_{l_\delta}}{\kappa}\right)_{\eta_i}\right] \quad \text{(equation 6.2.1.1-a)}$$

$$= \frac{0.981}{0.917}\,[0.420 - 0.320] = 0.107 \text{ per rad}$$

Section lift effectiveness α_δ (Section 6.1.1.1)

$$\left(c_{\ell_\delta}\right)_{\text{theory}} = 4.35 \text{ per rad (figure 6.1.1.1-39a)}$$

$$\frac{c_{\ell_\delta}}{\left(c_{\ell_\delta}\right)_{\text{theory}}} = 0.840 \text{ (figure 6.1.1.1-39b)}$$

$$K' = 0.98 \text{ (figure 6.1.1.1-40)}$$

$$\Delta c_\ell = \delta\left[\frac{c_{\ell_\delta}}{\left(c_{\ell_\delta}\right)_{\text{theory}}}\right]\left(c_{\ell_\delta}\right)_{\text{theory}} K' \text{ (equation 6.1.1.1-c)}$$

$$= \frac{15.0}{57.3}(0.840)(4.35)(0.98) = 0.937$$

$$\alpha_\delta = -\frac{\left(c_{\ell_\delta}\right)_\alpha}{\left(c_{\ell_\alpha}\right)_\delta} \text{ (equation 6.1.1.1-b)}$$

$$= -\frac{\Delta c_\ell}{\left(c_{\ell_\alpha}\right)_\delta^\delta} = -\frac{(0.937)}{(6.73)\frac{15.0}{57.3}} = -0.532$$

Solution:

$$C_{l_\delta} = C'_{l_\delta}\,|\alpha_\delta| \text{ (equation 6.2.1.1-b)}$$

$$= (0.107)(0.532) = 0.0569 \text{ per rad}$$

The rolling-moment coefficient is given by

$$C_l = \left(\frac{C_{l_\delta}}{2}\right)_L \delta_L - \left(\frac{C_{l_\delta}}{2}\right)_R \delta_R$$

$$= \frac{0.0569}{2(57.3)}\,[15 - (-15)] = 0.0149 \text{ (based on } S_w b_w)$$

2. Spoiler

Given: The wing-body configuration of reference 4 with a partial-span constant-chord spoiler hinged at the 55-percent-chord line.

Wing Characteristics:

$A_w = 4.0$ $\quad \lambda_w = 0.60$ $\quad S_w = 324.0$ sq in. $\quad b_w = 36.0$ in.

$\Lambda_{c/4} = 32.6^o$ $\quad \Lambda_{TE} = 24.3^o$ $\quad$ NACA 65006 airfoil (streamwise)

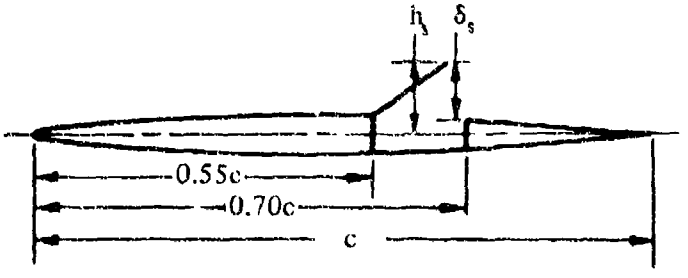
Spoiler Characteristics:

$$\eta_i = \frac{y_i}{b/2} = 0.139 \qquad \eta_o = \frac{y_o}{b/2} = 0.639 \qquad \frac{c_s}{c} = 0.150$$

Spoiler projection δ_s measured from the airfoil surface at 0.70c, and corresponding spoiler chordwise location

$$\frac{\delta_s}{c} = 0.100$$

$$\frac{x_s}{c} = 0.662$$



Additional Characteristics:

$M = 0.40$; $\beta = 0.917$

Compute:

Determine C'_{l_δ}

$c_{\ell_\alpha} = 0.105$ per deg $= 6.02$ per rad (table 4.1.1-B)

$$\left(c_{\ell_\alpha}\right)_M = \frac{c_{\ell_\alpha}}{\beta} = \frac{6.02}{0.917} = 6.56 \text{ per rad}$$

$$\kappa = \frac{\left(c_{\ell_\alpha}\right)_M}{2\pi/\beta} = \frac{6.56}{2\pi/\beta} = 0.958$$

$$\Lambda_\beta = \tan^{-1}\frac{\tan\Lambda_{c/4}}{\beta} = \tan^{-1}\frac{0.6395}{0.917} = 34.9^o$$

$$\frac{\beta A}{\kappa} = \frac{0.917\,(4.0)}{0.958} = 3.85$$

Determine $\eta_{i_{eff}}$ and $\eta_{o_{eff}}$

$$\tan\Lambda_s = \tan\Lambda_{c/4} - \frac{4\left[0.75 - \left(1 - \frac{x_s}{c}\right)\right]}{A}\left(\frac{1-\lambda}{1+\lambda}\right)$$

$$= 0.6395 - \frac{4}{4.0}\,[0.75 - (1 - 0.662)]\,\frac{0.40}{1.60}$$

$$= 0.6395 - (0.412)(0.25) = 0.5365$$

$$\Lambda_s = \tan^{-1} 0.5365 = 28.2^{\circ}$$

$$\theta = 28.3^{\circ} \text{ (figure 6.2.1.1-26a)}$$

$$\frac{\cos \Lambda_{TE} \sin \theta}{\cos (\Lambda_{TE} + \theta)} = \frac{0.9114\,(0.4741)}{0.6074} = 0.7114$$

$$\frac{4\left(1 - \frac{x'_s}{c}\right)}{A(1+\lambda)} = \frac{4\,(1 - 0.662)}{4.0\,(1.60)} = 0.211$$

$$[1 - (1 - \lambda)\,\eta_i] = [1 - (1 - 0.6)\,(0.139)] = 0.944$$

$$[1 - (1 - \lambda)\,\eta_o] = [1 - (1 - 0.6)\,(0.639)] = 0.744$$

$$\left.\begin{aligned} \Delta\eta_i &= \frac{4\left(1 - \frac{x'_s}{c}\right)}{A(1+\lambda)}\,[1 - (1 - \lambda)\,\eta_i]\,\frac{\cos \Lambda_{TE} \sin \theta}{\cos (\Lambda_{TE} + \theta)} \\ &= (0.211)\,(0.944)\,(0.7114) = 0.142 \end{aligned}\right\} \text{(equation 6.2.1.1-e)}$$

$$\left.\begin{aligned} \Delta\eta_o &= \frac{4\left(1 - \frac{x'_s}{c}\right)}{A(1+\lambda)}\,[1 - (1 - \lambda)\,\eta_o]\,\frac{\cos \Lambda_{TE} \sin \theta}{\cos (\Lambda_{TE} + \theta)} \\ &= (0.211)\,(0.744)\,(0.7114) = 0.112 \end{aligned}\right\}$$

$$\left.\begin{aligned} \eta_{i_{eff}} &= \eta_i + \Delta\eta_i = 0.139 + 0.142 = 0.281 \\ \eta_{o_{eff}} &= \eta_o + \Delta\eta_o = 0.639 + 0.112 = 0.751 \end{aligned}\right\} \text{(equation 6.2.1.1-d)}$$

$$\left.\begin{aligned} \left(\frac{\beta C'_{l\,\delta}}{\kappa}\right)_{\eta_{i_{eff}}} &= 0.061 \text{ per rad} \\ \left(\frac{\beta C'_{l\,\delta}}{\kappa}\right)_{\eta_{o_{eff}}} &= 0.350 \text{ per rad} \end{aligned}\right\} \text{(figures 6.2.1.1-23a through -23c, interpolated)}$$

$$C'_{l_\delta} = \frac{\kappa}{\beta}\left[\left(\frac{\beta C'_{l_\delta}}{\kappa}\right)_{\eta_{o_{eff}}} - \left(\frac{\beta C'_{l_\delta}}{\kappa}\right)_{\eta_{i_{eff}}}\right] \quad \text{(equation 6.2.1.1-a)}$$

$$= \frac{0.958}{0.917}\left[0.350 - 0.061\right] = 0.302 \quad \text{per rad}$$

Determine $\Delta\alpha'_s$

The upper-surface ordinate of the NACA 65006 airfoil section at 0.70c is 0.0194c. (see reference 5)

$$\frac{h_s}{c} = \frac{\delta_s}{c} + 0.0194 = 0.100 + 0.0194 = 0.1194$$

$\Delta\alpha'_s = 0.134$ (figure 6.1.1.1-52 at $x_s/c, h_s/c$)

Solution:

$$C_l = \frac{C'_{l_\delta}}{2}\Delta\alpha'_s \quad \text{(equation 6.2.1.1-c)}$$

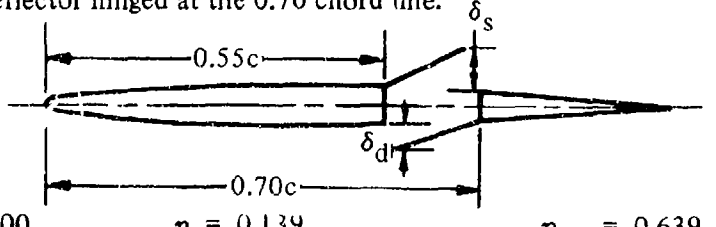
$$= \left(\frac{0.302}{2}\right)(0.134)$$

$= 0.0202$ (based on $S_W b_W$) (Spoiler deflected on one wing panel)

This result compares with a test value of 0.0215 from reference 4.

3. Spoiler-Slot-Deflector

Given: The wing-body configuration of reference 4 with a partial-span constant-chord spoiler-slot-deflector on one wing panel. This is the configuration of sample problem 2 with the addition of a slot opening between the 55- and 70-percent-chord lines extending from $\eta_i = 0.139$ to $\eta_o = 0.639$, and a 0.15c deflector hinged at the 0.70 chord line.



$S_W = 324.0$ sq in.

$b_W = 36.0$ in.

$\frac{\delta_s}{c} = 0.100$ $\eta_i = 0.139$ $\eta_o = 0.639$

$(C_l)_{\text{plain spoiler}} = 0.0202$ (sample problem 2)

$\frac{\delta_d}{c} = 0.025,\ 0.050,\ 0.075,\ 0.100$

Solution:

$$(C_l)_{\text{spoiler-slot-deflector}} = K(C_l)_{\text{plain spoiler}} \qquad \text{(equation 6.2.1.1-f)}$$

$$= (0.0202)\,K \qquad \text{(based on } S_w\, b_w\text{)}$$

B. TRANSONIC

No accurate method is available for predicting C_{l_δ} at transonic speeds. Mixed flow conditions and interrelated shock-wave and boundary-layer-separation effects cause extreme nonlinearities in this parameter. The discussion of paragraph B of Section 4.1.3.2 gives some insight into these effects for plain wings.

The method presented here is intended to give a first-order approximation only and to provide a guide to aid in fairing between subcritical and supersonic speeds.

Published experimental data in the transonic speed range are available for only a specific flap-type control tested on a wing-planform series in which only the wing sweep was varied (references 6 through 9).

DATCOM METHOD

No specific charts are presented for determining the transonic rolling effectiveness of lateral-control devices. The best source of information of this type is experimental data on similar configurations. If such information is not available, the following approach may be used as a guide in fairing between subcritical and supersonic speeds.

A first-order approximation of the transonic rolling effectiveness of lateral-control devices is given by

$$C_l = (C_l)_{M=0.6} \frac{(C_{L_\alpha})}{(C_{L_\alpha})_{M=0.6}} \qquad \text{6.2.1.1-g}$$

where

$(C_l)_{M=0.6}$ is the rolling effectiveness of the control at M = 0.6, obtained by using the appropriate method of paragraph A of this section.

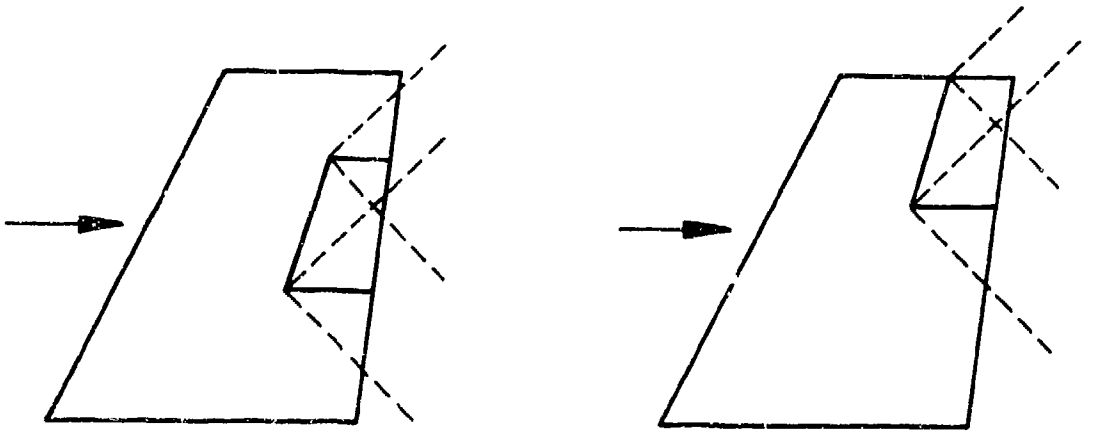
$\left(C_{L_\alpha}\right)$ is the transonic wing-lift-curve slope, obtained from paragraph B of Section 4.1.3.2.

$\left(C_{L_\alpha}\right)_{M=0.6}$ is the wing-lift-curve slope at M = 0.6, obtained by using the straight-tapered wing method of paragraph A of Section 4.1.3.2 (figure 4.1.3.2-41).

C. SUPERSONIC

Plain Trailing-Edge Flaps

Supersonic linear theory is used in reference 10 to derive conical-flow solutions for the rolling effectiveness of wing trailing-edge flap-type control surfaces. The theory is based on the following assumptions (see sketch (h)):



SKETCH (h)

1. The leading (hinge line) and trailing edges of the control surface are supersonic (swept ahead of the Mach lines).

2. The control surfaces are located at the wing tip or are far enough inboard to prevent the outermost Mach lines from the control surface from crossing the wing tip.

3. The innermost Mach lines from the deflected control surface do not cross the root chord.

4. The root and tip chords of the control surfaces are streamwise.

5. Controls are not influenced by the tip conical flow from the opposite wing panel or by the interaction of the wing-root Mach cone with the wing tip.

An approximate correction is given in reference 10 to account for the effect of airfoil thickness in the case of slab-sided controls.

Spoilers

The method presented for determining the supersonic rolling moment due to spoilers is taken from reference 11. The derivation is based on an analysis, presented in reference 12, of the pressure distributions adjacent to the spoiler. Although data on spoiler rolling characteristics at supersonic speeds are limited, the method appears satisfactory for both plug and flap-type spoilers within the Mach number range of the available data (M = 1.6 to 3.0).

No method is presented for determining the supersonic rolling moment due to spoiler-slot-deflectors. Published test data on spoiler-slot-deflector characteristics at supersonic speeds are extremely limited. References 13 and 14 present test data on spoiler-slot-deflector controls at supersonic speeds.

DATCOM METHODS

Plain Trailing-Edge Flaps

The supersonic rolling effectiveness of plain trailing-edge flap-type controls is given by

$$C_{l_\delta} = \left(1 - \frac{C_2}{C_1}\phi_{TE}\right) C'_{L_\delta} \frac{S_f}{S_W} \frac{1}{2}\left[\frac{y_i}{b_W} + \left(\frac{b_f}{2\,b_W}\right)\frac{C'_{l_\delta}}{C'_{L_\delta}}\right] \qquad 6.2.1.1\text{-h}$$

where

C_{l_δ} is the control-surface rolling effectiveness of one control surface deflected on one wing panel, based on the total wing area and span.

C'_{l_δ} is the theoretical rolling-moment derivative based on total control area S_f for thin wings for the following cases:

(a) Tapered control surfaces with outboard edge coincident with wing tip (use figure 6.2.1.1-27).

(b) Tapered control surfaces with outboard edge not coincident with wing tip (use figure 6.2.1.1 -28).

(c) Untapered control surfaces with outboard edge coincident with wing tip (use figure 6.2.1.1 -29a).

(d) Untapered control surface with outboard edge not coincident with wing tip (use figure 6.2.1.1 -29b).

$\frac{S_f}{S_W}$ is the ratio of the total control area (both sides of wing) to the total wing area.

$\frac{b_f}{b_W}$ is the ratio of the total control span (both sides of wing) to the total wing span.

$\frac{y_i}{b_W}$ is the distance from the wing root chord to the control root chord in wing spans.

$\left(1 - \frac{C_2}{C_1}\phi_{TE}\right)$ is a thickness correction factor to the supersonic flat-plate derivative.

$$C_1 = \frac{2}{\sqrt{M^2 - 1}} \text{ (per radian)}$$

$$C_2 = \frac{(\gamma + 1)\,M^4 - 4\,(M^2 - 1)}{2\,(M^2 - 1)^2} \quad \text{(per radian)}$$

θ_{TE} is the trailing-edge angle in radians, measured normal to the control hinge line.

γ is the ratio of specific heats, $\gamma = 1.4$.

C'_{L_δ} is the lift-effectiveness of one symmetric, straight-sided control, based on the area of the control. This parameter is obtained from figures 6.1.4.1-20a through 6.1.4.1-20j for controls located at the wing tip, and from figure 6.1.4.1-25 for controls located inboard from the wing tip.

It should be noted that in applying this method the control deflection angle and all dimensions (with the exception of ϕ_{TE}) are measured in planes parallel and perpendicular to the plane of symmetry.

The limitations of this method are noted in the introduction to paragraph C. A comparison of test values with results calculated by this method is presented as table 6.2.1.1-B.

Sample problem 1 at the conclusion of this paragraph illustrates the use of the method.

Spoilers

Plug and Flap-Type Spoilers

The supersonic rolling-moment coefficient of a plug or a flap-type spoiler deflected on one panel, based on the total wing area and span, is obtained from figure 6.2.1.1-30 as a function of Mach number and configuration geometry.

A comparison of test values with results calculated by using this method is presented as table 6.2.1.1-C.

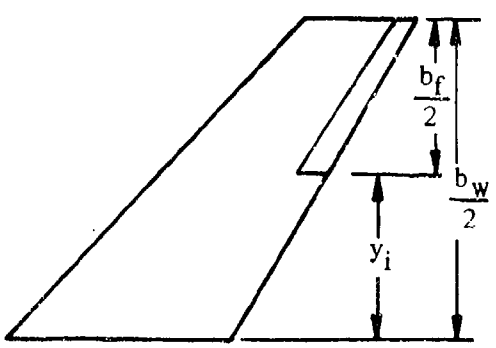
Sample problem 2 at the conclusion of this paragraph illustrates the use of the method.

Sample Problems

1. Plain Trailing-Edge-Flap Ailerons

Given: The wing-body-tail configuration of reference 18, with plain trailing-edge ailerons.

Wing Characteristics:



$S_W = 166.8$ sq in. $\quad b_W = 25.86$ in.

$\lambda_W = 0.50 \quad A_W = 4.0$

$\Lambda_{c/4} = 40^\circ \quad \Lambda_{TE} = 30.5^\circ$

$\Lambda_{LE} = 42.7^\circ$

Control Characteristics:

Symmetric, straight-sided outboard control $\Lambda_{HL} = 33.26^{o}$ $\lambda_f = 0.666$

$b_f = 12.93$ in. (both sides of wing) $S_f = 13.89$ sq in. (both sides of wing)

$\frac{y_i}{b_w} = 0.25$ $\phi_{TE} = 6^{o}$ $c_f/c = 0.20$

Additional Characteristics:

$M = 1.61$; $\beta = 1.262$; $M^2 - 1 = 1.592$

Compute:

$$C_1 = \frac{1}{\sqrt{M^2 - 1}} = \frac{1}{1.262} = 0.792 \text{ per rad}$$

$$C_2 = \frac{(\gamma + 1) M^4 - 4 (M^2 - 1)}{2 (M^2 - 1)^2} = \frac{(2.40) (1.61)^4 - 4 (1.592)}{2 (1.592)^2} = 1.925 \text{ per rad}$$

$$\frac{\tan \Lambda_{HL}}{\beta} = \frac{0.6558}{1.262} = 0.520; \quad \frac{\tan \Lambda_{TE}}{\beta} = \frac{0.5891}{1.262} = 0.467$$

$\beta C'_{L_\delta} = 0.0745$ per deg (figures 6.1.4.1-20g through -20i, interpolated)

$C'_{L_\delta} = 0.0590$ per deg

$\beta C'_{l_\delta} = 0.0370$ per deg (figure 6.2.1.1-27)

$C'_{l_\delta} = 0.0293$ per deg

Solution:

$$C_{l_\delta} = \left(1 - \frac{C_2}{C_1} \phi_{TE}\right) C'_{L_\delta} \frac{S_f}{S_w} \frac{1}{2}\left[\frac{y_i}{b_w} + \left(\frac{b_f}{2b_w}\right)\frac{C'_{l_\delta}}{C'_{L_\delta}}\right] \text{ (equation 6.2.1.1-h)}$$

$$= \left[1 - \frac{1.925}{0.792}\left(\frac{6}{57.3}\right)\right](0.0590) \frac{13.89}{166.8} \left(\frac{1}{2}\right)\left[0.25 + \frac{6.465}{25.86}\left(\frac{0.0293}{0.0590}\right)\right]$$

$= 0.000686$ per deg (based on $S_w b_w$) (one control surface deflected on one wing panel)

This compares with a test value of 0.00056 per degree from reference 18.

2. Plug and Flap-Type Spoilers

Given: The wing-body-tail configuration of reference 18, equipped with plug and flap-type spoilers.

Wing Characteristics:

$A_W = 4.0 \qquad \lambda_W = 0.500 \qquad \Lambda_{c/4} = 40^o$

Spoiler Characteristics:

Case	Type	$\frac{y_i}{b_W/2}$	$\frac{y_o}{b_W/2}$	Chordwise Location %c	$\frac{\delta_s}{c}$

6.2.1.2 ROLLING MOMENT DUE TO A DIFFERENTIALLY DEFLECTED HORIZONTAL STABILIZER

A large amount of theoretical and experimental work has been directed toward the development of efficient roll-control devices. The initial studies and tests concentrated on ailerons, optimizing their size and location to maximize the available roll-control power. However, the more recent studies have investigated auxiliary surfaces or techniques that supplement aileron control to improve aircraft maneuverability. Among these auxiliary devices considered is the differentially deflected horizontal stabilizer.

Methods are presented in this section for estimating the rolling moments generated by a differentially deflected horizontal tail, at subsonic, transonic, and supersonic speeds. These methods are valid only for body-mounted horizontal tails (due to the empirical tail-effectiveness parameter) and are applicable throughout the angle-of-attack range until separation is encountered on the horizontal tail. No provisions are made to estimate the effects of flap deflections, horizontal-tail dihedral, or the rolling-moment contribution of the vertical tail; i.e., they are assumed to be negligible. Comparisons of the estimated and experimental values indicate relatively good correlation to moderate angles of attack (see Tables 6.2.1.2-A and -B).

Body vortices can have a strong influence on the horizontal-tail loading at high angles of attack. For body vortices, the flow separates just above or behind the area of minimum pressure along the side of the body near the nose and wraps up into a pair of symmetrical vortices that proceed downstream. The point at which separation first takes place depends upon the angle of attack (the higher the angle of attack, the nearer the nose separation occurs), the nose-profile shape (the blunter the nose, the nearer the nose separation occurs), and body cross-sectional shape (sharply curving lateral contours promote early separation). The vortices increase in size and strength with increasing downstream distance. These body vortices are accounted for in the methods herein by using the vortex interference charts found in Section 4.3.1.3. However, the effect of the wing shock-expansion field on the body vortices is neglected in the supersonic method.

Wing vortices are of equal interest in determining the horizontal-tail loading at high angles of attack. For closely-coupled configurations having wings and tails of nearly equal span, the wing-vortex effects can be of particular significance. The wing-vortex effects are accounted for in the downwash gradient parameter $\partial\bar{\epsilon}/\partial\alpha$ calculated in Section 4.4.1. (Care should be used to select the method best suited for the configuration.)

To familiarize the reader with the more salient aspects associated with horizontal-tail roll control, a basic discussion is presented. The discussion is supplemented by graphical comparisons of tail-roll-control and aileron-roll-control characteristics to illustrate similarities and differences. (Both the discussion and the illustrations are taken from Reference 1, except where noted.)

The interest in evaluating roll control for a differentially deflected horizontal tail is, in general, due to the inadequate roll-control power provided by conventional roll-control systems; i.e., ailerons and/or spoilers in the transonic and supersonic speed regimes. This inadequacy is due primarily to wing twist and shock-induced separation of the boundary layer ahead of the control surface. For a thin flexible wing of a high-speed airplane, the deflection of conventional outboard ailerons can produce a substantial amount of wing twist that can result in a significant reduction in roll-control

effectiveness. The boundary-layer separation results in a loss of roll-control effectiveness, as well as an increase in buffet and drag and a decrease in lift.

The most recent results of tail-roll-control investigations (Reference 2) indicate that tail roll control is best suited as an auxiliary roll-control device, where only moderate differential deflections are required.

In general, three basic considerations should be kept in mind when designing a tail-roll-control system:

(1) The tail must provide adequate effectiveness without excessive deflections (large tail and good effectiveness).

(2) The longitudinal trim requirements of the tail should be minimized to avoid interaction of roll and pitch controls.

(3) The horizontal tail should be positioned vertically to avoid excessive favorable or adverse yawing moments.

The first item requires no discussion, as the advantages are apparent. The second item can be a critical factor and is worthy of careful consideration. For a specific configuration, a wind-tunnel test is required to determine the interaction effects, since no methods presently exist for estimating this effect. Both the effects of roll control on pitching moments and the variation of roll control with angle of attack for different stabilizer settings must be considered. It is necessary to avoid stabilizer trim settings where the roll control might be limited or significantly reduced because of separation on the horizontal tail as a result of high angles of attack. For example, the landing configuration for some aircraft may produce control interaction problems. The effects of Item 3 above are discussed in detail in Section 6.2.2.2.

Mach Number Effects

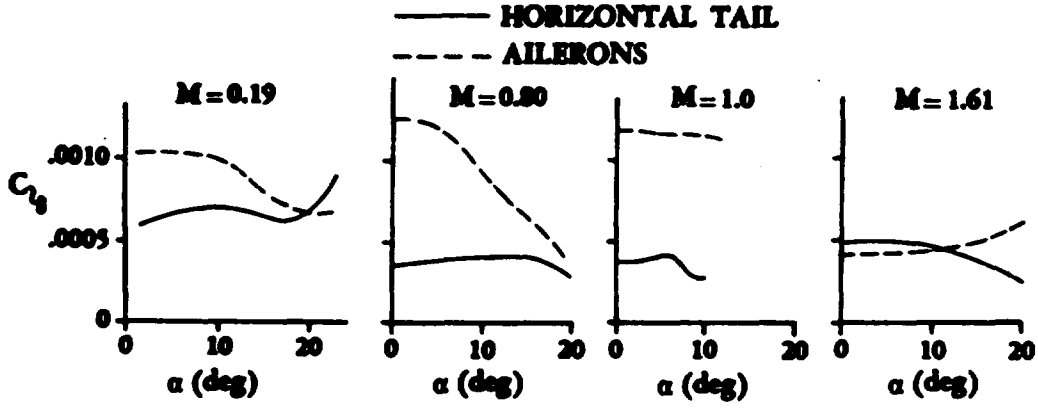
From the limited available test data (References 1 through 8), it can be concluded that the variation of tail-roll-control effectiveness C_{l_δ} with Mach number is small. Within the subsonic regime, the effectiveness is relatively constant. In the supersonic regime, a slight increase in C_{l_δ} is noted at a Mach number of approximately 1.2, and then a progressive decrease in effectiveness is noted with increasing Mach number because of the decreasing lift-curve slope of the horizontal tail.

In the subsonic regime, values for C_{l_δ} due to tail roll control are approximately one-half to one-third of those produced by conventional ailerons at comparable speeds. In the supersonic speed regime, values for C_{l_δ} due to tail roll control are comparable to those obtained by using ailerons. However, since there will usually be more control deflection available for the ailerons, they will provide more roll control, assuming no aileron reversal is encountered due to wing twist.

Angle-of-Attack Effects

For subsonic Mach numbers, the variation of C_{l_δ} with angle of attack is not large for most configurations. However, for some configurations C_{l_δ} can decrease to one-half its original value at

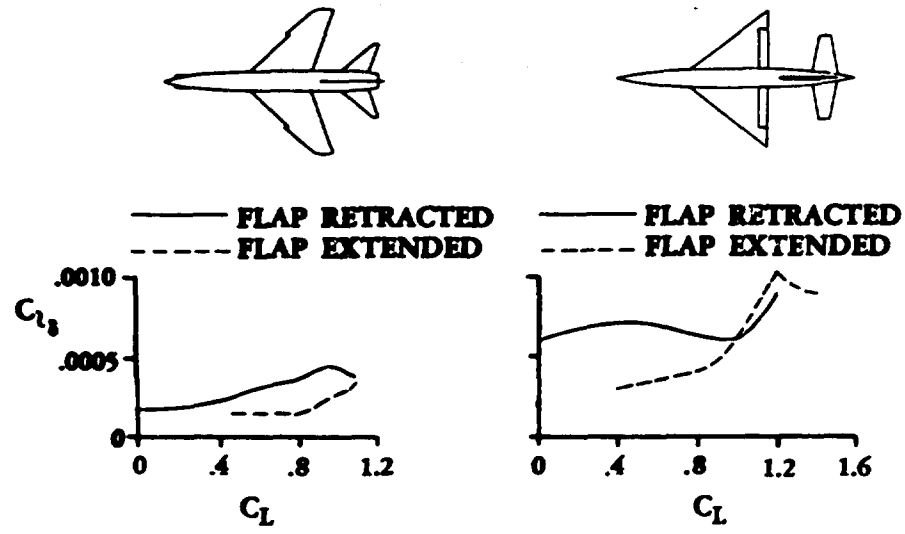
α = 16° to 20° (Reference 8). For aileron control at subsonic speeds, the effectiveness generally drops off rapidly with increasing angle of attack, so that at high angles of attack the values of C_{l_δ} can begin to approximate those for tail roll control (Reference 3). Sketch (a) presents representative trends for both aileron and horizontal-tail deflections at four different Mach numbers as a function of angle of attack. (These results were obtained on wind-tunnel models with essentially rigid wings.) In contrast to the subsonic speed regime, at M = 1.61 the aileron effectiveness increases with angle of attack while the tail roll control decreases with angle of attack.



SKETCH (a)

Flap Effects

The effects of flaps on the tail roll control are shown in Sketch (b) for two different configurations. Both configurations show a detrimental effect of flaps at low lift coefficients. However, as the lift coefficient is increased, the tail roll control increases to equal or exceed the flap-retracted value of C_{l_δ}. Insufficient data exist to determine if this trend is consistent for all configurations.



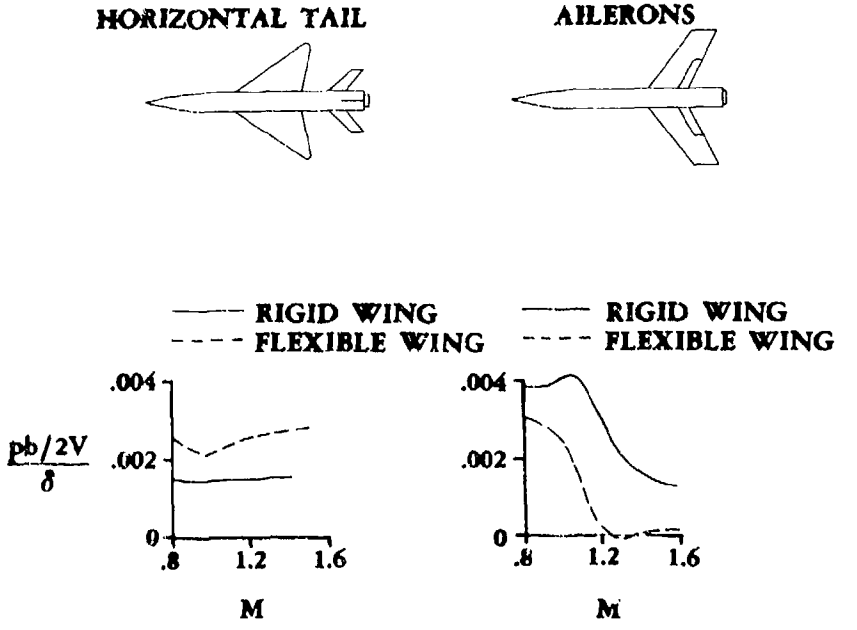
SKETCH (b)

Dihedral Effects

Reference 6 presents the results of a systematic variation of dihedral angle from 0 to -30° on the lateral-control effectiveness and the stabilizer characteristics for tail roll control at subsonic speeds. The results of the investigation show a small variation in the roll effectiveness C_{l_δ} with negative tail-dihedral angle. These small variations did not form a set pattern, but rather were dependent upon the initial stabilizer angle prior to differential deflection.

Aeroelastic Effects

The effects of wing flexibility are analyzed in the literature (References 1 and 4) through an overall rolling effectiveness parameter $(pb/2V)/\delta$, which can be expressed as C_{l_δ}/C_{l_p}. Thus, for a flexible-wing airplane in comparison to a rigid-wing airplane, greater rolling effectiveness will be realized for the flexible-wing aircraft because of the reduction in the wing contribution to roll damping C_{l_p}. Sketch (c) presents a comparison of data for a stiff and a flexible wing for both tail roll control and aileron roll control as a function of Mach number. These data illustrate the wing-twist problem encountered for thin flexible wings employing ailerons at supersonic speeds. In contrast, the horizontal-tail roll control shows no adverse effects, but rather an increase for the flexible wing. Thus one can conclude that for certain cases, i.e., a thin flexible-wing configuration at supersonic speeds, the tail-roll-control contribution may be superior to that of conventional ailerons.



SKETCH (c)

A SUBSONIC

DATCOM METHOD

The following method is a modification of the method found in Reference 1, with the additional terms accounting for the effects of downwash, body vortices, and tail effectiveness. At angles of attack less than six degrees the body vortex interference factor $i_{v_{B(H)}}$ can be neglected. The roll-control effectiveness of a body-mounted differentially deflected horizontal stabilizer, based on $S_W b_W$, is given by

$$C_{l_\delta} = \frac{1}{2}\left[\left(1 - \frac{\pi A_W}{57.3}\frac{\partial\bar{\epsilon}}{\partial\alpha}\right) + i_{v_{B(H)}}\left(\frac{\Gamma}{2\pi\alpha Vr}\right)\left(\frac{r}{b_{H_e}/2}\right)\right]\eta\left(\frac{q_H}{q}\right)\frac{\bar{y}_H S_{H_e}}{b_W S_W}\left(C_{L_{\alpha_H}}\right)_e \qquad 6.2.1.2\text{-a}$$

The proper sign of the rolling-moment coefficient will result from the expression $C_l = C^*_{l_\delta}(\delta_L - \delta_R)$. The subscript e refers to the exposed surface (see Section 4.3.1.2 for a definition of exposed surfaces), and

A_W is the aspect ratio of the total wing.

$\frac{\partial\bar{\epsilon}}{\partial\alpha}$ is the average rate of change of downwash with respect to angle of attack at the horizontal tail, obtained from Section 4.4.1. Care should be exercised to select the method of Section 4.4.1 best suited for the aircraft configuration.

$i_{v_{B(H)}}$ is the vortex interference factor for a lifting surface mounted on the body center line. This parameter is given in Figures 4.3.1.3-7a through -7ℓ for various exposed-tail taper ratios, relative exposed-tail sizes, and vortex center-line positions.

The vertical and lateral vortex positions required to obtain $i_{v_{B(H)}}$ are $\frac{z_o}{r}$ and $\frac{y_o}{r}$, respectively. At any given station x, they may be obtained from Figures 4.3.1.3-13b and 4.3.1.3-14, respectively, as functions of the parameter $\frac{\alpha(x - x_s)}{r}$ where

α is the angle of attack in radians.

x is the distance from the body nose to the quarter-chord point of the MAC of the exposed horizontal tail for subsonic flow. (However, for supersonic flow x is measured to the midchord point of the MAC of the exposed horizontal tail.)

r is the average body radius in the region of the horizontal tail. For noncircular bodies use the average body depth in the region of the horizontal tail.

*It should be noted that the definition of C_{l_δ} based on the total differential deflection (consistent with the literature) does not agree with C_{l_δ} in other sections.

$\frac{x_s}{r}$ is the nondimensional position of vortex separation, from Figure 4.3.1.3-13a.

It should be noted that Figures 4.3.1.3-7a through -7ℓ give the vortex interference factors for a lifting surface mounted on the body center line. If the lifting surface is not mounted on the body center line, the vertical distance of the body vortices from the body center line, obtained from Figure 4.3.1.3-13b, must be corrected to their distance from the tail before obtaining $i_{v_{B(H)}}$. This is illustrated in the sample problem following the subsonic method.

In using Figures 4.3.1.3-7a through -7ℓ a possible problem can develop when interpolation must be made with respect to λ and $\frac{r}{b_W/2}$. For positions of the vortex near the body, the interpolation in $\frac{r}{b_W/2}$ can carry the vortex inside the body. Under these circumstances, it is recommended that the interpolation be made using $\frac{y_o - r}{b_W/2 - r}$ for the vortex lateral position in place of $\frac{y_o}{b_W/2}$, to avoid vortex positions inside the body.

For noncylindrical bodies, caution must be exercised in using the curves in Section 4.3.1.3 as they are based entirely on cylindrical body shapes.

$\frac{\Gamma}{2\pi\alpha V r}$ is the nondimensional vortex strength from Figure 4.3.1.3-15.

$\frac{r}{b_{H_e}/2}$ is the ratio of the average radius of the body (or average fuselage depth for noncircular bodies) in the region of the tail to the semispan of the exposed tail.

$\eta\left(\frac{q_H}{q}\right)$ is the tail-effectiveness factor for configurations with body-mounted horizontal tails, obtained from Figure 6.2.1.2-22 (from Reference 9).

b_W is the total wing span.

$\frac{S_{H_e}}{S_W}$ is the ratio of the area of the exposed horizontal tail to the total wing area.

$\bar{y}_H$ is the lateral c.p. coordinate of the horizontal tail, measured from and normal to the longitudinal axis. This parameter is given by

$$\bar{y}_H = \eta_{c.p.}\left(\frac{b_{H_e}}{2}\right) + r \qquad 6.2.1.2\text{-b}$$

where

$\eta_{c.p.}$ is the spanwise location of the c.p. of the exposed horizontal tail (based on the exposed aspect ratio, sweep, and exposed taper ratio), obtained from Figure 6.2.1.2-23 (from Reference 10).

$\frac{b_{H_e}}{2}$ is the semispan of the exposed horizontal tail.

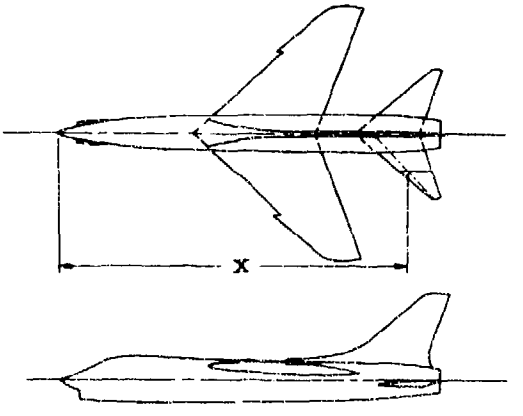
r is the body radius in the region of the horizontal tail. For noncircular bodies use the average body depth in the region of the horizontal tail.

$\left(C_{L_{\alpha_H}}\right)_e$ is the lift-curve slope of the exposed horizontal stabilizer, obtained from Section 4.1.3.2. Care should be exercised to use the appropriate method in determining this parameter because of its significant influence.

The total angular deflection of the control surfaces δ is measured in a plane parallel to the plane of symmetry, and is positive for the left control surface deflected trailing edge down and the right control surface deflected trailing edge up.

Sample Problem

Given: The configuration of Reference 3



Wing Characteristics:

S_W = 666.7 sq in. b_W = 47.56 in. A_W = 3.39

λ_W = 0.247 $\Lambda_{c/4}$ = 42° Root Section NACA 65-006

Tip Section NACA 65-005

Horizontal-Tail Characteristics:

S_{H_e} = 102.4 sq in. b_{H_e} = 18.24 in. b_H = 24.11 in.

A_{H_e} = 3.25 A_H = 3.50 λ_{H_e} = 0.187

λ_H = 0.148 $\Lambda_{c/4}$ = 45° $\Lambda_{c/2}$ = 38.2°

h_H = −3.0 in. ℓ_H = 18.25 in.

Additional Characteristics:

Low speed; $\beta \cong 1.0$ d_H = 5.87 in. x = 66.0 in.

r = 2.935 in. z' = 0.49 in.

Compute:

Calculate $\left(C_{L_{\alpha_H}}\right)_e$ from Section 4.1.3.2

c_{ℓ_α} = 0.105 per deg (Table 4.1.1-B, for 65-006)

$$\kappa = \frac{\left(c_{\ell_\alpha}\right)_M}{2\pi/\beta} = \frac{c_{\ell_\alpha}/\beta}{2\pi/\beta} = \frac{57.3\,(0.105)}{2\pi} = 0.9576$$

$$\frac{A_{H_e}}{\kappa}\left[\beta^2 + \tan^2\Lambda_{c/2}\right]^{1/2} = \frac{3.25}{0.9576}\left[1.0 + (0.788)^2\right]^{1/2} = 4.32$$

$$\frac{\left(C_{L_{\alpha_H}}\right)_e}{A_{H_e}} = 0.935 \text{ per rad} \quad \text{(Figure 4.1.3.2-49)}$$

$$\left(C_{L_{\alpha_H}}\right)_e = 3.039 \text{ per rad}$$

$$= 0.0530 \text{ per deg}$$

Calculate $\eta\left(\frac{q_H}{q}\right)$

$$\frac{d_H}{b_H} = \frac{5.87}{24.11} = 0.243$$

$\eta\left(\frac{q_H}{q}\right)$ = 0.789 (Figure 6.2.1.2-22)

Calculate $\bar{y}_H$

$$(\Lambda_\beta)_H = \tan^{-1}\left(\frac{\tan \Lambda_{c/4}}{\beta}\right) = \tan^{-1}\left(\frac{1}{1}\right) = 45°$$

$$\frac{\beta A_{H_e}}{\kappa} = \frac{(1)(3.25)}{0.9576} = 3.394$$

$\eta_{c.p.} = 0.429$ (Figure 6.2.1.2-23)

$$\bar{y}_H = \eta_{c.p.}\left(\frac{b_{H_e}}{2}\right) + r \quad \text{(Equation 6.2.1.2-b)}$$

$$= (0.429)\left(\frac{18.24}{2}\right) + 2.935 = 6.85$$

$$\frac{\bar{y}_H S_{H_e}}{b_W S_W} = \frac{6.85}{47.56}\,\frac{102.4}{666.7} = 0.0221$$

Calculate $\frac{\partial \bar{\epsilon}}{\partial \alpha}$ from Section 4.4.1. (Method 2 is used because this configuration is similar to other configurations used in the substantiation of the method presented in Table 4.4.1-B.)

$$\frac{\partial \bar{\epsilon}}{\partial \alpha} = 4.44\left[K_A\, K_\lambda\, K_H\, (\cos \Lambda_{c/4})^{1/2}\right]^{1.19} \quad \text{(Equation 4.4.1-h)}$$

$K_A = 0.183$ (Figure 4.4.1-69a)

$K_\lambda = 1.324$ (Figure 4.4.1-69b)

$$\frac{2\ell_H}{b} = \frac{2(18.25)}{47.56} = 0.767$$

$$\frac{2h_H}{b} = \frac{2(-3.0)}{47.56} = -0.126$$

$K_H = 1.16$ (Figure 4.4.1-70, extrapolated)

$$\frac{\partial \bar{\epsilon}}{\partial \alpha} = 4.44\,[(0.183)(1.324)(1.16)(0.862)]^{1.19}$$

$$= 4.44\,[0.2423]^{1.19} = 4.44\,[0.1851]$$

$$= 0.822$$

Calculate the body vortex interference factors from Section 4.3.1.3

$$\frac{r}{\left(b_{H_e}/2\right)} = \frac{2.935}{9.12} = 0.322$$

$$\alpha\left(\frac{x - x_s}{r}\right) = \frac{\alpha}{57.3}\left(\frac{66.0}{2.935} - \frac{x_s}{r}\right) = \frac{\alpha}{57.3}\left(22.5 - \frac{x_s}{r}\right)$$

*The vertical location of the body vortex must be adjusted to account for the true location of the horizontal tail (Figures 4.3.1.3-7a through -7ℓ assume the horizontal tail is mounted on the body center line). Since the horizontal tail is located below the body center line, the vertical distance of the vortex is increased; i.e., $\left(\frac{z_o}{r}\right)_{\text{corrected}} = \frac{z_o}{r} + \frac{z'}{r}$ where z' is the distance of the horizontal tail below the center line.

Solution:

$$C_{l_\delta} = \frac{i}{2}\left[\left(1 - \frac{\pi A_W}{57.3}\frac{\partial\bar{\epsilon}}{\partial a}\right) + i_{v_{B(H)}}\left(\frac{\Gamma}{2\pi\alpha Vr}\right)\left(\frac{r}{b_{H_e}/2}\right)\right]\eta\left(\frac{q_H}{q}\right)\frac{\bar{y}_H S_{H_e}}{b_W S_W}\left(C_{L_{\alpha_H}}\right)_e$$

(Equation 6.2.1.2-a)

$$= \frac{1}{2}\left[\left\{1 - \frac{\pi(3.39)}{57.3}(0.822)\right\} + i_{v_{B(H)}}\left(\frac{\Gamma}{2\pi\alpha Vr}\right)\left(\frac{r}{b_{H_e}/2}\right)\right](0.789)(0.0221)(0.0530)$$

$$= 0.000391 + 0.000462\left[i_{v_{B(H)}}\left(\frac{\Gamma}{2\pi\alpha Vr}\right)\left(\frac{r}{b_{H_e}/2}\right)\right]$$

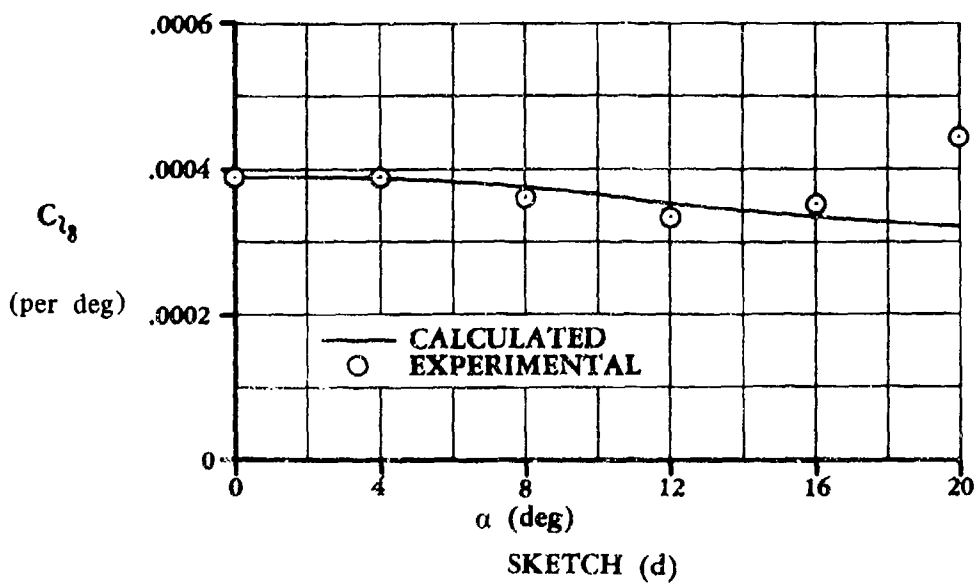
The calculated results are compared with test values from Reference 3 in Sketch (d).



SKETCH (d)

B. TRANSONIC

DATCOM METHOD

Because Mach number effects on roll-control effectiveness are very small, no separate solution is presented in the transonic regime. The existing methods are considered to be applicable in the transonic regime; i.e., the subsonic method for $M < 1.0$, and the supersonic method for $M > 1.0$. However, it should be emphasized that the transonic methods must be used to calculate the various components of the roll-control-effectiveness equations; i.e., the values of $\partial\bar{\epsilon}/\partial\alpha$, $\left(C_{L_{\alpha_H}}\right)_e$, and $\left(C_{N_{\alpha_H}}\right)_e$, in the transonic speed regime.

C. SUPERSONIC

DATCOM METHOD

The following method is a modification of the method found in Reference 1, with the additional terms accounting for the effects of body vortices and tail effectiveness. In contrast to the subsonic method, this method accounts for the tail effectiveness and the downwash due to wing vortices in the empirical factor of 0.35. At angles of attack less than six degrees the body vortex interference factor $i_{v_{B(H)}}$ can be neglected. The roll-control effectiveness of a body-mounted differentially deflected horizontal stabilizer, based on $S_W b_W$, is given by

$$C_{l_\delta} = 0.35\left[i_{v_{B(H)}}\left(\frac{\Gamma}{2\pi\alpha V r}\right)\left(\frac{r}{b_{H_e}/2}\right) + \left(k_{H(B)} + k_{B(H)}\right)\right]\left(C_{N_{\alpha_H}}\right)_e \frac{\bar{y}_H S_{H_e}}{b_W S_W} \qquad 6.2.1.2\text{-c}$$

The proper sign of the rolling-moment coefficient will result from the expression $C_l = C_{l_\delta}(\delta_L - \delta_R)$. The subscript e refers to the exposed surface (see Section 4.3.1.2 for a definition of exposed surfaces), and

$k_{H(B)}$ and $k_{B(H)}$ are tail-body interference factors obtained from Figures 4.3.1.2-12b and -12a, respectively, of Section 4.3.1.2. Care should be taken to use the appropriate empennage geometry with these figures; i.e., the average body diameter in the region of the horizontal tail and the horizontal-tail span.

$\left(C_{N_{\alpha_H}}\right)_e$ is the normal-force variation with angle of attack of the exposed horizontal tail obtained from Paragraph C of Section 4.1.3.2. Care should be exercised to use the correct method for the specific geometry and to apply the appropriate correction factors where applicable, e.g., those on Figure 4.1.3.2-60.

$\bar{y}_H$ is the lateral center-of-pressure coordinate of the horizontal tail measured from and normal to the longitudinal axis. For the supersonic case, it is assumed that the lateral center-of-pressure coordinate is located at the 40-percent position of the semispan of the exposed tail; i.e.,

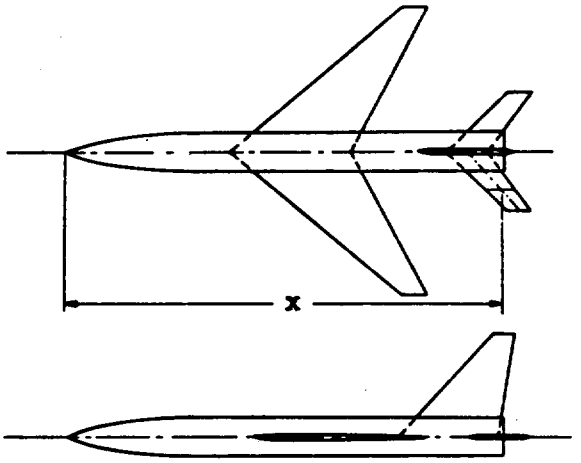
$$\bar{y}_H = 0.4\left(\frac{b_{H_e}}{2}\right) + r \qquad 6.2.1.2\text{-d}$$

All remaining terms have been previously defined in the subsonic method of this section. (It should be noted that the c.p. of the horizontal tail at supersonic speeds is assumed to be located at the midchord point of the exposed tail MAC in defining the parameter x.)

The total angular deflection of the control surfaces δ is measured in a plane parallel to the plane of symmetry, and is positive for the left control surface deflected trailing edge down and the right control surface deflected trailing edge up.

Sample Problem

Given: Model 2 of Reference 8



Wing Characteristics:

S_W = 144.0 sq in. b_W = 24.0 in. $\Lambda_{c/4}$ = 45°

Horizontal-Tail Characteristics:

S_{H_e} = 18.24 sq in. b_H = 10.73 in. b_{H_e} = 7.4 in.

A_H = 4.0 A_{H_e} = 3.0 λ_H = 0.6 λ_{H_e} = 0.685

$\Lambda_{c/4}$ = 45° Λ_{LE} = 46.7° Airfoil: Double Wedge; t/c = 0.04

Additional Characteristics:

M = 2.01; β = 1.744 r = 1.665 in. x = 36.59 in.

Compute:

Calculate $\left(C_{N_{\alpha_H}}\right)_e$ from Section 4.1.3.2

$$\frac{\tan \Lambda_{LE}}{\beta} = \frac{1.0625}{1.744} = 0.609$$

$$A_{H_e} \tan \Lambda_{LE} = (3.0)(1.0625) = 3.1875$$

$\beta\left(C_{N_\alpha}\right) = 4.02$ per rad (Figure 4.1.3.2-56 (d), (e), (f), interpolated)

$C_{N_\alpha} = 2.305$ per rad

$\beta \cot \Lambda_{LE} = (1.744)(0.9424) = 1.64$ (supersonic leading edge)

The supersonic wing lift-curve-slope correction factor will be applied because of the supersonic leading edge.

t/c = 0.04 and double-wedge airfoil

$\Delta y = 0.25$ (Figure 2.2.1-8)

$$\Delta y_\perp = \frac{\Delta y}{\cos \Lambda_{LE}} = \frac{0.25}{0.6858} = 0.365$$

$$\frac{C_{N_\alpha}}{\left(C_{N_\alpha}\right)_{theory}} = 0.995 \quad \text{(Figure 4.1.3.2-60)}$$

$$\left(C_{N_{\alpha_H}}\right)_e = (0.995)(2.305) = 2.293 \text{ per rad} = 0.040 \text{ per degree}$$

Calculate the tail-body interference factors from Section 4.3.1.2

$$\frac{d_H}{b_H} = \frac{2(1.665)}{10.73} = 0.3103$$

$k_{B(H)} = 0.324$ (Figure 4.3.1.2-12a)

$\beta A_{H_e} = (1.744)(3.0) = 5.232$

$k_{H(B)} = 0.983$ (Figure 4.3.1.2-12b)

$k_{B(H)} + k_{H(B)} = 0.324 + 0.983 = 1.307$

Calculate the lateral center-of-pressure coordinate

$$\bar{y}_H = 0.4\left(\frac{b_{H_e}}{2}\right) + r \quad \text{(Equation 6.2.1.2-d)}$$

$$= (0.4)(3.7) + 1.665 = 3.145 \text{ in.}$$

$$\frac{\bar{y}_H S_{H_e}}{b_W S_W} = \frac{(3.145)(18.24)}{(24.0)(144.0)} = 0.0166$$

Calculate the body vortex interference factors from Section 4.3.1.3

$$\frac{r}{b_{H_e}/2} = \frac{1.665}{3.7} = 0.45$$

$$\alpha\left(\frac{x - x_s}{r}\right) = \frac{\alpha}{57.3}\left(\frac{36.59}{1.665} - \frac{x_s}{r}\right) = \frac{\alpha}{57.3}\left(21.98 - \frac{x_s}{r}\right)$$

6.2.2 YAWING MOMENT DUE TO ASYMMETRIC DEFLECTION OF CONTROL DEVICES

6.2.2.1 YAWING MOMENT DUE TO CONTROL DEFLECTION

Yawing moments due to aileron deflection arise from two sources. The first is the asymmetric change in the induced drag of the wings; the induced drag of the wing with the down-going aileron increases and that of the wing with the up-going aileron decreases. The second is the increase in profile drag due to flap deflection. The profile drag increases almost equally for positive and for negative flap deflections. The yawing moments due to the profile-drag increments of antisymmetrically deflected ailerons therefore tend to cancel. The methods of this section for estimating the yawing moment due to aileron deflection are derived from induced-drag changes and neglects contributions due to profile drag.

For spoilers that deflect on one wing panel at a time, the profile drag cannot be neglected. The methods presented for estimating the yawing moment due to spoiler deflection therefore include the contributions due to induced-drag and profile-drag changes.

Additional discussion on the aerodynamic aspects of aileron and spoiler controls is found in Sections 6.1.1.1, 6.1.1.2, 6.1.1.3, and 6.2.1.1.

A. SUBSONIC

DATCOM METHODS

Aileron-Type Controls

The method for determining the yawing moment of plain trailing-edge-flap controls is taken from Reference 1 The method is empirical in nature and is based on a limited amount of test data.

For aileron-type controls that extend to the wing tip, the yawing moment due to aileron deflection resulting from the unsymmetrical change in induced drag may be approximated by

$$C_n = KC_L C_{l_\delta} \frac{(\delta_L - \delta_R)}{2} \qquad 6.2.2.1\text{-a}$$

where

- K is an empirical factor, depending upon planform geometry, obtained from Figure 6.2.2.1-9. This design chart is taken from Reference 1 and is based on the data of References 2 through 7.
- C_{l_δ} is the rolling effectiveness of the aileron (per radian), obtained by using the method of Paragraph A of Section 6.2.1.1 for the appropriate subcritical Mach number.
- C_L is the lift coefficient for zero aileron deflection.
- δ_R is the right-hand control deflection in radians (positive trailing edge down).
- δ_L is the left-hand control deflection in radians (positive trailing edge down).

For aileron-type controls not extending to the wing tip, Equation 6.2.2.1-a is used to compute the difference in the yawing moments of two hypothetical ailerons—one extending from the inboard location of the actual aileron to the wing tip and the other extending from the outboard location of the actual aileron to the wing tip. The difference in the yawing moments of these two hypothetical ailerons gives the yawing moment of the actual aileron.

The method is valid for attached-flow conditions only; i.e., wing angle of attack and control deflection where no flow separation exists.

A sample problem illustrating the use of this method is presented on Page 6.2.2.1-3.

Not enough test data are available to permit either an independent verification or an extension of this method. Therefore, caution should be used in applying the method to configurations whose geometric parameters fall outside the ranges of those of the configurations of References 2 through 7 (see Figure 6.2.2.1-9).

Spoilers

Plug and Flap-Type Spoilers

The subsonic yawing moment due to spoiler deflection is obtained from Figures 6.2.2.1-10 and 6.2.2.1-11 for straight wings and swept wings, respectively. The charts are from Reference 1 and are based on the data of References 6 through 11. They are applicable to plug and to flap-type spoilers at zero angle of attack and for spoiler heights above the wing surface between 2 and 10 percent of the local wing chord. However, the applicability of the charts to inboard spoilers on swept wings is questionable.

Not enough experimental data are available to permit either an independent verification or an extension of this method. Therefore, the method is limited to the ranges of parameters presented on the design charts. It should be noted that the swept-wing design chart is based on test data from configurations with a constant spoiler chordwise location of 0.70c.

The design chart values of C_n are for a spoiler deflected on one panel based on the total wing area and wing span.

Sample Problem 2 on Page 6.2.2.1-4 illustrates the use of this method.

Spoiler-Slot-Deflector

The use of spoiler-slot-deflector combinations increases the effectiveness and hence the yawing moment due to spoiler deflection. The yawing moment due to a spoiler-slot-deflector combination at zero angle of attack, where the spoiler deflection is equal to the deflector deflection ($\delta_s/\delta_d = 1.0$) is given by

$$(C_n)_{\text{spoiler-slot-deflector}} = K\,(C_n)_{\text{plain spoiler}} \qquad 6.2.2.1\text{-b}$$

where

K — is the ratio of the yawing-moment coefficient of a spoiler-slot-deflector to that of a plain spoiler, obtained from Figure 6.2.2.1-12 as a function of the compressible sweep parameter $M \cos \Lambda_{c/4}$. This chart is based on data from References 12 through 14.

$(C_n)_{\text{plain spoiler}}$ — is the yawing-moment coefficient of a plain flap-type spoiler deflected on one wing panel, based on the total wing area and span, obtained from either Figure 6.2.2.1-10 or 6.2.2.1-11.

For higher angles of attack, a decrease in C_n due to plug and to flap spoilers is experienced. As the stall is approached, the yawing moment for these spoilers becomes zero. The use of a slot and deflector in combination with a plug or a flap spoiler improves its effectiveness at high angles of attack (see Section 6.2.1.1) and hence gives a significant yawing-moment increment for these angles.

Not enough test data are available to extend this method to configurations employing differential spoiler-deflector deflections.

Application of this method is illustrated by Sample Problem 3 on Page 6.2.2.1-4.

Sample Problems

1. Aileron-Type Control

Given: The wing-control configuration of Reference 4.

Wing-Control Characteristics:

$A_W = 3.94$ $\quad \lambda_W = 0.625$ $\quad \Lambda_{LE} = 42^o$ $\quad b_W = 11.38$ ft

$S_W = 32.8$ sq ft $\quad \frac{y_i}{b_W/2} = 0.50$ $\quad \delta_L = 15^o$ $\quad \delta_R = -15^o$

Additional Characteristics:

Low speed

α (deg)	C_L	C_{l_δ} (per rad)	
2	0.110	0.1180	Test results
4	0.230	0.1158	
6	0.350	0.1126	

Compute:

$K = -0.261$ (Figure 6.2.2.1-9)

$\frac{\delta_L - \delta_R}{2} = 15^o = 0.262$ rad

Solution.

$$C_n = KC_L C_{l_\delta} \frac{(\delta_L - \delta_R)}{2} \text{ (Equation 6.2.2.1-a)}$$

$$= (-0.261)(0.262) C_L C_{l_\delta}$$

$$= -0.0684 C_L C_{l_\delta}$$

①	②	③	④	⑤	⑥
α (deg)	C_L	C_{l_δ} (per rad)	②③	$(C_n)_{calc}$ -0.0684 ④	$(C_n)_{test}$
2	0.110	0.1180	0.01298	-0.00089	-0.0010
4	0.230	0.1158	0.02663	-0.00182	-0.0018
6	0.350	0.1126	0.03941	-0.00270	-0.0026

These test data have been used in the derivation of Figure 6.2.2.1-9; therefore, the sample problem is not an independent verification of the method.

2. Spoiler

Given: The wing-control configuration of Reference 15.

Wing-Control Characteristics:

S_W = 324 sq in. $\quad \lambda_W = 0.60 \quad A_W = 4.0 \quad b_W$ = 36.0 in. $\quad \Lambda_{LE} = 35.1^o$

Flap-type spoiler $\quad x_s/c = 0.70 \quad \frac{b_s}{b_W/2} = 0.50$

$\frac{y_o}{b_W/2} = 0.639 \quad \frac{\delta_s}{c} = 0.025, 0.05, 0.075, 0.100$

Solution:

$\frac{\delta_s}{c}$	$\frac{C_n}{\delta_s/c}$ Fig. 6.2.2.1-11	C_n Calc	C_n Test
.025	0.04	0.0010	0.00085
.050	0.04	0.0020	0.0020
.075	0.04	0.0030	0.0031
.100	0.04	0.0040	0.0034

3. Spoiler-Slot-Deflector

Given: The wing-control configuration of Reference 15. This is the configuration of Sample Problem 2 with the addition of a slot opening and a hinged deflector.

Wing-Control Characteristics:

S_W = 324.0 sq in. $\quad b_W$ = 36.0 in. $\quad \Lambda_{c/4} = 32.6^o \quad \frac{\delta_s}{c} = \frac{\delta_d}{c}$

The following test values of $(C_n)_{\text{plain spoiler}}$:

$\frac{\delta_s}{c}$	$(C_n)_{\text{plain spoiler}}$ (test results from Ref. 15)
.025	0.00085
.050	0.0020
.075	0.0031
.100	0.0034

Additional Characteristics:

$M = 0.40$

Compute:

$M \cos \Lambda_{c/4} = 0.40\ (0.8425) = 0.3370$

$K = 2.33$ (Figure 6.2.2.1-12)

Solution:

$(C_n)_{\substack{\text{spoiler-}\\\text{slot-}\\\text{deflector}}} = K\,(C_n)_{\substack{\text{plain}\\\text{spoiler}}}$ (Equation 6.2.2.1-b)

$\frac{\delta_s}{c}$	$(C_n)_{\text{plain spoiler}}$	$(C_n)_{\text{spoiler-slot-deflector}}$ Calc	$(C_n)_{\text{spoiler-slot-deflector}}$ Test
.025	0.00085	0.0020	0.0025
.050	0.0020	0.0047	0.0042
.075	0.0031	0.0072	0.0080
.100	0.0034	0.0079	0.0090

B. TRANSONIC

Force and moment characteristics at transonic speeds are difficult to generalize because of the nonlinear nature of the flow equations and interacting shock-wave–boundary-layer separation effects (see Section 4.1.3.2). The method presented here is intended to give a first-order approximation only and to provide a guide to aid in fairing between subcritical and supersonic speeds.

DATCOM METHOD

No specific charts are presented for determining the transonic yawing moment of lateral-control devices. The best source of information of this type is experimental data on similar configurations. If such information is not available, the following approach may be used as a guide in fairing between subcritical and supersonic speeds.

A first-order approximation of the transonic yawing moment of lateral-control devices is given by

$$C_n = (C_n)_{M=0.6} \frac{C_{L_\alpha}}{(C_{L_\alpha})_{M=0.6}} \qquad 6.2.2.1\text{-c}$$

where

$(C_n)_{M=0.6}$ is the yawing moment of the control at $M = 0.6$, obtained by using the appropriate method of Paragraph A of this section.

(C_{L_α}) is the transonic wing-lift-curve slope, obtained from Paragraph B of Section 4.1.3.2.

$(C_{L_\alpha})_{M = 0.6}$ is the wing-lift-curve slope at M = 0.6; obtained by using the straight-tapered-wing method of Paragraph A of Section 4.1.3.2 (Figure 4.1.3.2-49).

It should be noted that this approximation applied to spoilers neglects the effect of transonic wave drag, which can be very significant. Therefore, when applied to spoilers, the method should be considered only for the purpose of establishing the trend through the transonic region, and not as an approximation of the magnitude of the yawing moment.

C. SUPERSONIC

Methods are presented at supersonic speeds for approximating the yawing moment due to aileron-type controls and to plug or to flap-type spoilers. No method is presented for estimating the supersonic yawing moment due to spoiler-slot-deflectors. Published test data on spoiler-slot-deflector characteristics at supersonic speeds are extremely limited. References 16 and 17 present test data on spoiler-slot-deflector controls at supersonic speeds.

DATCOM METHOD

Aileron-Type Controls

Supersonic values of yawing moment due to flap deflection are obtained from Figure 6.2.2.1-13. This chart is taken from Reference 1 and is based on the method of computing drag due to lift in Reference 18 and on a limited amount of test data from References 19 and 20.

Not enough test data are available to permit either an independent verification or an extension of this method. Therefore, caution should be used in applying the method to configurations whose geometric parameters fall outside those of the configurations of References 19 and 20 (see Figure 6.2.2.1-13).

Spoilers

Plug and Flap-Type Spoilers

The supersonic yawing-moment coefficient due to spoiler deflection of a plug or a flap-type spoiler, deflected on one panel, based on the total wing area and span, is obtained from Figure 6.2.2.1-14 as a function of Mach number and configuration geometry. The design chart is based on the data from References 10 and 21 through 23.

A comparison of test values with results calculated by using this method is presented as Table 6.2.2.1-A.

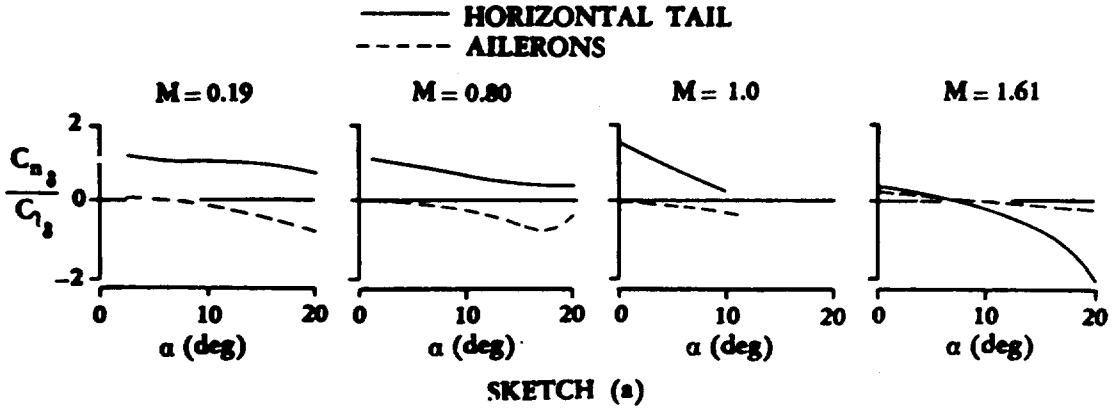
6.2.2.2 YAWING MOMENT DUE TO A DIFFERENTIALLY DEFLECTED HORIZONTAL STABILIZER

No methods are available for estimating the yawing moments due to a differentially deflected horizontal stabilizer, and the data available for correlation are limited. However, a brief discussion, taken essentially from Reference 1, is given pertaining to the qualitative and quantitative aspects of yawing moments associated with tail roll control.

Associated with tail roll control are yawing moments, varying in magnitude and direction as a function of Mach number, angle of attack, and vehicle geometry. These yawing moments can be attributed to (1) the pressure differential induced on the vertical tail as a result of the differentially deflected horizontal tail, (2) the drag component associated with each horizontal-tail panel, and (3) the dihedral of the horizontal tail. For most configurations and test conditions, the differential pressure on the vertical tail is the dominating factor.

Yawing-moment data are generally presented in the form of the parameter $C_{n_\delta}/C_{l_\delta}$ (ratio of yawing moment to rolling moment produced by roll control). For low-horizontal-tail configurations, tail roll control up to $M \approx 1.0$ produces very large favorable yawing moments, which decrease with increasing angle of attack but tend to remain positive over the angle-of-attack range ($\alpha \approx 0$ to $22°$) for which test data are available. These large yawing moments are due primarily to the induced pressure differential on the vertical panel. This pressure differential on the vertical tail also tends to reduce the rolling moment for a low-tail configuration.

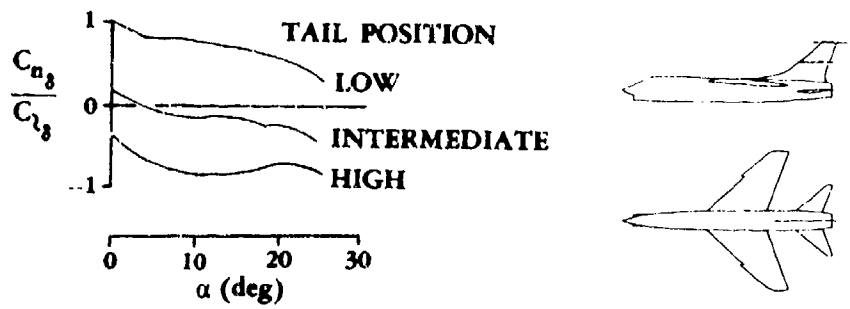
At supersonic speeds, the load carry-over from the horizontal tail to the vertical tail decreases with increasing Mach number. The attendant result is that at supersonic speeds the tail roll control will produce smaller favorable yawing moments at low angles of attack and possibly adverse yawing moments at high angles of attack. For a specific configuration, if the Mach number is high enough, adverse yaw due to tail roll control is a possibility throughout the angle-of-attack range. Sketch (a) presents representative yawing-moment data produced by roll control for a low-tail configuration as a function of Mach number and angle of attack.



SKETCH (a)

The vertical position of the horizontal tail is the most important parameter in determining the relative magnitude and direction of the yawing moment due to roll control (References 1 and 2). The variations in yawing moment due to roll control shown in Sketch (b) are representative of the

effect of the horizontal-tail location. These variations would enable the designer to position the horizontal tail to avoid large undesirable yawing moments, longitudinal stability permitting. In this connection, it may also be pointed out that if a ventral fin is used on the airplane for high-speed stability, the yawing moments for a low tail position would be smaller. If the yawing moments cannot be adjusted to a satisfactory value by positioning the tail, it might be necessary to adjust them by linking the rudder in with the tail roll control.

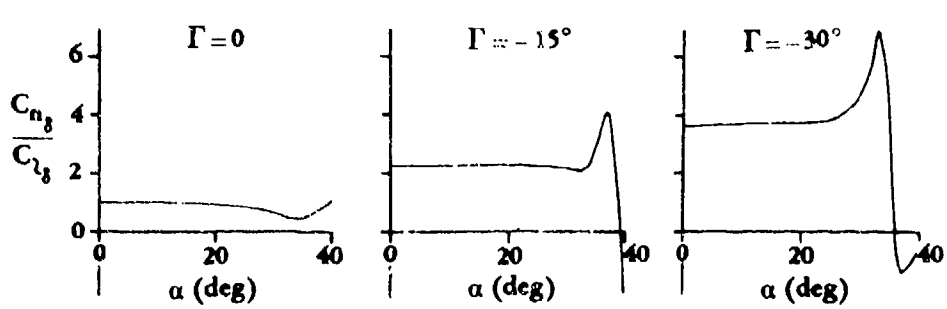


SKETCH (b)

Dihedral Effects

The results of dihedral variation on yawing moment due to roll $C_{n_\delta}/C_{l_\delta}$ are of significant importance. The lateral component of the horizontal-tail loads increases with negative dihedral, and the load induced on the vertical tail by differential horizontal-tail deflection is reduced by increases in negative dihedral. The combined effect of these two phenomena is a substantial increase in the yawing-moment parameter $C_{n_\delta}/C_{l_\delta}$ with increasing negative dihedral angle over a large angle-of-attack range. The variation of the yawing moment due to tail roll control is shown in Sketch (c) (Reference 3). Consequently, if negative tail dihedral is employed on a low-tail configuration to improve the linearity of the pitching-moment curves, for example, and differential tail deflection is utilized to augment low-speed roll control; then the favorable yawing moment associated with tail roll control will be aggravated further. Of course, if a ventral fin is employed on the configuration, the loads induced on the ventral would be increased, tending to offset the additional yawing moment due to negative dihedral; however, this effect would not be strong enough to cancel the effect created by negative dihedral. On the other hand, for low-tail configurations at supersonic speeds where the yawing moment due to tail roll control is adverse, negative tail dihedral would be favorable.

SUBSONIC SPEEDS



SKETCH (c)

Flap Effects

The effects of flaps on yawing moment due to roll control are shown for two different configurations in Sketch (d). Both configurations show a substantial increase of $C_{n_\delta}/C_{l_\delta}$ with flap deflection at low lift coefficients. This increase is primarily the result of a decrease in roll effectiveness C_{l_δ}.

6.2.3 SIDE FORCE DUE TO ASYMMETRIC DEFLECTION OF CONTROL DEVICES

The side-force increment due to the asymmetric deflection of control devices on a plain wing is usually small enough to be neglected. At supersonic speeds, however, strong shock waves can be generated from deflected controls. These shock waves frequently impinge on vehicle components and cause considerable forces and moments by means of their direct pressure effect and by boundary-layer-separation effects.

For the purpose of the Datcom, it is assumed that the side force due to asymmetric control deflection is sufficiently small to be neglected. Some data on the side force due to asymmetric control deflection on wing-body combinations at supersonic speeds may be found in reference 1.

6.3 SPECIAL CONTROL METHODS

6.3.1 AERODYNAMIC CONTROL EFFECTIVENESS AT HYPERSONIC SPEEDS

The interest in aircraft and re-entry vehicles operating at hypersonic speeds has created the need for establishing preliminary-design methods for predicting the effectiveness of aerodynamic controls of such vehicles at hypersonic speeds.

This section presents a procedure, taken from reference 1, for applying the correlation results presented in reference 1 to the prediction of hypersonic control effectiveness.

The development of efficient hypersonic vehicles involves solutions of complex problems associated with the severe environment of hypersonic flight. Control characteristics, particularly at hypersonic speeds, are greatly affected by flow separation phenomena. Flow separation can occur ahead of deflected flaps, on the leeward side of a surface inclined at large angles of attack, near the impingement of a shock wave upon the boundary layer of a body, and on a curved surface. Control effectiveness may be increased, limited, or completely nullified because of boundary-layer separation. Pressure distributions over the control and the basic configuration can be greatly altered because of separation effects. Heat-transfer rates are changed on the control surfaces and the basic configuration both upstream and downstream of the control. The interaction region is characterized by a reduction of local heating rates in the separated region and a substantial heating rate increase at the reattachment point. It is therefore essential to understand the flow-separation phenomena and to describe the flow conditions in the separated region.

In reference 1, semiempirical correlations are developed for the characteristic parameters of a separated flow at hypersonic speeds. These correlations describe the pressure and heat-transfer distributions in terms of local flow properties by defining characteristic magnitudes and distance parameters. Knowing these quantities, relations for incremental aerodynamic force and moment coefficients are developed.

In order that the Datcom user may better understand the control effectiveness methods presented in this section, general discussions of hypersonic flow separation and the effects of the influence of separation on controls are presented. These general discussions are essentially quoted from reference 2 and present only the salient aspects of hypersonic-flow separation and its influence on aerodynamic controls. The reader can obtain a more thorough review of hypersonic-flow separation phenomena from references 1 and 3.

HYPERSONIC-FLOW SEPARATION

Separated flows are characterized by the prevailing type of boundary layer: laminar, turbulent, or transitional. The pressure rise and the extent of the separated region depend upon the characteristics of the boundary layer.

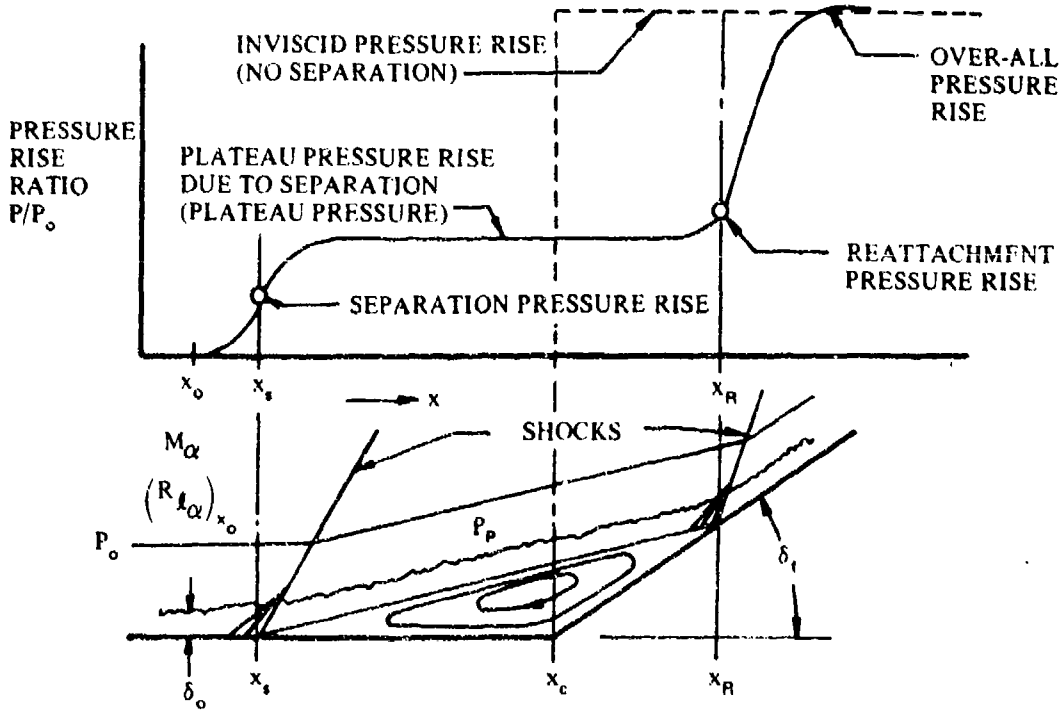
In general, boundary-layer separation occurs whenever the streamwise pressure increase along a surface is sufficient to overcome the forces acting to accelerate a fluid particle, or when the streamline curvature necessary to follow the surface contour cannot be sustained by the pressure gradient normal to the surface. In steady-flow aerodynamic problems the only forces acting to accelerate the low-momentum fluid near the wall against a pressure gradient are the shear forces between layers of fluid. Because the momentum of the fluid near the wall is quite low, a relatively small amount of deceleration by the pressure gradient is sufficient to bring about separation. Turbulent flow helps to delay the occurrence of separation, because the turbulent fluctuations increase the effective shear forces and thereby increase the adverse pressure force necessary to reverse the flow of the fluid near the wall.

The greatly increased effective viscosity due to turbulent fluctuations enables the equilibrium between pressure and shear forces near the wall to occur at much greater adverse pressure rises in turbulent boundary layers. Because of the connection between pressure rise and flow turning angle, this higher pressure corresponds to a much shorter, thicker separated zone for the same initial boundary-layer thickness. Cases presented by Schlichting (reference 4) and Howarth (reference 5) show turbulent pressure rises twice the lami-

nar ones, while the laminar separation zone extends 10 times farther than the turbulent one. A similar thickening (and simultaneous pressure rise) occurs in a transitional separation when the mixing zone becomes turbulent, and the downstream flow soon approaches a condition very similar to the equivalent turbulent separation. Upstream of the transition point, the flow has the character of the corresponding laminar separation zone. The location of the transition point therefore plays a distinct role in determining the pressure distribution (see references 6 and 7).

Present indications are that shock-induced laminar separation pressure distributions, and to a limited extent turbulent ones, are independent of the type of geometry producing separation (see reference 6). However, the turbulent peak pressure rise often depends significantly on geometry (references 6 and 8 through 11). This difference in dependence can probably be attributed to the greatly increased effective viscosity in turbulent flow enabling the wall contour within the separated zone to transmit its effect more strongly to the outer flow.

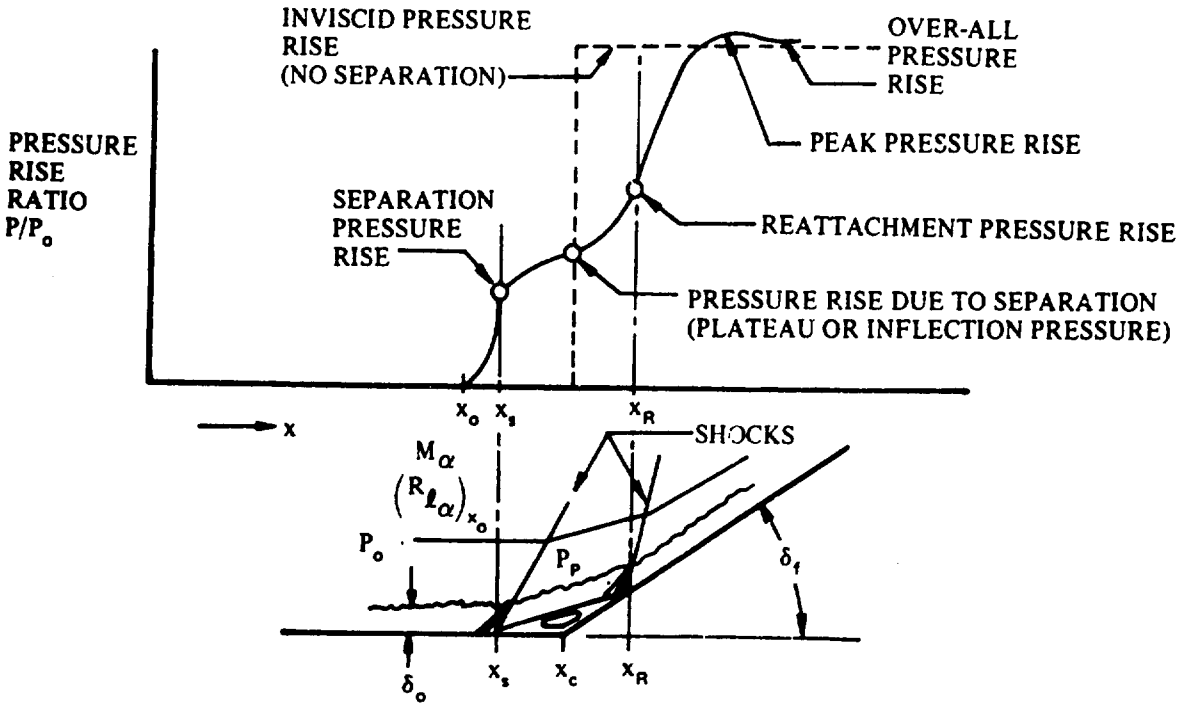
Typical surface pressure distributions for laminar and turbulent boundary layers are presented in sketches (a) and (b), respectively.



WALL PRESSURE DISTRIBUTION IN THE VICINITY OF LAMINAR SEPARATION

SKETCH (a)

The laminar boundary layer has a characteristic plateau where the pressure remains almost constant over most of the separated flow region. The separation pressure coefficient is based on the pressure rise from the undisturbed stream to the separation point. As explicitly mentioned by Love (reference 12), this is not to be confused with the pressure rise needed to cause separation.



WALL PRESSURE DISTRIBUTION IN THE VICINITY OF TURBULENT SEPARATION

SKETCH (b)

The separated turbulent boundary-layer pressure distribution has no plateau region but rises to an inflection value. The final pressure after reattachment is usually that given by inviscid theory. Occasionally, a situation arises wherein there is a pressure rise above the inviscid value followed by an expansion to the inviscid value. This is caused by a lower local entropy level due to the multiple-shock compression of the inviscid flow near the separation and reattachment points. The multiple-shock compression is a more efficient process than the single-shock compression, resulting in a higher local total pressure. It has been observed occasionally in three-dimensional hypersonic separation, and there is good reason to expect it in other situations at high Mach numbers where multiple oblique-shock compression can exist.

The critical pressure-rise coefficient, referred to herein as the incipient pressure-rise coefficient $C_{p_{inc}}$, corresponds to the minimum over-all pressure for which separation will occur (see references 4, 7, 9, 10, 12, and 13). The current indications are that it is independent of the particular geometry causing the pressure rise (see references 11 and 14), although this may not prove to be a general rule. $C_{p_{inc}}$ is much greater and is a much weaker function of Reynolds number for turbulent boundary layers ($C_{p_{inc}} \sim (R_\ell)^{1/10}$) than for laminar boundary layers ($C_{p_{inc}} \sim (R_\ell)^{1/4}$). Recent correlations presented in reference 1 substantiate this 1/4-power Reynolds-number dependence for laminar boundary layers; however, the range of Reynolds numbers of the available test data is too small to validate the 1/10-power relation for turbulent boundary layers. Nevertheless, this dependence does correlate the available turbulent data over the ranges of the test conditions.

The pressure rise due to separation (plateau pressure) is of the same order of magnitude as the critical pressure rise, and exhibits the same type of dependence on Mach and Reynolds numbers. Detailed correlation formulas for predicting the pressure-distribution parameters in various situations are developed in reference 1, and are presented in the Datcom method in the form of design charts.

Two further points should be made concerning the general characteristics of laminar and turbulent separations. First, the high altitudes and large stream-to-wall temperature ratios characteristic of hypersonic flight greatly increase the probability of finding laminar flow. And second, the large viscous interaction associated with high Mach number and low Reynolds number will often make it very difficult to determine experimentally or theoretically whether separation has even occurred, let alone the separation location. For those conditions where separation is difficult to detect, the effect of separation on loads is quite small, but the understanding of the flow and the prediction of heat transfer and flow stability become uncertain.

The stability and steadiness of separated flows cannot be predicted with certainty using present information. In general, cavities appear to be the most unstable type of separated geometry. Unsteadiness can result from a hysteresis between laminar and turbulent separated-zone conditions if the flow conditions and geometry are of certain types, e.g., a sharply deflected ramp near the transition point of a flat plate. Whether all separated-zone instabilities are associated with transition or whether other mechanisms participate must be determined by future investigations. The resonant frequency of a cavity would be one important parameter in such an investigation. Violent macroscopic flow fluctuations affect heat-transfer rates and wall shear forces near the separation and reattachment points because of the Reynolds stress effect.

The relationships between heat transfer and separation in laminar and turbulent flow are poorly understood. Chapman (reference 15) theoretically estimates a ratio of heat transfer in a laminar separated zone to that in the attached layer, of 0.56. The experiments of Larson (reference 16) substantiate this estimate. Chapman mentions that turbulent separation regions can have heat-transfer rates as high as six times the equivalent rates for the attached layer at low Mach numbers, but this ratio decreases greatly with increasing Mach number. The turbulent-flow measurements of Larson do not show this high ratio at low Mach numbers, but the theory appears to approach the measurements at high Mach numbers. Larson states that the discrepancy is probably due to the failure of the theory to include the proper temperature – heat-transfer relationships for the experiments. It appears doubtful whether very large increases in heat transfer will ever be found in steady, separated regions. In short, turbulent and transitional separations may lead to heat-transfer rates higher than the equivalent attached boundary layer, but at high Mach numbers the ratio appears to be about 0.50 to 0.70, which is not indicated satisfactorily by present theory. Local increases in heat-transfer rate near reattachment are mentioned in reference 16, but these were not always found by the other investigators mentioned in reference 16.

The converse effect, i.e., the effect of heat-transfer on separation characteristics, is also not understood (see references 16 through 25). Sogin states in his survey report (reference 24) that there is much disagreement between theory and experiment regarding the effects of heat transfer on either laminar or turbulent separated flows. Thus, theoretical results for laminar boundary layers (references 17 through 23 and 32 and 33) indicate separation should be delayed by cooling; experimental results in references 32 and 33 tend to substantiate this theory, while those in references 16 and 26 through 28 do not. Gadd further states that if the turbulent boundary layer could be treated analytically it should also show separation delayed by cooling (references 26 and 27), but poor experimental agreement is obtained. The resolution of this uncertainty is very important, as it bears directly on the application of wind-tunnel data (equilibrium wall) to flight problems (usually cold wall).

INFLUENCE OF SEPARATION ON CONTROLS

Control characteristics, particularly at hypersonic speeds, are often greatly affected by separation. As previously noted, control effectiveness may be increased, limited, or completely nullified because of boundary-layer separation. Pressure distributions over controls and on the basic configuration may be greatly altered due to separation effects, changing drastically the moment coefficients predicted by inviscid theory. Heat-transfer rates are changed on the control surfaces and on the basic configuration both upstream and downstream of the control. Separation effects must therefore be considered in both the design and loca-

tion of controls. In general, separation tends to smooth out the sharp changes in pressure distributions predicted by inviscid theory, and can cause local "hot spots" which have heat-transfer rates many times higher than those that would exist for attached boundary layers. Separated flow phenomena are frequently unsteady and three-dimensional in nature, and undergo large changes with transition from laminar to turbulent flow, further complicating the analytical treatment of a design. Thus, for example, hysteresis effects are noticeable in the C_m versus α curves for some control configurations.

Aerodynamic forces and moments on a vehicle may be changed as much by changing the pressure distribution on the basic configuration as they would be by changes in the normal forces acting on controls. Leading-edge controls, for example, usually are not directly influenced by separation but, by causing separation, they can affect the pressures and heat-transfer rates over the entire configuration. Some effects of separation associated with controls on windward and leeward surfaces and some important three-dimensional and unsteady flow effects of separation on control characteristics are presented below.

Leading-Edge Controls

Leading-edge controls contemplated for hypersonic vehicles include flaps, spoilers, fins, spikes, and all-movable noses. The importance of separation for such controls is in the influence on the entire flow field downstream of the control. Separation behind a deflected leading-edge flap makes any control or stabilizing surface downstream of the flap ineffectual. Heat-transfer rates on the surface are reduced in the separated-flow region, but if the boundary layer reattaches on the surface the heat-transfer rate at reattachment can be several times larger than that for an attached boundary layer. The control forces and hinge moments of leading-edge fins and flaps would not be directly influenced by separation. Fins, which may be canards, create strong vortices which can cause boundary-layer transition and contribute to the possibility of unsteady flow over the downstream surfaces of the configuration. Comparable effects would be expected for large amounts of all-movable nose deflection which, nevertheless, is anticipated to be a very effective trimming device at high angles of attack. The importance of leading-edge controls in influencing the entire afterbody is epitomized by the use of spikes. Flow-separation spikes in front of blunt bodies may reduce the total drag of the body by effectively streamlining it. Average heat-transfer rates in the separated-flow region created by the spike are significantly reduced in laminar flow, although the local heat-transfer rate at reattachment may be quite high. Deflectable spikes might be used as control devices because they alter the pressure distribution in the forward region of a body. The separated-flow region caused by spikes, however, is frequently unsteady, which is a most unsatisfactory control characteristic. If these problems can be worked out, spike controls could become a very effective system for blunt vehicles.

Downstream Controls

Frequently control surfaces located downstream of the leading edge are also used as stabilizing devices. Their effectiveness, however, may be greatly affected by upstream separation of the boundary layer. The inviscid estimate of the pressure rise due to deflecting a control into the local stream is a discontinuous jump in the pressure distribution on the surface at the leading edge of the control. A similar sudden increase in the inviscid pressure distribution occurs at the trailing-edge shock required to recompress the flow over an expansion surface. In the actual flow, the sudden pressure rise may be transmitted upstream through the subsonic portion of the boundary layer, and separation may occur far upstream as a result. This is particularly likely for hypersonic flow, where shocks are highly swept, and for laminar boundary layers, which have thicker subsonic portions than turbulent boundary layers. Depending upon flow conditions, the boundary layer may be separated over the major portion of the surface, thereby greatly influencing the effectiveness of controls located downstream on either compression or expansion surfaces.

Laminar boundary-layer separation ahead of a deflected flap on the windward surface of a vehicle spreads the flow-deflection pressure rise over a much larger region than does turbulent separation. The effectiveness of the flap in creating a moment is lessened both by the decrease in the pressure distribution on the flap and by any pressure increase occurring on the surface upstream of the moment reference center. These effects tend to restrict the desired rearward movement of the center of pressure and reduce the effectiveness of the control. In extreme cases the center-of-pressure location with laminar separation may be well forward of that for a turbulent boundary layer.

The extent of the separated-flow region and the pressures imposed on the surface depend on the flap deflection, flow conditions, and nature of the boundary layer ahead of the flap. Reattachment of the separated flow on the flap is usually accompanied by a local heat-transfer rate several times larger than that corresponding to an attached boundary layer; the average heat transfer to the separated-flow region, however, is reduced. Similarly, separation affects the pressure distribution on vehicles having flared-skirt-type stabilizing surfaces. Laminar boundary-layer flow ahead of small protuberances yields pressure distributions closer to the inviscid predictions than does turbulent flow. A small step on a surface is effectively streamlined by laminar separation far ahead of it, whereas for turbulent separation, a strong shock exists ahead of the step and there is a large increase in the local pressure.

Separation on the leeward side of a vehicle may make shielded controls (i.e., controls which do not "see" the free stream) useless. Several factors combine in making leading-edge separation from the leeward surface of hypersonic vehicles particularly probable. Large angles of attack may be desirable for many hypersonic flight paths. Because high Mach number flows have small limiting expansion angles, much of the upper surface feels only the leakage flow from the boundary layer where the Mach number is lower. The pressure rise due to the strong trailing-edge shock may be propagated far forward through the thick hypersonic boundary layer, thus increasing the possibility of leading-edge separation.Another factor enhancing the probability of separation is the likelihood of the boundary layer being laminar with consequently thicker subsonic regions and at the same time less able to overcome an adverse pressure gradient than the corresponding turbulent boundary layer. The effectiveness of controls located entirely within the separated-flow region, such as trailing-edge flaps or fins, would be nullified. On the other hand, flow separation over notches (cavities) may advantageously be used to control the drag of a hypersonic vehicle; for essentially the same average rate of heat transfer to a hypersonic vehicle, the drag may be increased by an order of magnitude by the employment of notches in the surface of the vehicle. Separation influences both the type and the location of control devices. Spoilers, for example, would be ineffectual on leeward surfaces of hypersonic vehicles even if they were near the leading edge. Positive controls that always "see" the free stream are required.

Three-Dimensional and Unsteady Flow Effects

Separated-flow regions rarely are purely two-dimensional and usually are unsteady. Although much insight into separation phenomena may be gained by using two-dimensional flow analyses, there are important effects that must be considered three-dimensionally. One such effect is the large venting of the separated region in front of a ramp of finite span. The fluid in the separated region, having low velocity and relatively high pressure, expands readily into the low-pressure stream at the tip, and the mass balance of the two-dimensional separation is upset. Another case is that associated with the streamwise flow in the corner at the juncture of a fin and the surface of the configuration. A strong vortex may be set up in such a corner with extreme rates of heat transfer associated with the vortical motion. Another important three-dimensional effect is the coupling effect of a control on another surface. The shock wave ahead of a blunt control or ahead of a separated-flow region may impinge on a transverse surface. Thus, the deflection of a vertical fin or rudder may cause nonsymmetrical separation on the horizontal surface and create an undesired rolling or pitching moment. Particularly for separation occurring near the point of transition of a laminar to turbulent boundary layer, the point of separation and the associated shock wave may

oscillate about some mean position. Large buffeting loads may be experienced on the surface and on adjoining surfaces of the configuration. Unsteady flow in cavities in the surface of a missile may also cause structural failure. Laminar boundary-layer separation with large center-of-pressure shift may be experienced at a small control deflection, while if the deflection is increased and then decreased to its initial value, the separation may be turbulent with a far different value of pitching moment because of the different center-of-pressure location. This hysteresis is extremely difficult to predict, and can be quite dangerous.

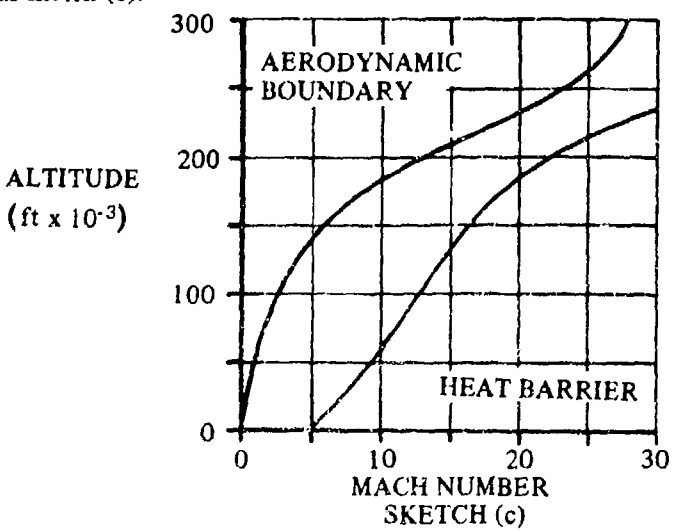
In high Mach number flows, the pressure loads produced by compression surfaces are much greater than those produced by expansion surfaces. Consequently, the most effective aerodynamic controls usually employ deflections which involve compression of the local flow. Therefore, shock-induced separation, either ahead of a compression surface or due to an incident shock, is the type most prevalent with hypersonic controls and has been treated most extensively in the literature.

When separation occurs in high-speed flight, the changes in the pressure distribution and heat-transfer rate can have catastrophic effects. Trim and stability are radically affected by sudden center-of-pressure shifts and changes in pressure magnitude. Local hot spots at separation and reattachment points can cause failure of thermal protection. Heat-transfer rates can also be greatly increased by streamwise vortices originating from three-dimensional separations.

HYPERSONIC CONTROL EFFECTIVENESS

The method presented in this section to determine the aerodynamic control effectiveness at hypersonic speeds is taken from reference 1. The method is intended for use over a broad range of flight conditions encountered by a typical hypersonic cruise/glide vehicle. However, it should be noted that the semiempirical correlation charts used in the method are based on presently available data covering a limited range of test conditions and that the validity of extrapolations for conditions outside the experimental range has not been established. The range of variables covered by experimental data is indicated on the correlation charts.

The flight conditions encountered by a typical hypersonic vehicle are illustrated by the altitude-velocity envelop presented as sketch (c).



SKETCH (c)

For a given velocity the maximum attainable altitude is determined by the minimum dynamic pressure which will sustain flight, and the minimum altitude is a function of the vehicle's capability to withstand aerodynamic heating. The Datcom method is restricted to free-stream flight conditions in the flight envelop for Mach numbers greater than 5.0.

The angle of attack of the vehicle is limited by vehicle performance and structural heating conditions. The angle of attack below which the L/D ratio is favorable and structural heating is not excessive is approximately 20°. Therefore, the angle-of-attack range of the Datcom method is $0 \leq \alpha \leq 20^{\circ}$. Since the study conducted in connection with reference 1 was concerned primarily with flat-plate surfaces, the angle of attack also represents the flow-deflection angle in the method that follows.

The prediction method has been derived on the basis of compression-corner flow separation. It is limited to the analysis of controls on windward surfaces, and is applicable only to regions where the assumption of two-dimensional flow is valid.

In applying the method to complex three-dimensional configurations, the degree of deviation from two-dimensional flow should be established so that the proper method of determining the local-flow properties can be selected. Then the correlations presented herein can be applied to the separated-flow region. For such approximations exact streamline direction is not as important as static pressure and Mach number. However, there can be substantial reductions in control effectiveness due to finite span. Section V of reference 1 presents some insight into methods that can be employed to determine the degree of deviation from two-dimensional flow when the actual flow is three-dimensional. The use of flow-visualization studies, and lengthwise and spanwise pressure distributions on similar models are suggested. Reference 1 presents brief summaries of separated three-dimensional flow on fin-plate configurations, flat surfaces with compression flaps and end plates, and delta wings with variations (blunt leading edges, pyramidal configurations with and without flat-bottom surfaces, etc.)

Since leeward surfaces in hypersonic flow are generally ineffective, the restriction of the method to the analysis of controls on the windward surface is not a serious limitation.

For many practical cases the control surfaces are located near the trailing edge of essentially planar surfaces and are sufficiently far from the leading edge for bluntness effects to be negligible. For such cases, the local-flow properties upstream of the control surface are approximately the same as flow conditions behind an oblique shock, and oblique-shock properties can be used to define the local-flow properties. The Datcom method is restricted to cases of this sort.

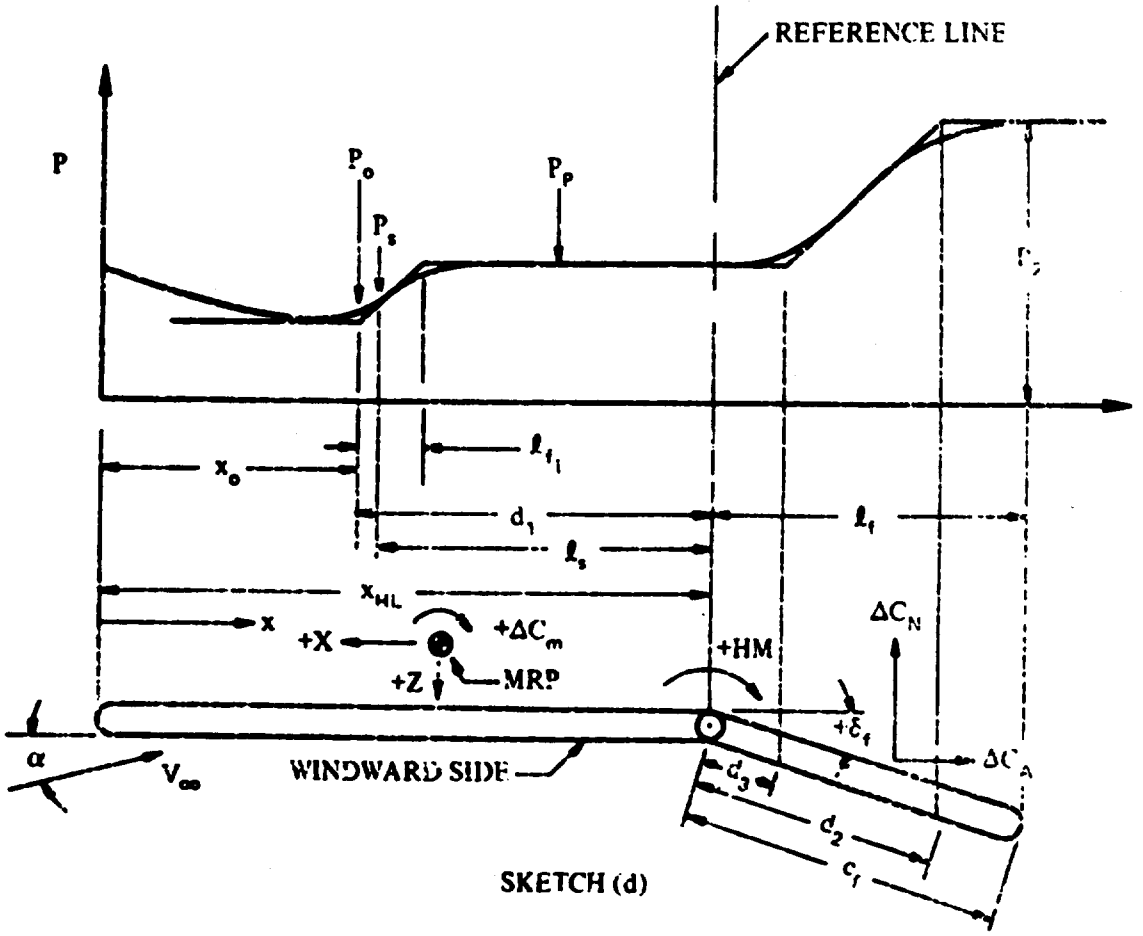
The Datcom method consists of first determining the local-flow properties upstream of the control surface. Then by using the local-flow properties, a complete pressure distribution is defined for compression-corner flow separation in terms of interaction parameters and pressure levels for either laminar or turbulent separated-flow conditions. Finally, the pressure distribution is integrated to obtain the two-dimensional force and moment increments produced by separated compression-corner flow. Force and moment equations have been developed in terms of the distances and pressure levels which define the pressure distribution. These equations are presented in the Datcom method.

The local-flow conditions have been determined by using oblique-shock properties for a number of conditions in the flight envelop. The design charts presented in this section include local-flow properties based on both perfect-gas and equilibrium-real-gas assumptions. For the flight regimes where flow properties deviate from those given by oblique-shock theory for a perfect gas, equilibrium-real-gas effects have been determined by means of similarity parameters from approximate theory and the effective ratio of specific heats presented in reference 29 (see Sections III and VI of reference 1). In using the local-flow charts (figure 6.3.1-31 through -49) the equilibrium-real-gas curves are used for velocity-altitude conditions and flow-deflection angles where the equilibrium-real-gas value differs from the perfect-gas value.

The equations used for the prediction of the separated-flow pressure distributions are developed in reference 1. Where applicable, the final equations are presented on the design charts of this section; however, the developments of the semiempirical correlations for laminar and turbulent separated flows are not discussed herein.

In reference 1 the transition phenomenon is investigated and a criterion for establishing the location of transition based on the results of Deem and Murphy (reference 30) is established. The minimum pressure rise required to cause flow separation, and incipient-separation criteria for both laminar and turbulent flow, are based on test data.

The characteristics of the separated-flow region of a typical pressure profile are illustrated in sketch (d). The distance parameters are based on a common reference line which is defined for various model configurations as a geometrical shock impingement point, hinge line (for corner flow), or the forward face of a step.



SKETCH (d)

NOTATION

Symbol	Definition
x_o	beginning of pressure interaction (point where pressure just begins to rise)
d_1	upstream pressure interaction length (distance from the beginning of interaction to the reference line)
ℓ_{f_i}	free interaction length (distance from the beginning of interaction to the point where the pressure distribution reaches the straight section of the pressure plateau)
d_2	downstream interaction length (distance from the reference line to the point of intersection of two lines tangent to the pressure curve in the downstream region, measured along the chord (see sketch (d))
d_3	distance from the reference line to the point of intersection of two lines tangent to the pressure curve as illustrated in sketch (d)
ℓ_s	separation length (distance from the separation point to the reference line)

Symbol	Definition
ℓ_f	length of the control (undeflected)
c_f	control chord
d_{LE}	diameter of leading edge
x_{HL}	distance of the control hinge line measured from the nose of the configuration
δ_f	control deflection, positive trailing edge down
b	span of surface
C_A	axial-force coefficient
C_p	pressure coefficient
C_m	pitching-moment coefficient
C_N	normal-force coefficient
HM	hinge moment
L	reference length
P	pressure
q	dynamic pressure
R_ℓ	Reynolds number
S	reference area
T	temperature
V	velocity
x	longitudinal coordinate, measured from leading edge to point of interest
α	angle of attack or flow-deflection angle
γ	ratio of specific heats
δ	boundary-layer thickness
θ	shock-wave angle measured from upstream flow direction
ϕ	angle associated with geometry of separation
Λ_{LE}	leading-edge-sweep angle

Symbol	Definition

*	reference condition

DATCOM METHOD

The control effectiveness at hypersonic speeds of a deflected control located on the windward surface is obtained from the procedure outlined in the following steps:**

Step 1. Determine the local-flow conditions:

The ratios of pressure, temperature, Mach number, and Reynolds number behind an oblique shock to their respective values in the free stream are obtained from figures 6.3.1-31, -37, -43, and -49, respectively.

**The subscript α used throughout the Datcom method has two different meanings as follows: (1) The value of the parameter being considered is its local value upstream of interaction, examples being $(C_{p\infty})_\alpha$, P_α, M_α, $R\ell_\alpha$; (2) The value of the parameter being considered is its value at some specific location downstream of interaction, referred to local conditions upstream of interaction, examples being $(C_{p_\alpha})_2$, $(R\ell_\alpha)_{HL}$, $(C_{p_\alpha})_P$.

The pressure coefficient upstream of the control surface, referred to free-stream conditions, is given by

$$(C_{p_\infty})_\alpha = \frac{(P_\alpha/P_\infty) - 1}{\frac{\gamma}{2} M_\infty^2} \qquad 6.3.1\text{-a}$$

Step 2. Determine if the flow is laminar or turbulent:

It is assumed that the state of the boundary layer is laminar if $x_t > x_{HL}$, and turbulent if $x_t < x_{HL}$. Based on the results of Deem and Murphy (reference 29) and recent experimental data, the following expression for transition distance is given in reference 1:

$$x_t(\text{feet}) = \frac{5.38 \times 10^2 + 1.94 \times 10^2 \, (M_\alpha - 3)^{3/2} (\cos \Lambda)^{1/2}}{(R\ell_\alpha/\text{in.})^{0.6}} \qquad 6.3.1\text{-b}$$

For configurations with no sweepback ($\Lambda = 0$), the state of the boundary layer at the hinge line is obtained from figure 6.3.1-55 as a function of $\left(R\ell_{\alpha/HL}\right.$ and M_α, where

$$\left(R\ell_{\alpha}\right)_{HL} = x_{HL} \left(R\ell_\alpha\right)$$

Of course, if the transition Reynolds number is known, then the transition distance is given by $x_t = \left(R\ell_{\alpha}\right)_{x_t} / R\ell_\alpha$, where $R\ell_\alpha$ is the Reynolds number per foot.

Step 3. Determine if flow separation exists:

Obtain the pressure coefficient for incipient separation $\left(C_{p_\alpha}\right)_{inc}$ from figure 6.3.1-56 for laminar flow or figure 6.3.1-57 for turbulent flow.

Obtain the final pressure-rise coefficient by

$$\left(C_{p_\alpha}\right)_2 = \frac{(P_2/P_\alpha) - 1}{\frac{\gamma}{2} M_\alpha^2} \qquad 6.3.1\text{-c}$$

where P_2/P_α is obtained from figure 6.3.1-58 as a function of M_α. For laminar flow the average of the isentropic and single-shock values should be used for $M_\alpha < 6$, and the single-shock value should be used for $M_\alpha > 6$. For turbulent flow use the single-shock value. If $\left(C_{p_\alpha}\right)_2 \geq \left(C_{p_\alpha}\right)_{inc}$, the flow is separated.

Step 4. Determine the separation location if separated flow exists:

If flow separation exists an iterative procedure is required to determine the separation location. For a given local Mach number M_α, the upstream interaction distance d_1 is a function of the plateau-pressure level P_p, which is a function of the Reynolds number at the interaction point $\left(R\ell_{\alpha/x_0}\right.$.

Therefore, for any interaction point x_o a corresponding plateau-pressure level and upstream interaction distance must be defined. In solving for the interaction location, the upstream interaction distances corresponding to a number of assumed interaction locations are calculated until the point is found for which the sum of the downstream distance to the interaction point and the upstream interaction distance is equal to the distance to the hinge line; i.e., $x_o + d_1 = x_{HL}$. The procedure is as follows:

a. Assume an interaction location x_o (For vehicles of practical dimensions the difference between x_o and x_{HL} will be small).

b. Calculate the Reynolds number for the assumed x_o by $\left(R_{\ell_\alpha}\right)_{x_o} = x_o\left(R_{\ell_\alpha}\right)$, and obtain the plateau-pressure level $\left(C_{p_\alpha}\right)_P$ as a function of $\left(R_{\ell_\alpha}\right)_{x_o}$ and M_α from figure 6.3.1-59 or figure 6.3.1-60 for laminar or turbulent flow, respectively.

c. Obtain the upstream interaction distance, nondimensionalized by boundary-layer thickness d_1/δ_o, as a function of $\left(C_{p_\alpha}\right)_P$ and M_α from figure 6.3.1-61 or figure 6.3.1-62 for laminar or turbulent flow, respectively.

d. For a given wall temperature, obtain the reference temperature Reynolds-number ratio $\left(R_{\ell_\alpha}^*/R_{\ell_\alpha}\right)$ as a function of T_w/T_α and M_α from figure 6.3.1-63 or figure 6.3.1-64 for laminar or turbulent flow, respectively.

e. Calculate the reference temperature Reynolds number by $R_{\ell_\alpha}^* = \left(R_{\ell_\alpha}^*/R_{\ell_\alpha}\right)R_{\ell_\alpha}$, and obtain the corresponding boundary-layer thickness δ_o from figure 6.3.1-65 or figure 6.3.1-66 for laminar or turbulent flow, respectively, by $\delta_o = (\delta_o/\sqrt{x_o})\sqrt{x_o}$.

f. Calculate the upstream interaction distance by $d_1 = (d_1/\delta_o)\delta_o$.

g. Sum d_1 and x_o. If $d_1 + x_o \neq x_{HL}$, repeat the procedure until $d_1 + x_o = x_{HL}$.

Step 5. Having determined the separation point x_o, define the windward pressure distribution (see sketch (d)) as follows:

a. Calculate the Reynolds number for x_o by $\left(R_{\ell_\alpha}\right)_{x_o} = x_o\left(R_{\ell_\alpha}\right)$.

b. Obtain the plateau-pressure level $(C_{p_\alpha})_P$ as a function of $\left(R_{\ell_\alpha}\right)_{x_o}$ and M_α from figure 6.3.1-59 or figure 6.3.1-60 for laminar or turbulent flow, respectively.

c. Calculate the plateau pressure, referred to free-stream conditions, by

$$\left(C_{p_\infty}\right)_P = \left(C_{p_\alpha}\right)_P \left(\frac{M_\alpha}{M_\infty}\right)^2 \frac{P_\alpha}{P_\infty} + \left(C_{p_\infty}\right)_\alpha \qquad 6.3.1\text{-d}$$

where M_α/M_∞, P_α/P_∞, and $\left(C_{p_\infty}\right)_\alpha$ are obtained from step 1.

d. Obtain the free interaction length nondimensionalized by boundary-layer thickness ℓ_{f_i}/δ_o as a function of $(C_{p_\alpha})_P$ and M_α from figure 6.3.1-67 or figure 6.3.1-68 for laminar or turbulent flow, respectively.

e. Calculate the free interaction length by $\ell_{f_i} = \left(\ell_{f_i}/\delta_o\right)\delta_o$ where δ_o is the boundary-layer thickness determined as outlined in step 4e.

f. Obtain the upstream interaction distance nondimensionalized by boundary-layer thickness d_1/δ_o as a function of $(C_{p_\alpha})_P$ and M_α from figure 6.3.1-61 or figure 6.3.1-62 for laminar or turbulent flow, respectively.

g. Calculate the upstream interaction distance by $d_1 = (d_1/\delta_o)\delta_o$.

h. Obtain the downstream interaction length d_2 from figure 6.3.1-69 or figure 6.3.1-70 for laminar or turbulent flow, respectively.

i. Determine the downstream interaction length to the pressure rise d_3. For turbulent flow $d_3 = 0$. For laminar flow the ratio d_3/d_1 is obtained from figure 6.3.1-71 as a function of flap deflection δ_f and the equivalent flow-deflection angle ϕ for $(C_{p_\alpha})_P$.

The equivalent flow-deflection angle for $(C_{p_\alpha})_P$ may be obtained as a function of the shock-wave angle θ and M_α. The shock-wave angle is given by

$$\theta = \sin^{-1}\sqrt{\frac{6(P_P/P_\alpha)+1}{7(M_\alpha)^2}} \qquad 6.3.1\text{-e}$$

where

$$\frac{P_P}{P_\alpha} = (C_{p_\alpha})_P \frac{\gamma}{2}(M_\alpha)^2 + 1 \qquad 6.3.1\text{-f}$$

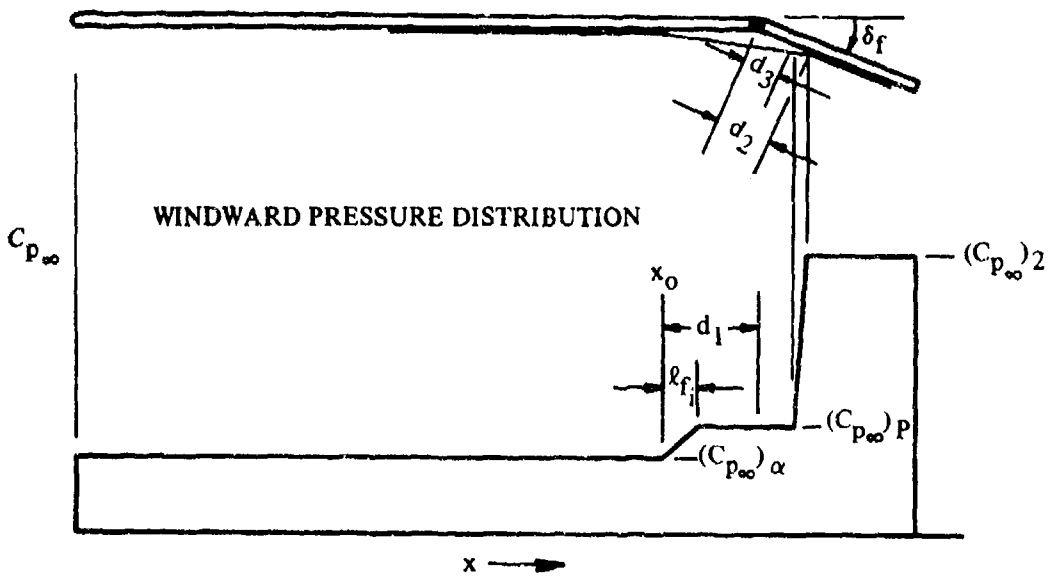
Enter figure 4.4.1-81 with θ and M_α and read $\phi = |\delta'|$.

j. Calculate the peak flap pressure, referred to free-stream conditions, by

$$(C_{p_\infty})_2 = (C_{p_\alpha})_2 \left(\frac{M_\alpha}{M_\infty}\right)^2 \frac{P_\alpha}{P_\infty} + (C_{p_\infty})_\alpha \qquad 6.3.1\text{-g}$$

where M_α/M_∞, P_α/P_∞, and $(C_{p_\infty})_\alpha$ are obtained from step 1, and $(C_{p_\alpha})_2$ is obtained from step 2 (equation 6.3.1-c).

Step 6. The windward pressure distribution may now be constructed as illustrated in sketch (e).



SKETCH (e)

Step 7. The two-dimensional force and moment increments produced on the windward surface of a deflected control are given by

Normal-force increment:

$$\frac{\Delta C_N S}{b} = \left[(C_{p_\infty})_P - (C_{p_\infty})_\alpha\right]\left[d_1 - \frac{\ell_{f_i}}{2} + \cos\delta_f c_f\right] + \left[(C_{p_\infty})_2 - (C_{p_\infty})_P\right](\cos\delta_f)\left[c_f - \frac{d_2}{2} - \frac{d_3}{2}\right] \text{ (ft)} \qquad 6.3.1\text{-h}$$

Increment of pitching moment about HL due to normal force increment:

$$\left[\frac{(\Delta C_m)_{HL} SL}{b}\right]_{\Delta C_N} = \left[(C_{p_\infty})_P - (C_{p_\infty})_\alpha\right]\left[\frac{(\ell_{f_i})^2}{6} - \frac{(\ell_{f_i})(d_1)}{2} + \frac{(d_1)^2}{2} - \frac{\cos^2\delta_f (c_f)^2}{2}\right]$$

$$- \left[(C_{p_\infty})_2 - (C_{p_\infty})_P\right](\cos^2\delta_f)\left[\frac{(c_f)^2}{2} - \frac{(d_2)^2}{6} - \frac{d_2 d_3}{6} - \frac{(d_3)^2}{6}\right] \text{ (ft)}^2 \qquad 6.3.1\text{-i}$$

Center of pressure of normal-force increment, measured from the MRP, negative aft:

$$(x_{c.p.})_{\Delta C_N} = -(x_{HL} - x_{MRP}) + \frac{\left[(\Delta C_m)_{HL} L\right]_{\Delta C_N}}{\Delta C_N} \text{ (ft)} \qquad 6.3.1\text{-j}$$

Axial-force increment:

$$\frac{\Delta C_A S}{b} = (\sin\delta_f)\left\{\left[(C_{p_\infty})_P - (C_{p_\infty})_\alpha\right] c_f + \left[(C_{p_\infty})_2 - (C_{p_\infty})_P\right]\left[c_f - \frac{d_2}{2} - \frac{d_3}{2}\right]\right\} \text{ (ft)} \qquad 6.3.1\text{-k}$$

Increment of pitching moment about HL due to axial-force increment:

$$\left[\frac{(\Delta C_m)_{HL}\,SL}{b}\right]_{\Delta C_A} = -(\sin^2\delta_f)\left\{\left[(C_{p_\infty})_P - (C_{p_\infty})_\alpha\right]\frac{(c_f)^2}{2} + \left[(C_{p_\infty})_2 - (C_{p_\infty})_P\right]\left[\frac{(c_f)^2}{2} - \frac{(d_2)^2}{6} - \frac{d_2 d_3}{6} - \frac{(d_3)^2}{6}\right]\right\} \quad (ft)^2 \qquad 6.3.1\text{-}\ell$$

Center of pressure of axial-force increment, measured from the MRP, positive down:

$$(z_{c.p.})_{\Delta C_A} = z_{HL} - \frac{\left[(\Delta C_m)_{HL}L\right]_{\Delta C_A}}{\Delta C_A} \quad (ft) \qquad 6.3.1\text{-m}$$

Increment of pitching moment about vehicle MRP:

$$\left[\frac{(\Delta C_m)_{MRP}S}{b}L\right] = \left[\frac{(\Delta C_N)\,S}{b}(x_{c.p.})\right]_{\Delta C_N} - \left[\frac{(\Delta C_A)\,S}{b}(z_{c.p.})\right]_{\Delta C_A} \quad (ft)^2 \qquad 6.3.1\text{-n}$$

Windward component of control hinge moment (based on absolute pressure):

$$\frac{HM}{bq} = -\left\{(C_{p_\infty})_2\frac{(c_f)^2}{2} - \frac{1}{6}\left[(C_{p_\infty})_2 - (C_{p_\infty})_F\right]\left[(d_2)^2 + d_2 d_3 + (d_3)^2\right]\right\} \quad (ft)^2 \qquad 6.3.1\text{-o}$$

An approximate correction for the effect of finite control span on the two-dimensional pressure distribution in the separated region over the control is presented as figure 6.3.1-72. This empirical correlation, taken from reference 1, is based on a limited amount of test data. Unfortunately, not enough test data are available for partial-span control effect to identify the effects of Mach number, Reynolds number, or control position.

Two sample problems are presented at the conclusion of this section. The first sample problem is straightforward in that the Datcom method is directly applicable. The second sample problem illustrates an application of the method to a flight condition where the separated region extends forward to the leading edge of the configuration.

It should be recalled that the use of oblique-shock relations implies small leading-edge-bluntness effects and negligible viscous effects. On bodies with a blunted leading edge, pressure near the leading edge will be higher than that predicted by the oblique-shock theory. When leading-edge bluntness is not zero, the actual value for M_α will be between that given by oblique-shock and shock-loss theories. Values of M_α on surfaces with leading edges of various bluntness dimensions were obtained from test data during the analysis conducted in connection with reference 1. It is suggested therein that oblique-shock properties result in acceptable values of local Mach number M_α for

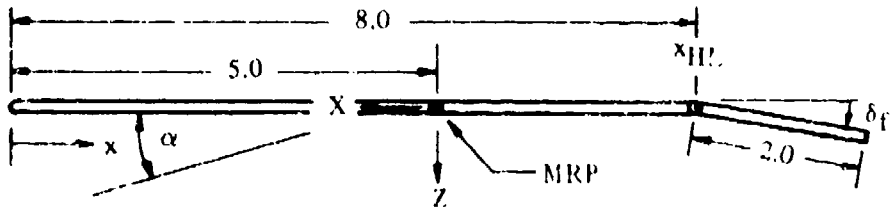
$$\frac{0.1375\,\frac{x_{HL}}{d_{LE}} + 2.0}{M_\infty} > 1.0$$

If the leading-edge bluntness is comparatively large, the local-flow properties should be calculated by other available methods, such as tangent-wedge, blast-wave, or the Moeckel shock-loss theory (reference 31). Blunt leading edges or large viscous-induced pressure gradients also reduce the boundary-layer thickness. The effects of leading-edge bluntness and viscous interaction on the flow properties along a body surface are discussed in Section III of reference 1.

Sample Problems

1.

Given: A two-dimensional flat plate with negligible thickness.



$L = 10.0$ ft $\quad x_{MRP} = 5.0$ ft $\quad x_{HL} = 8.0$ ft $\quad z_{HL} = 0 \quad c_f = 2.0$ ft

$\delta_f = 10^o \quad R_{\ell_\infty} = 1.06 \times 10^5$ per ft

Altitude: 150,000 ft $\quad P_\infty = 2.84$ lb/(ft)$^2 \quad T_\infty = 480^o$ R

$T_w = 1500^o$R $\quad \alpha = 15^o$ Negligible viscous interaction (assumed)

$M_\infty = 10.0$

Compute:

Determine the local flow conditions:

$$\frac{P_\alpha}{P_\infty} = 13.5 \text{ (figure 6.3.1-31c)}$$

$$\frac{T_\alpha}{T_\infty} = 3.0 \text{ (figure 6.3.1-37c) (equilibrium real gas)}$$

$$M_\alpha = 5.5 \text{ (figure 6.3.1-43c) (equilibrium real gas)}$$

$$\frac{R_{\ell_\alpha}}{R_{\ell_\infty}} = 1.94 \text{ (figure 6.3.1-49c) (equilibrium real gas)}$$

$$T_\alpha = T_\infty \frac{T_\alpha}{T_\infty} = 1440^o \text{ R}$$

$$R_{\ell_\alpha} = R_{\ell_\infty} \frac{R_{\ell_\alpha}}{R_{\ell_\infty}} = 2.06 \times 10^5 \text{ per ft}$$

$$\frac{\delta_o}{\sqrt{x_o}} = 0.0215 \text{ (figure 6.3.1-65)}$$

$$\delta_o = \sqrt{x_o}\,\frac{\delta_o}{\sqrt{x_o}} = (\sqrt{7.0})\,(0.0215) = 0.057 \text{ ft}$$

$$d_1 = \delta_o \left(\frac{d_1}{\delta_o}\right) = (0.057)\,(20.0) = 1.14 \text{ ft}$$

$d_1 + x_o = 1.14 + 7.0 = 8.14 \text{ ft} > x_{HL}$. Try a second iteration.

Second iteration (assume $x_o = 6.5$ ft)

$$\left(R\ell_\alpha\right)_{x_o} = x_o \left(R\ell_\alpha\right) = (6.5)\,(2.06 \times 10^5) = 1.339 \times 10^6$$

$$\left(C_{p_\alpha}\right)_f = 0.019 \text{ (figure 6.3.1-59)}$$

$$\frac{d_1}{\delta_o} = 21.5 \text{ (figure 6.3.1-61)}$$

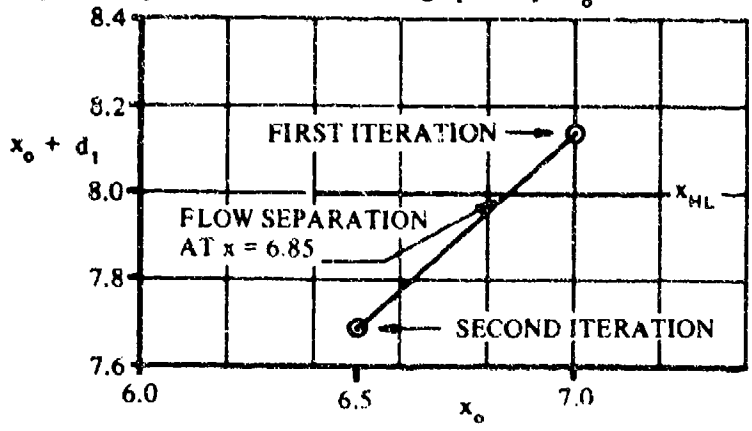
$$\frac{\delta_o}{\sqrt{x_o}} = 0.0215 \text{ (calculation to determine } \delta_o/\sqrt{x_o} \text{ is same as first iteration)}$$

$$\delta_o = \sqrt{x_o}\,\frac{\delta_o}{\sqrt{x_o}} = \sqrt{6.5}\,(0.0215) = 0.055 \text{ ft}$$

$$d_1 = \delta_o \left(\frac{d_1}{\delta_o}\right) = (0.055)\,(21.5) = 1.183 \text{ ft}$$

$d_1 + x_o = 1.183 + 6.50 = 7.683 \text{ ft} < x_{HL}$

The flow separation point is now determined graphically. $x_o = 6.85$ ft



Define the windward pressure distribution:

$$\left(R_{\ell_\alpha}\right)_{x_o} = x_o \left(R_{\ell_\alpha}\right) = (6.85)(2.06 \times 10^5) = 1.41 \times 10^6$$

$$\left(C_{p_{\alpha_P}}\right) = 0.019 \text{ (figure 6.3.1-59)}$$

$$\left(C_{p_\infty}\right)_P = \left(C_{p_\alpha}\right)_P \left(\frac{M_\alpha}{M_\infty}\right)^2 \frac{P_\alpha}{P_\infty} + \left(C_{p_\infty}\right)_\alpha \text{ (equation 6.3.1-d)}$$

$$= (0.019)\left(\frac{5.5}{10.0}\right)^2 (13.5) + 0.179 = 0.257$$

$$\frac{\ell_{f_i}}{\delta_o} = 8.0 \text{ (figure 6.3.1-67)}$$

$$\delta_o = \sqrt{x_o}\ \frac{\delta_o}{\sqrt{x_o}} = \sqrt{6.85}\,(0.0215) = 0.056 \text{ ft}$$

$$\ell_{f_i} = \delta_o \left(\frac{\ell_{f_i}}{\delta_o}\right) = (0.056)(8.0) = 0.448 \text{ ft}$$

$$\frac{d_1}{\delta_o} = 21.4 \text{ (figure 6.3.1-61)}$$

$$d_1 = \delta_o \left(\frac{d_1}{\delta_o}\right) = (0.056)(21.4) = 1.20 \text{ ft}$$

$$\frac{c_f}{d_1} = \frac{2.0}{1.20} > 1; \text{ therefore, } \frac{d_2}{\sqrt{(c_f)(d_1)}} = \frac{d_2}{d_1} = 0.506 \text{ (figure 6.3.1-69)}$$

$$d_2 = d_1 \left(\frac{d_2}{d_1}\right) = (1.20)(0.506) = 0.607 \text{ ft}$$

Equivalent flow deflection angle for $\left(C_{p_\alpha}\right)_P$

$$\frac{P_P}{P_\alpha} = \left(C_{p_\alpha}\right)_P \frac{\gamma}{2} (M_\alpha)^2 + 1 \text{ (equation 6.3.1-f)}$$

$$= (0.019)\left(\frac{1.4}{2}\right)(5.5)^2 + 1 = 1.402$$

$$\theta = \sin^{-1}\sqrt{\frac{6(P_p/P_\alpha)+1}{7(M_\alpha)^2}} \quad \text{(equation 6.3.1-e)}$$

$$= \sin^{-1}\sqrt{\frac{6(1.402)+1}{7(5.5)^2}} = 12.2^{o}$$

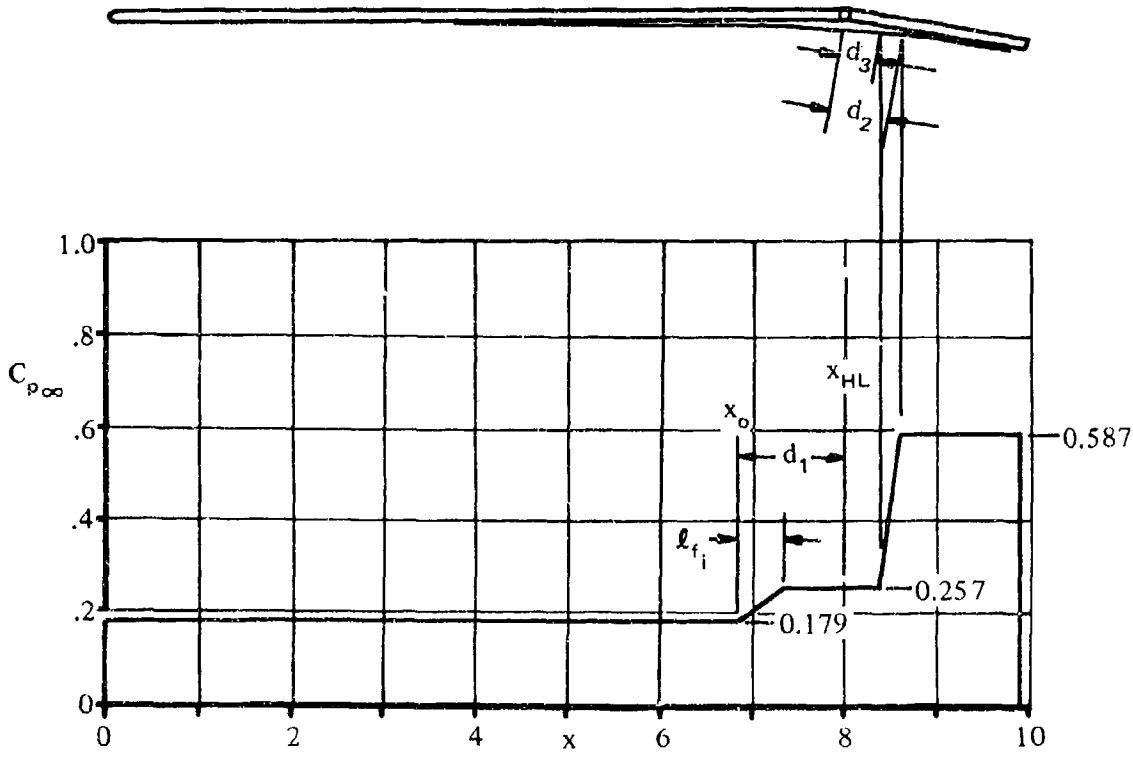
$\phi = 2.6^{o}$ ($\phi = |\delta'|$ at M_α and θ from figure 4.4.1-81)

$$\frac{d_3}{d_1} = 0.35 \quad \text{(figure 6.3.1-71)}$$

$$d_3 = d_1\left(\frac{d_3}{d_1}\right) = (1.20)(0.35) = 0.42 \text{ ft}$$

$$\left(C_{p_\infty}\right)_2 = \left(C_{p\alpha}\right)_2\left(\frac{M_\alpha}{M_\infty}\right)^2\frac{P_\alpha}{P_\infty} + \left(C_{p_\infty}\right)_\alpha \quad \text{(equation 6.3.1-g)}$$

$$= (0.100)\left(\frac{5.5}{10.0}\right)^2(13.5) + (0.179) = 0.587$$



Solution:

Normal-force increment:

$$\frac{\Delta C_N S}{b} = \left[\left(C_{p_\infty}\right)_P - \left(C_{p_\infty}\right)_\alpha\right]\left[d_1 - \frac{\ell_{f_i}}{2} + \cos\delta_f c_f\right] + \left[\left(C_{p_\infty}\right)_2 - \left(C_{p_\infty}\right)_P\right](\cos\delta_f)\left[c_f - \frac{d_2}{2} - \frac{d_3}{2}\right]$$

(equation 6.3.1-h)

$$= [(0.257) - (0.179)]\left[1.20 - \frac{0.448}{2} + (0.985)(2.0)\right]$$

$$+ [(0.587) - (0.257)](0.985)\left[2.0 - \frac{0.607}{2} - \frac{0.42}{2}\right]$$

$$= 0.713 \text{ ft}$$

Increment of pitching moment about HL due to normal force increment:

$$\left[\frac{(\Delta C_m)_{HL} SL}{b}\right]_{\Delta C_N} = \left[\left(C_{p_\infty}\right)_P - \left(C_{p_\infty}\right)_\alpha\right]\left[\frac{(\ell_{f_i})^2}{6} - \frac{(\ell_{f_i})(d_1)^2}{2} + \frac{(d_1)^2}{2} - \frac{\cos^2\delta_f (c_f)^2}{2}\right]$$

$$- \left[\left(C_{p_\infty}\right)_2 - \left(C_{p_\infty}\right)_P\right](\cos^2\delta_f)\left[\frac{(c_f)^2}{2} - \frac{(d_2)^2}{6} - \frac{(d_2 d_3)}{6} - \frac{(d_3)^2}{6}\right]$$

(equation 6.3.1-i)

$$= [(0.257) - (0.179)]\left[\frac{(0.448)^2}{6} - \frac{(0.448)(1.20)}{2} + \frac{(1.20)^2}{2}\right.$$

$$\left. - \frac{(0.985)^2 (2.0)^2}{2}\right] - [(0.587) - (0.257)](0.985)^2\left[\frac{(2.0)^2}{2} - \frac{(0.607)^2}{6}\right.$$

$$\left. - \frac{(0.607)(0.42)}{6} - \frac{(0.42)^2}{6}\right]$$

$$= -0.713 \text{ (ft)}^2$$

Center of pressure for normal-force increment referred to MRP:

$$(x_{c.p.})_{\Delta C_N} = -(x_{HL} - x_{MRP}) + \frac{[(\Delta C_m)_{HL} L]_{\Delta C_N}}{\Delta C_N} \quad \text{(equation 6.3.1-j)}$$

$$= -(8.0 - 5.0) + \frac{-0.713}{0.713}$$

$$= -4.00 \text{ ft} \quad (4.00 \text{ feet aft of MRP})$$

Axial-force increment:

$$\frac{\Delta C_A S}{b} = (\sin \delta_f) \left\{ \left[\left(C_{p_\infty}\right)_P - \left(C_{p_\infty}\right)_\alpha \right] c_f + \left[\left(C_{p_\infty}\right)_2 - \left(C_{p_\infty}\right)_P \right] \left[c_f - \frac{d_2}{2} - \frac{d_3}{2} \right] \right\} \quad \text{(equation 6.3.1-k)}$$

$$= (0.174) \left\{ [(0.257) - (0.179)] (2.0) + [(0.587) - (0.257)] \left[2.0 - \frac{0.607}{2} - \frac{0.42}{2} \right] \right\}$$

$$= 0.1125 \text{ ft}$$

Increment of pitching moment about HL due to axial force:

$$\left[\frac{(\Delta C_m)_{HL} SL}{b} \right]_{\Delta C_A} = -(\sin^2 \delta_f) \left\{ \left[\left(C_{p_\infty}\right)_P - \left(C_{p_\infty}\right)_\alpha \right] \frac{(c_f)^2}{2} + \left[\left(C_{p_\infty}\right)_2 - \left(C_{p_\infty}\right)_P \right] \left[\frac{(c_f)^2}{2} - \frac{(d_2)^2}{6} - \frac{d_2 d_3}{6} - \frac{(d_3)^2}{6} \right] \right\} \quad \text{(equation 6.3.1-ℓ)}$$

$$= -(0.174)^2 \left\{ [(0.257) - (0.179)] \frac{(2.0)^2}{2} + [(0.587) - (0.257)] \left[\frac{(2.0)^2}{2} - \frac{(0.607)^2}{6} - \frac{(0.607)(0.42)}{6} - \frac{(0.42)^2}{6} \right] \right\}$$

$$= -0.0234 \text{ (ft)}^2$$

Center of pressure of axial-force increment:

$$(z_{c.p.})_{\Delta C_A} = Z_{HL} - \frac{[(\Delta C_m)_{HL} L]_{\Delta C_A}}{\Delta C_A} \quad \text{(equation 6.3.1-m)}$$

$$= 0 - \left(\frac{-0.0234}{0.1125} \right)$$

$$= 0.208 \text{ (ft)}$$

Increment of pitching moment about vehicle MRP:

$$\left[\frac{(\Delta C_m)_{MRP} S}{b} L \right] = \left[\frac{(\Delta C_N) S}{b} (x_{c.p.}) \right]_{\Delta C_N} - \left[\frac{(\Delta C_A) S}{b} (z_{c.p.}) \right]_{\Delta C_A} \quad \text{(equation 6.3.1-n)}$$

$$= (0.713) (-4.00) - (0.1125) (0.208) = -2.875 \text{ (ft)}^2$$

Windward component of control hinge moment (based on absolute pressure):

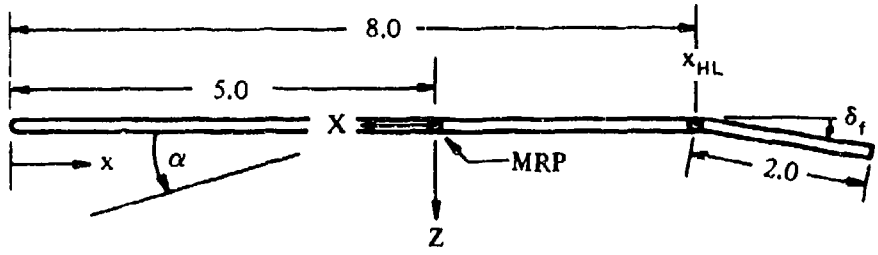
$$\frac{HM}{bq} = -\left\{ \left(C_{p_\infty}\right)_2 \frac{(c_f)^2}{2} - \frac{1}{6} \left[\left(C_{p_\infty}\right)_2 - \left(C_{p_\infty}\right)_P \right] [(d_2)^2 + d_2 d_3 + (d_3)^2] \right\} \quad \text{(equation 6.3.1-o)}$$

$$= -\left\{(0.587)\frac{(2.0)^2}{2} - \frac{1}{6}[(0.587) - (0.257)][(0.607)^2 + (0.607)(0.42) + (0.42)^2]\right\}$$

$$= -1.130\ (\text{ft})^2$$

2.

Given: A two-dimensional flat plate with negligible thickness.



$L = 10.0$ ft $\quad x_{MRP} = 5.0$ ft $\quad x_{HL} = 8.0$ ft $\quad z_{HL} = 0$

$c_f = 2.0$ ft $\quad \delta_f = 10^o \quad R_{\ell_\infty} = 3.27 \times 10^4$ per ft

Altitude: 200,000 ft $\quad P_\infty = 0.413$ lb/(ft)^2 $\quad T_\infty = 458^o$ R

$T_w = 2000^o$ R $\quad \alpha = 10^o$ Negligible viscous interaction (assumed)

$M_\infty = 20$

Compute:

Determine the local-flow conditions:

$\frac{P_\alpha}{P_\infty} = 21$ (figure 6.3.1-31d) (equilibrium real gas)

$\frac{T_\alpha}{T_\infty} = 4.30$ (figure 6.3.1-37d) (equilibrium real gas)

$M_\alpha = 9.80$ (figure 6.3.1-43d) (equilibrium real gas)

$\frac{R_{\ell_\alpha}}{R_{\ell_\infty}} = 1.87$ (figure 6.3.1-49d) (equilibrium real gas)

$T_\alpha = T_\infty \frac{T_\alpha}{T_\infty} = 1970^o$R

$$R_{\ell_\alpha} = R_{\ell_\infty} \frac{R_{\ell_\alpha}}{R_{\ell_\infty}} = 6.11 \times 10^4 \text{ per ft}$$

$$\left(C_{p_\infty}\right)_\alpha = \frac{(P_\alpha/P_\infty) - 1}{\frac{\gamma}{2} M_\infty^2} = \frac{21.0 - 1}{\frac{1.4}{2}(20)^2} = 0.071 \text{ (equation 6.3.1-a)}$$

Determine if the flow is laminar or turbulent:

$$\left(R_{\ell_\alpha}\right)_{HL} = x_{HL} \left(R_{\ell_\alpha}\right) = (8.0)(6.11 \times 10^4) = 4.9 \times 10^5$$

At $\left(R_{\ell_\alpha}\right)_{HL}$ and M_α, figure 6.3.1-55 indicates a laminar boundary layer.

Determine if separation exists:

$$\left(C_{p_\alpha}\right)_{inc} = 0.019 \text{ (figure 6.3.1-56)}$$

$$\frac{P_2}{P_\alpha} = 6.80 \text{ (figure 6.3.1-58) (single-shock value)}$$

$$\left(C_{p_{\alpha/2}}\right)_2 = \frac{(P_2/P_\alpha) - 1}{\frac{\gamma}{2} M_\alpha^2} = \frac{6.80 - 1}{\frac{1.4}{2}(9.8)^2} = 0.0863 \text{ (equation 6.3.1-c)}$$

Since $\left(C_{p_\alpha}\right)_2 > \left(C_{p_\alpha}\right)_{inc}$, the flow is separated.

Determine the separation location (see step 4 of Datcom method for iteration procedure):

First iteration (assume x_o = 7.0 ft)

$$\left(R_{\ell_{\alpha/x_o}}\right) = x_o \left(R_{\ell_\alpha}\right) = (7.0)(6.11 \times 10^4) = 4.277 \times 10^5$$

$$\left(C_{p_{\alpha/P}}\right) = 0.0185 \text{ (figure 6.3.1-59)}$$

$$\frac{d_1}{\delta_o} = 110 \text{ (figure 6.3.1-61)}$$

$$\frac{T_w}{T_\alpha} = \frac{2000}{1970} = 1.015$$

$$\frac{R_{\ell_\alpha}^*}{R_{\ell_\alpha}} = 0.079 \text{ (figure 6.3.1-63)}$$

$$R_{\ell_\alpha}^* = R_{\ell_\alpha}\left(\frac{R_{\ell_\alpha}^*}{R_{\ell_\alpha}}\right) = (6.11 \times 10^4)(0.079) = 4.83 \times 10^3$$

$$\frac{\delta_o}{\sqrt{x_o}} = 0.075 \text{ (figure 6.3.1-65)}$$

$$\delta_o = \sqrt{x_o}\,\frac{\delta_o}{\sqrt{x_o}} = \sqrt{7.0}\,(0.075) = 0.199 \text{ ft}$$

$$d_1 = \delta_o\left(\frac{d_1}{\delta_o}\right) = (0.199)(110) = 21.89 \text{ ft}$$

$d_1 + x_o = 21.89 + 7.0 = 28.89 \text{ ft} > x_{HL}$. Try a second iteration.

Second iteration (assume $x_o = 4.0$ ft)

$$\left(R_{\ell_\alpha}\right)_{x_o} = x_o\left(R_{\ell_\alpha}\right) = (4.0)(6.11 \times 10^4) = 2.444 \times 10^5$$

$$\left(C_{p_\alpha}\right)_p = 0.023 \text{ (figure 6.3.1-59)}$$

$$\frac{d_1}{\delta_o} = 230 \text{ (figure 6.3.1-61)}$$

$$\frac{\delta_o}{\sqrt{x_o}} = 0.075 \text{ (calculation to determine } \delta_o/\sqrt{x_o} \text{ is same as first iteration)}$$

$$\delta_o = \sqrt{x_o}\,\frac{\delta_o}{\sqrt{x_o}} = \sqrt{4.0}\,(0.075) = 0.150 \text{ ft}$$

$$d_1 = \delta_o\left(\frac{d_1}{\delta_o}\right) = (0.150)(230) = 34.50 \text{ ft}$$

$d_1 + x_o = 34.50 + 4.0 = 38.50 \text{ ft} > x_{HL}$. Try a third iteration.

Third iteration (assume $x_o = 2.0$ ft)

$$\left(R_{\ell_\alpha}\right)_{x_o} = x_o\left(R_{\ell_\alpha}\right) = (2.0)(6.11 \times 10^4) = 1.222 \times 10^5$$

$$\left(C_{p_\alpha}\right)_p = 0.0255 \text{ (figure 6.3.1-59)}$$

$$\frac{d_1}{\delta_o} = 350 \text{ (figure 6.3.1-61)}$$

$$\frac{\delta_o}{\sqrt{x_o}} = 0.075 \text{ (calculation to determine } \delta_o/\sqrt{x_o} \text{ is same as first and second iteration)}$$

$$\delta_o = \sqrt{x_o}\frac{\delta_o}{\sqrt{x_o}} = \sqrt{2.0}\ (0.075) = 0.106 \text{ ft}$$

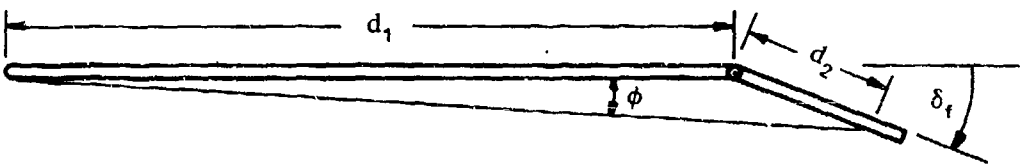
$$d_1 = \delta_o\left(\frac{d_1}{\delta_o}\right) = (0.106)\,(350) = 37.10 \text{ ft}$$

$$d_1 + x_o = 37.10 + 2.0 = 39.10 \text{ ft} > x_{HL}$$

The magnitudes of d_1 from the iterations indicate that the region of separation extends forward to the leading edge of the plate. For this case it is assumed that the plateau-pressure region extends forward to the leading edge. Then, $d_1 = x_{HL}$ and $\ell_{f_i} = 0$ (see sketch (d)).

Define the windward pressure distribution:

Assume the plateau pressure corresponds to the wedge pressure for a local flow deflection angle of ϕ degrees as illustrated below.



Then, by using d_1, d_2, and δ_f the angle ϕ can be defined. Knowing ϕ the plateau-pressure level is obtained by using oblique-shock relations.

Assume $d_1 = x_{HL} = 8.0$ ft

$$\frac{c_f}{d_1} = \frac{2.0}{8.0} = 0.25 \le 0.25; \text{ therefore, } \frac{d_2}{\sqrt{(c_f)\,(d_1)}} = 2\frac{d_2}{d_1} = 0.475 \text{ (figure 6.3.1-69)}$$

$$d_2 = \frac{0.475\, d_1}{2} = 1.90 \text{ ft}$$

$$\phi = \tan^{-1}\frac{d_2 \sin\delta_f}{d_1 + d_2\cos\delta_f} = \tan^{-1}\frac{(1.90)\,(0.174)}{8.0 + (1.90)\,(0.985)}$$

$$= \tan^{-1} 0.0335 = 1.9^o$$

$$\theta = 7.25^o \text{ (θ is obtained from figure 4.4.1-81 at } M_\alpha = 9.8 \text{ and } \phi = |\delta'|)$$

$$\frac{P_P}{P_\alpha} = \frac{7M_\alpha^2 \sin^2 \theta - 1}{6} \quad \text{(equation 6.3.1-e)}$$

$$= \frac{7(9.8)^2 (\sin 7.25^o)^2 - 1}{6} = 1.62$$

$$\left(C_{p_\alpha}\right)_P = \frac{(P_P/P_\alpha) - 1}{\frac{\gamma}{2} M_\alpha^2} \quad \text{(equation 6.3.1-f)}$$

$$= \frac{(1.62) - 1}{\frac{1.4}{2}(9.8)^2}$$

$$= 0.00922$$

$$\left(C_{p_\infty}\right)_P = \left(C_{p_\alpha}\right)_P \left(\frac{M_\alpha}{M_\infty}\right)^2 \frac{P_\alpha}{P_\infty} + \left(C_{p_\infty}\right)_\alpha \quad \text{(equation 6.3.1-d)}$$

$$= (0.00922)\left(\frac{9.8}{20.0}\right)^2 (21) + 0.071 = 0.117$$

$$\left(\frac{d_3}{d_1}\right) = 0.250 \quad \text{(figure 6.3.1-71)}$$

$d_3 = d_1\left(\frac{d_3}{d_1}\right) = (8.0)(0.25) = 2.0$ ft. However, d_3 must be less than or equal to d_2 (see sketch (d)). Therefore, let $d_3 = d_2 = 1.90$ ft

$$\left(C_{p_\infty}\right)_2 = \left(C_{p_\alpha}\right)_2 \left(\frac{M_\alpha}{M_\infty}\right)^2 \frac{P_\alpha}{P_\infty} + \left(C_{p_\infty}\right)_\alpha \quad \text{(equation 6.3.1-g)}$$

$$= (0.0863)\left(\frac{9.8}{20.0}\right)^2 (21) + 0.071 = 0.506$$

The windward pressure distribution is illustrated in the following sketch. The solutions for the force and moment increments are not shown, since the use of equations 6.3.1-h through 6.3.1-o is illustrated in sample problem 1.

6.3.2 TRANSVERSE-JET CONTROL EFFECTIVENESS

The interest in evaluating the feasibility of using transverse-jet control systems on high-speed flight vehicles within the atmosphere has created the need for establishing preliminary-design methods for predicting transverse-jet control effectiveness.

This section presents a procedure, taken from reference 1, for sizing a two-dimensional transverse-jet control system in hypersonic flow.

A transverse-jet control system is a control system that uses one or more jets as spoilers. Flow separation generally limits the use of conventional flap-type systems; however, it serves as the basic phenomenon in achieving an effective transverse-jet control system. The jet spoiler creates flow separation in the region surrounding the jet by forcing the primary flow to turn around the obstruction created by the jet exhaust. Transverse-jet control systems are often referred to as jet-interaction control systems to emphasize the important contribution provided by the jet-interaction phenomenon.

Transverse-jet control systems consist of a variety of different types and sizes of thrust units mounted on aerodynamic surfaces. The thrust can be provided by solid or liquid propellant rocket engines or bleed-thrust control units. These thrust units may be large single units or a group of small units strategically located.

In analyzing the performance of transverse jets, several theories have been developed that provide estimates of the principal parameters upstream and downstream of the nozzle. However, the complexity of the interaction has prevented obtaining a detailed physical description of the flow field. This has restricted investigators to limiting the scope of their analyses until fundamentals of the flow have been firmly established. Thus, the Datcom method presented herein is subject to limitations. The primary restriction limits analyses to two-dimensional nozzles. Considerable effort (references 2, 3, 4, and 5) has been directed towards analyzing the three-dimensional problem; however, no acceptable design methods are currently available. The other limiting condition pertains to the pressure forces downstream of the nozzle exit. Because of the conflicting theories regarding the merits of the downstream forces, all nozzles are assumed to be located at the aft end of their respective surfaces. Thus, no consideration is given to possible aft-end forces in the Datcom method; however, they are considered in the discussion of interaction forces.

The advantages (reference 6) of transverse jets in high-speed flow in comparison with conventional aerodynamic control systems have provided the impetus for investigating the possible implementation of transverse-jet control systems. The primary advantage is the possibility of achieving control forces greater than the impulse provided by the jet reaction. This increased force or amplification is due to the favorable interaction of the transverse jet with the local stream flow. The jet interaction substantially alters the surface pressure distribution and results in large additional surface loads, which augment the simple reaction force of the jet. Experimental tests have indicated that properly designed systems can achieve interaction forces that exceed the reaction jet force by factors of four or five.

A second advan age is the possible reduced control response time for transverse jets in comparison to conventional systems. This reduced response time enables the vehicle to be designed with less static stability. A potential increase in reliability provides a third advantage, since redundance is more readily achieved with a less severe weight penalty than for conventional systems and because rocket technology is felt to be more advanced than the technology involved in building high-speed actuators and the integral components required to operate in an extreme temperature environment. Another benefit is the wide range of flight conditions in which transverse jets can provide control forces, as compared with the limited envelope for conventional systems. Improvements are also derived from the elimination of structural problems associated with control surfaces and related heat-transfer problems prevalent in hypersonic flow.

Inherent with transverse jets are many problems and disadvantages which must be solved or accounted for before successful implementation can be achieved. The most crucial problem is the lack of a thorough knowledge involving the jet-interaction process. This prevents formulating a completely reliable prediction technique. Distinct disadvantages are the weight penalties imposed by the propulsion system and the limited quantity of propellant available for a given mission. Associated problems are also encountered in the growth potential when mission requirements change.

An evaluation and design comparison of transverse-jet controls and conventional aerodynamic control systems are presented in reference 6. The conclusions of the report are: (1) high L/D re-entry vehicles with the vehicle trimmed to maximum L/D are favorable to transverse-jet control systems, if trajectory control by roll control is used; (2) if a winged re-entry vehicle is to be maneuvered in pitch to angles appreciably different from the angle of attack required for maximum L/D, conventional flap-type aerodynamic controls are preferable. Additional comparisons regarding transverse jets, solid spoilers, and flap deflections can be found in references 6 and 7.

In order that the Datcom user may better understand the control-effectiveness methods presented in this section, a general discussion of hypersonic-flow separation and the effect of the jet-interaction phenomena upon augmenting the control force is presented. This general discussion is essentailly quoted from Section 6.3.1 of the Datcom and from reference 1. A more detailed description of hypersonic-flow separation and jet-interaction phenomena can be found in references 1, 2, 3, 4, and 8. A summary of the literature pertaining to transverse jets can be found in reference 9. A summation of the contents of each document is given, along with a qualitative discussion of the data and/or theory presented.

Hypersonic-Flow Separation

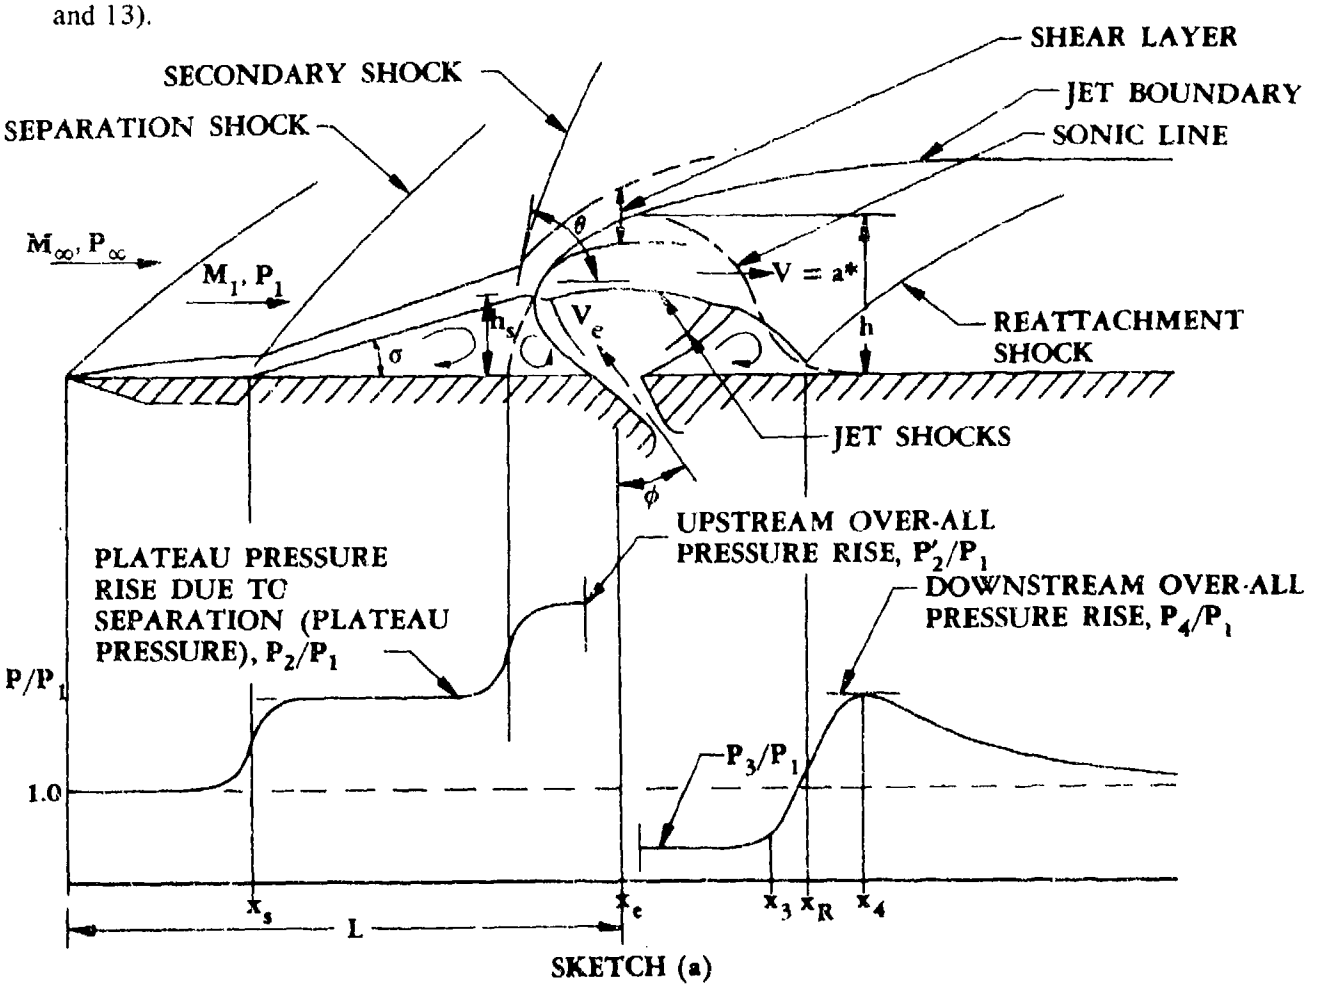
Separated flows are characterized by the prevailing type of boundary layer: laminar, turbulent, or transitional. The pressure rise and the extent of the separated region depend upon the characteristics of the boundary layer.

In general, boundary-layer separation occurs whenever the streamwise pressure increase along a surface is sufficient to overcome the forces acting to accelerate a fluid particle, or when the streamline curvature necessary to follow the surface contour cannot be sustained by the pressure gradient normal to the surface. In steady-flow aerodynamics the only forces acting to accelerate the low-momentum fluid near the wall against a pressure gradient are the shear forces between

layers of fluid. Because the momentum of the fluid near the wall is quite low, a relatively small amount of deceleration by the pressure gradient is sufficient to bring about separation. Turbulent flow helps to delay the occurrence of separation, because the turbulent fluctuations increase the effective shear forces and thereby increase the adverse pressure force necessary to reverse the flow of the fluid near the wall.

The greatly increased effective viscosity due to turbulent fluctuations enables the equilibrium between pressure and shear forces near the wall to occur at much greater adverse pressure rises in a turbulent boundary layer. Because of the connection between pressure rise and flow turning angle, this higher pressure corresponds to a much shorter, thicker separated zone for the same initial boundary-layer thickness. Cases presented by Schlichting (reference 10) and Howarth (reference 11) show turbulent pressure rises twice the laminar ones; whereas the laminar separation zone extends much farther than the turbulent one.

A similar thickening (and simultaneous pressure rise) occurs in a transitional separation when the mixing zone becomes turbulent and the downstream flow soon approaches a condition very similar to the equivalent turbulent separation. Upstream of the transition point, the flow has the character of the corresponding laminar separation zone. The location of the transition point therefore plays a significant role in determining the pressure distribution (see references 12 and 13).

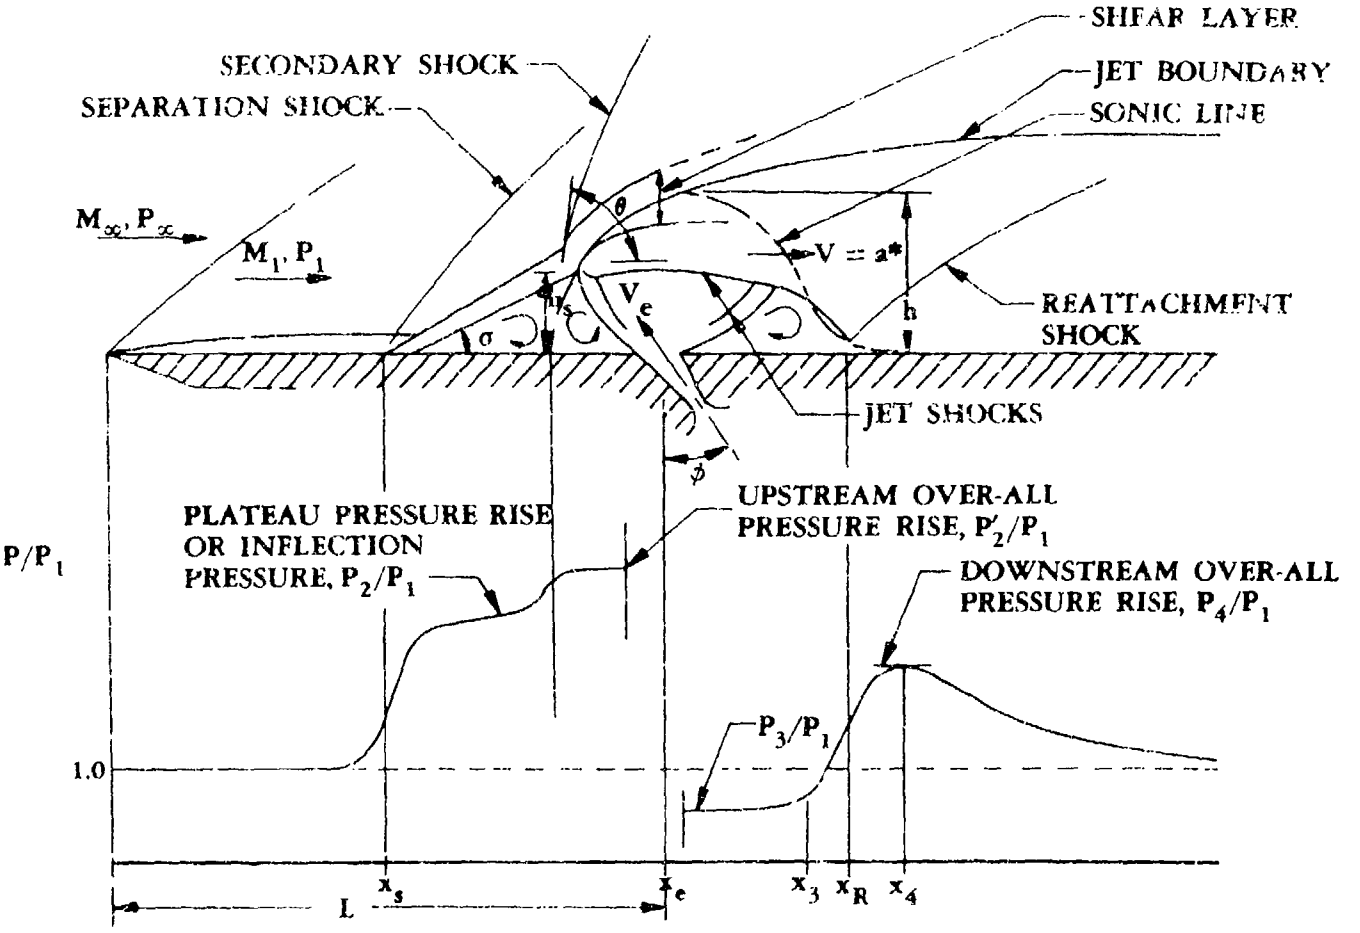


SKETCH (a)

JET INTERACTION FLOW MODEL FOR LAMINAR SEPARATION

Present indications are that shock-induced laminar-separation pressure distributions, and to a limited extent turbulent ones, are independent of the type of disturbing force that produces separation (see reference 12). However, the turbulent peak pressure rise often depends significantly on the disturbing force (references 12 and 14 through 17). This difference in dependence can probably be attributed to the greatly increased effective viscosity in turbulent flow, enabling the wall contour within the separated zone to transmit its effect more strongly to the outer flow.

Typical jet-interaction flow fields for laminar and turbulent boundary layers are presented in sketches (a) and (b), respectively (reference 1).



SKETCH (b)

JET INTERACTION FLOW MODEL FOR TURBULENT SEPARATION

For the upstream region, laminar boundary-layer separation has a characteristic plateau where the pressure remains almost constant over most of the separated flow region. The plateau pressure level depends only on local flow conditions at the location of the separation point (see reference 12). The upstream turbulent boundary-layer-separation pressure distribution is not characterized by a long pressure plateau region as in the case of laminar separation. Instead, the turbulent separation produces an increasing pressure gradient that exhibits an inflection point or a very

short plateau pressure, which appears to be dependent only upon the Mach number. Although some discrepancies exist in the literature (references 1, 4, and 18) regarding upstream pressure trends with boundary-layer condition, the majority of the later references indicate that larger upstream forces are exhibited for laminar separated boundary layers. These larger forces can be attributed to the integrated loads for the longer, lower pressure regions of laminar flow, being larger than those for the shorter, higher pressure regions of turbulent flow.

The problem of locating the boundary-layer transition point is one that has received wide-spread attention from theoreticians and experimentalists. However, no universally applicable prediction technique has been obtained. The best approach for predicting the transition point is to examine wind-tunnel data that most nearly approximate the actual flow conditions. Techniques for correlating the transition data from various sources are available. Reference 19 presents one such technique for correlating data for cone-shaped configurations. In the absence of similar wind-tunnel data, the method presented in the Datcom can serve as an approximate estimation for determining the state of the boundary layer or transition point.

Jet-Interaction Phenomena

The most prominent feature of jet-interaction phenomena is the formation of a strong jet shock that is nearly normal to the jet flow direction, resulting in a recompression and subsonic flow on the downstream side of the nozzle. Reference 8 indicates that because the injected stream must be turned by the primary flow, it acts as an obstruction, and as such, produces a strong shock in the primary flow. This shock interacts with the boundary layer on the wall and causes it to separate. Both the initial shock and the resulting boundary-layer separation produce a region of high pressure near the point of injection. This is the source of the interaction force that augments the simple reaction force of the jet.

Kaufman, in reference 20, describes the interaction pressure downstream of the nozzle as characteristically having a low-pressure region followed by a pressure rise to the reattachment value. At reattachment, the pressure can be either larger or smaller than the undisturbed free-stream pressure. Downstream of reattachment, the pressure approaches its undisturbed value asymptotically.

The low-pressure region downstream of the nozzle can have an adverse effect on the interaction force if the nozzle is not located at the aft end. However, the increasing pressure at reattachment can in some cases predominate, yielding a favorable force if the aft end of the surface is of sufficient length to capture the major portion of the positive pressure region.

The reattachment of the boundary layer downstream of the jet is not well understood. Experiments have indicated a pressure rise similar to that at separation, with the gradient at reattachment usually being in excess of that at separation.

The downstream pressure distributions have frequently been compared to pressure distributions behind rearward-facing steps. These pressure distributions have been estimated by using various base-flow analyses. As indicated by Kaufman (reference 20), determining the proper start conditions for the base-flow models has been difficult. This is due to the existence of large gradients in the flow and no detailed flow-field measurements in this region to guide the

selection of the proper jet-flow conditions to be utilized as the initial conditions in the base-flow analyses.

As stated earlier, the Datcom method does not account for aft-end forces, because all nozzles are assumed to be located at the aft end of their respective surfaces.

Three-Dimensional Effects

Three-dimensional flow fields result from low-aspect-ratio jets located on both flat plates and more complicated bodies. Reference 2 presents a description of the flow field and the relative differences between two- and three-dimensional flow. The more salient aspects are presented here for the reader's benefit.

Three-dimensional effects in the jet-interaction flow field are not well understood quantitatively. This is partly due to the fact that less effort has been devoted to the three-dimensional problem, but more significantly because of the general complexity of three-dimensional flow. The boundary-layer-separation problem alone is not very well understood for three-dimensional flow. Unfortunately, the more significant differences between two- and three-dimensional flow fields are observed to be the extent of the boundary-layer separation and the geometry of the shocks. In contrast to two-dimensional flow, the three-dimensional boundary-layer separation is greatly reduced as a result of the lateral flow component, allowing the boundary layer to bleed off around the sides of the plume. This minimizes the viscous effects and creates a largely inviscid phenomenon.

The most obvious concern with three-dimensional flow is the possible loss in effectiveness due to end effects. However, reference 5 points out that integration of the pressure distribution over a 7-degree cone shows that the normal-force coefficient obtained is the same as the normal-force coefficient per unit span of a two-dimensional jet with the same jet mass flux. This behavior is attributed to a favorable interaction between the cross flow and the main stream, which increases the effective span of the jet. However, this conclusion was based on limited test data and has not been corroborated for various flow conditions.

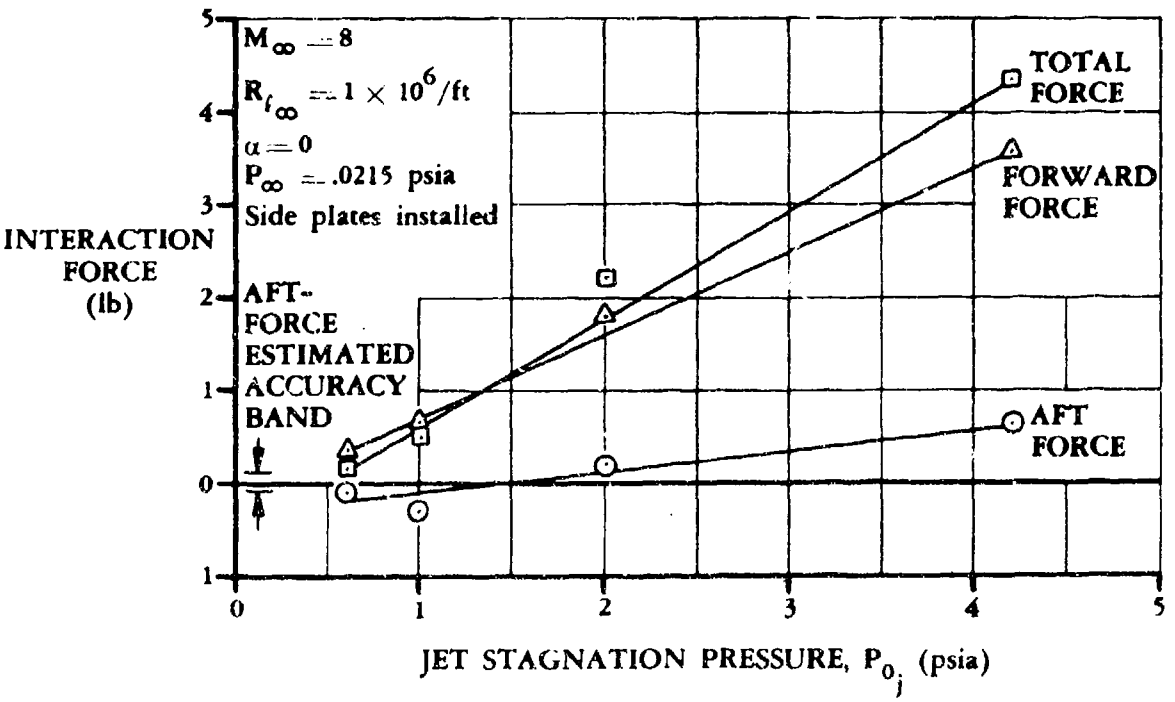
Unlike a jet on a flat plate, an adverse interaction has been observed to occur frequently on three-dimensional bodies. This is attributed to the effect of "wraparound," i.e., the propagation of the disturbance to the sides or the underside of the body. Much of the interaction force created by three-dimensional nozzles results from the high-pressure region immediately behind the bow shock, which forms a hyperbolic high-pressure ridge on the surface of the body extending out from the region of the nozzle. In addition, the low-pressure region directly downstream of the nozzle, which has an adverse effect on the interaction force, is virtually as effective on a cylindrical body as on a flat plate; therefore, negative interaction forces commonly occur on such vehicles.

Although the existing method of analysis in reference 2 provides fair agreement with experimental data, additional sophistication in the shock-body interaction analysis is contemplated, and improved correlation is expected. References 4, 5, 18, and 21 offer additional information regarding the pressure distributions and jet-interaction phenomena for three-dimensional flow.

Jet-Interaction Control Effectiveness

For obvious reasons it is desirable to obtain the highest possible jet-interaction forces. This leads to the consideration of various nozzle inclination angles. Figure 6.3.2-41 (reference 1) presents the amplification factor versus injection angle for various values of nozzle exit velocities and normal sonic amplification factors. From this figure it can be seen that substantial gains in performance may be achieved by inclining the nozzle upstream, provided that large amplification factors (control force normal to wall normalized with respect to vacuum thrust of sonic nozzle) are realized from a normal sonic nozzle. The reason for this is apparent when it is realized that inclining the nozzle upstream tends to increase the interaction force and to decrease the normal component of thrust. Hence, if only a moderate interaction force is realized for a normal sonic nozzle, then little may be gained by upstream injection because of the loss in the normal component of thrust. However, if injection normal to the wall produces a large interaction force relative to the thrust, then substantial improvement may be realized by inclining the nozzle. Maurer in reference 22 states that the optimum injection angles against the main stream were in the range of $15° < \phi < 45°$

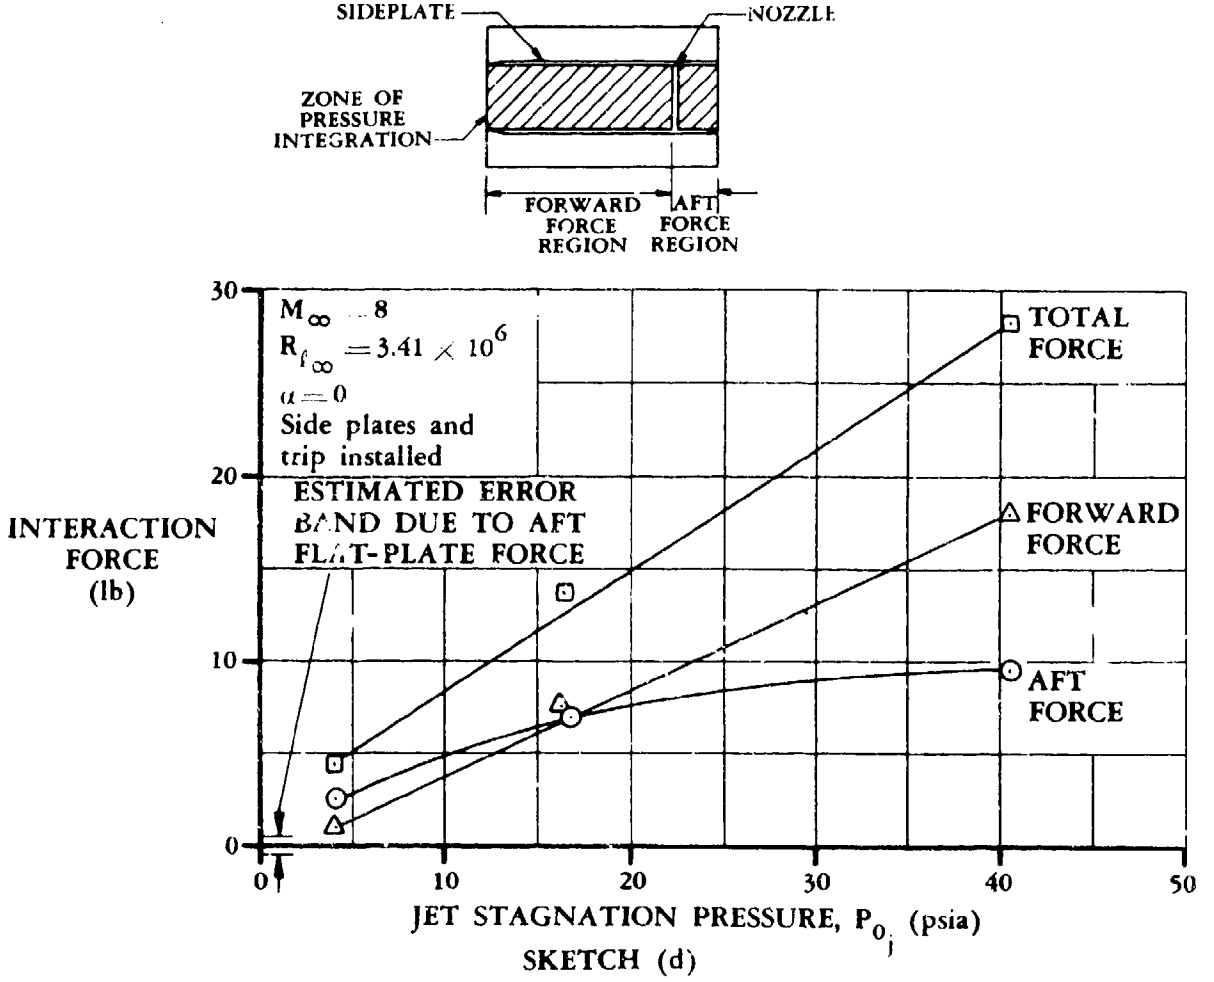
Inherent with obtaining the maximum control-force effectiveness is locating the nozzle to achieve the most desirable pressure distribution. Unfortunately, many discrepancies and questions are found in the literature regarding the contribution of aft-end forces. Pressure distributions downstream of the nozzle can be found in references 1, 8, 20, 23, and 24; to list a few. Barnes (reference 1) found that the aft interaction forces due to a laminar boundary layer are considerably smaller than the forward forces (see sketch (c)). In contrast, he found that for



SKETCH (c)

JET INTERACTION FORCES FOR A LAMINAR BOUNDARY LAYER

turbulent flows the aft-end forces added significantly to the total force, as is evident in sketch (d). However, the contribution of downstream forces in turbulent flow was found to decrease rapidly as the mass-flow rate increased. Although these sketches do not hold true for all nozzle configurations and flow conditions, they do indicate the relative contribution available from aft-end forces. Kaufman (reference 20), in addition to corroborating the findings of Barnes, found that the reattachment pressure increased strongly with increasing Mach number. Spaid and Zukoski, in reference 8, indicate a dependence of downstream pressure on Mach number, mass-flow rate, and injectant fluid properties. With helium as an injectant, higher downstream static pressure levels were obtained in comparison with those for nitrogen.



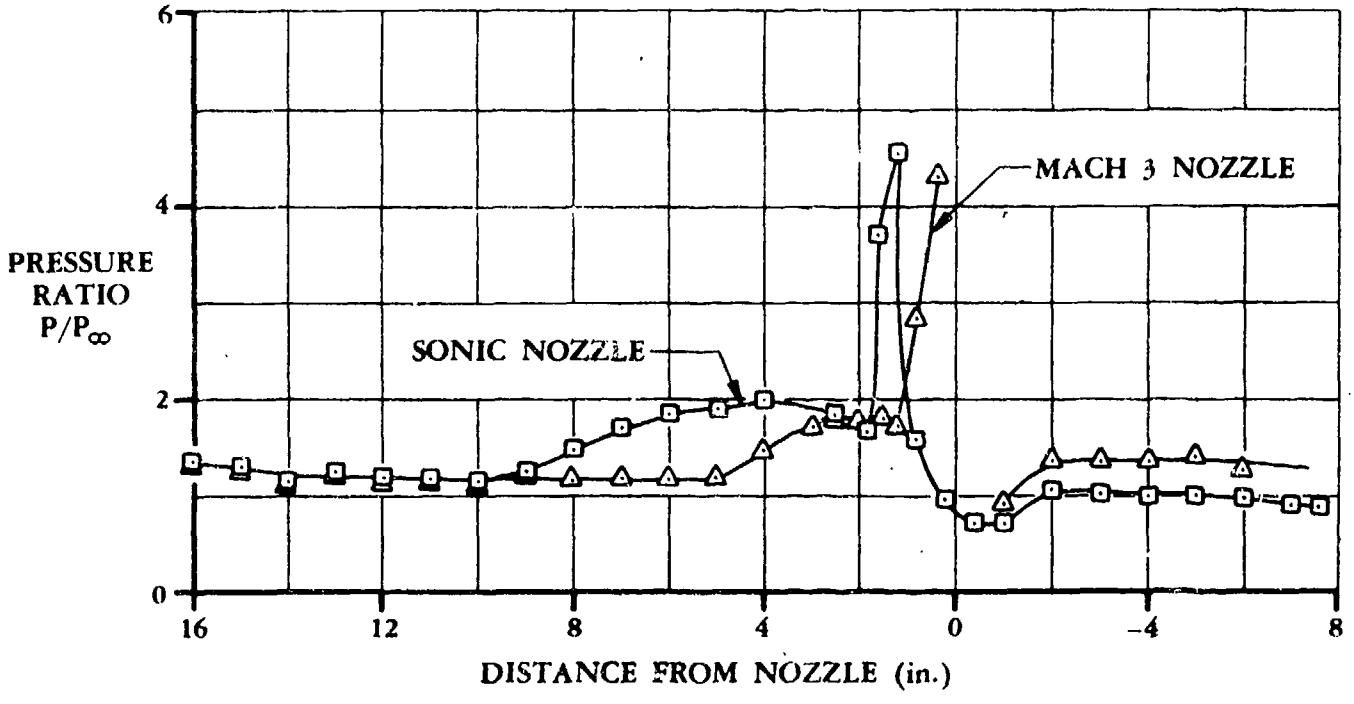
SKETCH (d)

JET INTERACTION FORCES FOR A TURBULENT BOUNDARY LAYER

An iterative method, utilizing experimental data classified according to nozzle aspect ratios (span/width), is presented in reference 20, which predicts upstream and downstream pressure distributions. The results of the method agree qualitatively with experimental data, although more theoretical analyses must be developed before it becomes a reliable predicting technique.

In general, because of the complexity involved in the interaction phenomena, no consistent nozzle angle or location yields the optimum design for the large range of possible applications and environments; each case must be considered separately.

Although the supersonic jet experiences an increase in reaction force over the sonic jet, it also experiences a decrease in the interaction force; it is not obvious which occurrence dominates. The decreased interaction force is a result of a lower pressure at the exit for a supersonic jet. This prevents the jet from expanding into a full plume upon leaving the nozzle, consequently the interaction force decreases. An example of the relative effect of nozzle exit velocity on surface pressure is shown in sketch (e), from reference 1. The Datcom method predicts improved performance by obtaining supersonic velocities at the nozzle exit. Although experimental data indicate that supersonic nozzles exhausting normal to a wall produce virtually no change in control force, the Datcom method predicts a moderate gain. Experiments show that a beneficial effect occurs principally at positive upstream injection angles.



SKETCH (e)

COMPARISON OF NORMAL SONIC AND NORMAL MACH 3 CIRCULAR NOZZLE CENTER-LINE PRESSURE DISTRIBUTIONS

Experimental data show that jet-flow parameters are dominating factors in the jet-interaction phenomena. The more prominent features of the flow are determined by the strength of the jet. For very weak jets (jets with very low pressure ratios (P_{0_j}/P_1)), the jet behavior has been described by Kaufman in reference 20 as similar to film cooling of the surface. There are no separated flow regions, and boundary-layer analysis can describe the resulting flow. In reference 25, Kaufman considers weak jets and focuses his work on the downstream pressure distributions.

Because the Datcom method applies only to strong jets (jets sufficient to induce separation of the boundary layer), it is pertinent to ascertain if separation exists. Available data are not conclusive, but it appears that the minimum nozzle exit pressure P_e to achieve separation must be of the order of twice the plateau pressure P_2 in the separated boundary layer. Turbulent

flow yields a higher plateau pressure, hence it is the determining condition for establishing a minimum jet-strength requirement. The minimum jet-pressure ratio (P_{0_j}/P_1) required to induce separation is presented in figure 6.3.2-43 (reference 1). At pressure ratios substantially below those in figure 6.3.2-43, the Datcom method is probably not valid.

When pressure ratios are above the minimum required, some discrepancy exists in the literature regarding the effect on the amplification factor. Werle in reference 26 concludes that a slight loss in effectiveness is displayed as P_{0_j}/P_1 approaches infinity, while Barnes in reference 1 indicates virtually no change in amplification factor. Reference 20 contains a summary of available jet-interaction data wherein pertinent flow parameters along with the various slot geometries are tabulated.

The Datcom method does not explicitly account for variations in angle of attack. These changes in angle of attack must be accounted for in evaluating local flow conditions and the state of the boundary layer. At high angles of attack, with the jet on the leeward side, caution must be used. The flow will begin to separate, and the jet will essentially be exhausting into a dead-air region that results in the interaction force decreasing to zero. Pressure distributions for small variations in angle of attack can be found in references 1 and 20 for flat plates, and in reference 3 for an ogive-cylinder.

Several methods for modulating the control force have been suggested. The more pragmatic methods are: pulsing the jet with a constant jet pressure with a pulse duration proportional to the impulse required, using multiple nozzles which are individually actuated, varying the jet plenum pressure, and combinations of these.

The Datcom equations describing the upstream jet interaction have been obtained from a momentum balance method. Several other techniques have been used by investigators in their attempts to establish the most complete and reliable prediction scheme. Blast-wave analogy has been used in references 2 and 27. Other investigators (references 5 and 28) employ finite difference techniques in conjunction with various methods in an attempt to describe the flow field.

NOTATION

SYMBOL	DEFINITION
a	speed of sound
b	span of slot nozzle (normal to flow direction)
c	nozzle discharge coefficient
C_{f_0}	vacuum-thrust coefficient
C_{F_c}	control-force coefficient
C_p	pressure coefficient, $C_p = (P - P_1)/q_1$

SYMBOL	DEFINITION
C_x	drag coefficient
d_e	width of nozzle exit in the flow direction
d_{LE}	diameter of surface leading edge
d_t	width of nozzle throat
F_c	control force
F_{j_0}	vacuum thrust
h	maximum height of sonic line above surface (effective jet height)
h_s	maximum height of separated boundary layer above the surface
I_{sp}	jet vacuum specific impulse
K	upstream amplification factor (control force normal to the surface normalized with respect to vacuum thrust of sonic nozzle)
K_o	upstream amplification factor of normal sonic nozzle
L	distance of nozzle from plate leading edge
M	Mach number
$\dot{m}$	nozzle mass-flow rate
P	pressure
P_{0_j}	jet plenum pressure
q	dynamic pressure, $q = \rho V^2/2$
R_{ℓ_L}	Reynold number based on length L (dimensionless)
R_{ℓ_s}	Reynolds number based on the distance to the separation point (dimensionless)
R_{ℓ_∞}	unit Reynolds number based on free-stream conditions
SF	safety factor

SYMBOL	DEFINITION
V	velocity
x_{cp}	center-of-pressure location measured relative to leading edge
α	angle of attack (positive with jet on lee side of model)
γ	specific-heat ratio of jet gases
θ	angle of secondary shock
λ	mean free path (average distance traveled between molecular collisions)
ξ	pressure ratio across secondary shock
ρ	density
σ	boundary-layer separation angle
ϕ	inclination of nozzle center line relative to an axis normal to surface

SUBSCRIPTS

cr	corrected
e	nozzle-exit conditions
max	maximum value
min	minimum value

DATCOM METHOD

A method for sizing a two-dimensional transverse-jet control system, modulated by varying the jet plenum pressure, is presented in the following procedure. This method is based on a continuum concept and is valid in the Mach number range of 2 to 20. When the mean free path of the surrounding flow λ approaches 0.1 of the jet width d_t, the method begins to break down. The method is completely invalid when the mean free path equals the jet width. The method is invalid because of angle-of-attack effects when (1) the angle of attack is such that the leading-edge shock interacts with the jet-interaction region, or (2) the boundary layer is separated at the jet location prior to jet discharge.

For a transverse-jet control system that is modulated by pulsing the jet with a constant jet plenum pressure, the sizing procedure is similar to the Datcom method. The primary objective is to determine the maximum jet plenum pressure required to satisfy the trim and separation requirements. This enables the nozzle throat width to be calculated.

The Datcom method consists of first obtaining a time history of the local-flow parameters at the nozzle exit prior to jet discharge. These parameters are then used in conjunction with the time history of the control force required to trim the vehicle, to obtain a control-force coefficient. This control-force coefficient is then corrected, and the sonic amplification factor is obtained as a function of the state of the boundary layer and the Reynolds number. The true value for the amplification factor is then obtained from design charts that account for the nozzle inclination angle and nozzle exit Mach number. From the local Mach number and the nozzle exit conditions, values for the minimum jet plenum pressure required to induce flow separation are obtained. This minimum jet plenum pressure and the vacuum thrust, calculated using the true amplification factor, allow calculation of the nozzle throat diameter. This in turn permits the calculation of the jet plenum pressure and propellant weight requirements to trim the vehicle.

Step 1. Determine if the boundary layer is separated at the jet location prior to jet discharge.

Because of the complex nature of boundary-layer separation at hypersonic speeds, no single criterion is available to accurately determine the location of separation. Exact locations can only be determined through wind-tunnel testing. However, for preliminary-design conditions, the simple Newtonian-shadowing criterion may be used. For a nozzle located on the leeward side, this criterion assumes the location of the separation point to be just downstream of the leading edge when the leeward surface is not directly visible to the free stream. Thus, using the Newtonian-shadowing criterion restricts the Datcom method to transverse-jet control systems located on the windward surface.

If the boundary layer is separated prior to jet discharge, the jet-interaction force is probably nil. For this case, the only force is that due to the reaction of the jet, nullifying the Datcom method.

Step 2. Determine the time-history values required for the control force F_c to trim or maneuver the vehicle, the associated free-stream Mach Number M_∞, and the associated angle of attack α_∞.

These parameters must be obtained from an outside source because of the numerous possibilities for vehicle design and mission trajectories. The jet-interaction center of pressure can be assumed to be located at the nozzle for determining the time history of the control force.

Step 3. Determine the time-history values of the local-flow parameters: P_1, q_1, M_1, and $R\ell_L$ in the absence of jet exhaust. The ratios of pressure, dynamic pressure, Mach number, and Reynolds number behind an oblique shock to their respective values in the free stream can be obtained from figures 6.3.2-30, -31, -32, and -33, respectively. These oblique shock ratios are valid so long as the following relationship holds:

$$\frac{0.1375 \dfrac{L}{d_{LE}} + 2.0}{M_\infty} > 1.0$$

For a thick leading edge and for high Mach numbers, the above relationship becomes invalid, disallowing the calculation of the local-flow parameters by oblique-shock theory. This requires calculating the local-flow properties by other available methods, such as tangent-wedge, blast-wave, Newtonian-impact (reference 29), or the Moeckel shock-loss theory (reference 30).

Step 4. Determine the time history of the state of the boundary layer from wind-tunnel data that approximate the actual flow conditions, or as a function of M_1 and $R\ell_L$ from figure 6.3.2-34.

Step 5. Make the following initial choices regarding nozzle geometry, if not already established.

a. Assume a nozzle span b that is as large as the vehicle geometry permits.

b. Choose a nozzle injection angle ϕ, where $0 < \phi < 45°$

Step 6. Determine the nozzle exit Mach number M_e and the jet vacuum specific impulse I_{sp}.

The calculation of these parameters requires knowledge of the propellant as well as of the plenum temperature and nozzle shape. It is therefore advisable that these parameters be determined by the propulsion engineer and designer.

Step 7. Determine the time-history values of the control-force coefficient C_{F_c} by

$$C_{F_c} = \frac{F_c}{q_1 bL} \qquad 6.3.2\text{-a}$$

Step 8. Calculate the value of the vacuum-thrust coefficient using the value of specific-heat ratio associated with the propellant by

$$C_{f_0} = \left(\frac{2}{\gamma + 1}\right)^{\frac{\gamma}{\gamma-1}} (\gamma + 1) \qquad 6.3.2\text{-b}$$

Step 9. Calculate the time-history values of the corrected control-force coefficient by

$$\left(C_{F_c}\right)_{cr} = \left(\frac{F_c}{q_1 bL}\right)\left(\frac{1.268}{C_{F_0}}\right) \qquad 6.3.2\text{-c}$$

Step 10. From the Reynolds number and the state of the boundary layer at each time interval, select the appropriate figure from the sizing charts (figures 6.3.2 -35a through -35e and -40) and determine the time-history values of the amplification factor K_o for a normal sonic nozzle. For a laminar boundary layer interpolate between figures 6.3.2 -35a through -35e. For a turbulent boundary layer, which is independent of Reynolds number, use figure 6.3.2-40.

Step 11. Determine the time-history values of the true amplification factor K from figure 6.3.2-41 or 6.3.2-42, or by

$$K = (K_o - 1)\left[1 + \frac{\gamma}{\gamma + 1}\,\frac{V_e}{a_t}\sin\phi\right] + \left[\frac{V_e}{a_t} + \frac{a_t}{V_e}\right]\frac{\cos\phi}{2} \qquad 6.3.2\text{-d}$$

where

$$\frac{V_e}{a_t} = \left[\frac{(\gamma + 1)M_e^2}{2 + (\gamma - 1)M_e^2}\right]^{1/2} \qquad 6.3.2\text{-e}$$

Step 12. Calculate the time-history values of the vacuum thrust by

$$F_{j_0} = \frac{F_c}{K} \qquad 6.3.2\text{-f}$$

Step 13. Determine a time-history value of the minimum jet plenum pressure required to induce separation $\left(P_{0_j}\right)_{min}$ as follows:

a. Obtain the time history of the minimum jet plenum pressure ratio $\left(P_{0j}/P_1\right)_{min}$ as a function of V_e/a_t and M_1 from figure 6.3.2-43.

b. Multiply these pressure ratios by the corresponding value of local pressure P_1 to obtain $\left(P_{0_j}\right)_{min}$; i.e.,

$$\left(P_{0_j}\right)_{min} = \left(P_{0_j}/P_1\right)_{min} P_1 \qquad 6.3.2\text{-g}$$

Step 14. From the time-history values in steps 12 and 13, determine the maximum value of the vacuum thrust $\left(F_{j_{0/}}\right)_{max}$ and the maximum value of plenum pressure $\left(P_{0_j}\right)_{max}$

Step 15. Calculate, using experimental data if available, a value for the nozzle discharge coefficient c (defined as the ratio of the actual nozzle flow to the flow calculated by isentropic laws). In reference 31, relations are given relating the nozzle discharge coefficient to the velocity coefficient, polytropic efficiency, and other nozzle parameters. However, all these relationships require some experimental k. owledge of the nozzle.

If no experimental data are available for the nozzle, a value of 0.90 can be assumed with concurrence of the nozzle designer. This value was the lower bound for nozzle discharge coefficients experienced by the investigators in reference 1. However, caution must be used because values as low as 0.71 for nozzle discharge coefficients have also been reported (reference 3).

Step 16. Calculate the nozzle throat width required to provide a vacuum thrust at least as large as the peak value predicted to trim the vehicle. The use of a safety factor to allow for dynamics and contingencies may be desirable (see sample problem). Compute the nozzle throat width as follows:

$$d_t = \frac{\left(F_{j_0}\right)_{max} SF}{c\, C_{f_0}\, b \left(P_{0_j}\right)_{max}} \qquad 6.3.2\text{-h}$$

Step 17. Calculate the time-history values of the jet plenum pressure required to trim the vehicle by

$$\left(P_{0_j}\right)_{trim} = \frac{F_{j_0}}{c C_{f_0}\, b\, d_t} \qquad 6.3.2\text{-i}$$

The jet plenum pressure required to trim the vehicle should always exceed the minimum jet plenum pressure required to induce separation $(P_{0_j})_{min}$ in step 13. When the jet plenum pressure required to trim the vehicle is less than the minimum jet plenum pressure required to induce separation, two choices are available: (a) the throat width can be reduced with a corresponding increase in jet plenum pressure; (b) no

change can be made, with a loss in effectiveness (amplification factor) for a short period of time. The second choice is preferable because economically and structurally it is advantageous to keep the jet plenum pressure as low as possible.

Step 18. Calculate the time-history values of the mass-flow rate by

$$\dot{m} = \frac{F_{j_0}}{I_{sp}} \qquad 6.3.2\text{-j}$$

Step 19. Calculate the required propellant weight by integrating the time history of the mass-flow rate.

Step 20. Revise the preliminary estimates made in step 5 and reiterate to obtain an optimum configuration based on trade-offs between system weight, jet-plenum-pressure requirements, and the available control force.

The approach described above is based on the assumption that the jet-interaction center of pressure is located at the nozzle (step 2). In many practical applications this assumption introduces only a small error, particularly for turbulent boundary layers and for relatively low-aspect-ratio nozzles. Present knowledge of jet interaction does not allow an accurate determination of the center of pressure, particularly for laminar boundary layers. However, an approximate method from reference 1 is presented.

The most extreme forward location of the center of pressure results from a two-dimensional nozzle located at the end of a plate. This location can be evaluated and used as a guide in estimating the true center-of-pressure location.

For three-dimensional nozzles the longitudinal extent of the separated boundary layer is much closer to the nozzle than for the two-dimensional case. Experimental data indicate that for most three-dimensional configurations one-half of the calculated value will be conservative and should suffice for preliminary-design purposes.

Step 21. Determine the time-history values of the center-of-pressure location for each time increment as follows:

a. For laminar flow

(1) Assume a value for the separation Reynolds number $R\ell_s$ of approximately one-fifth the Reynolds number based on the nozzle location $R\ell_L$. (It should be noted that although $R\ell_s$ is based on the separation location, it does not give an accurate value for the separation location.)

(2) Calculate the plateau-pressure coefficient C_{p_2} by

$$C_{p_2} = \frac{1.60}{\left[R\ell_s (M_1^2 - 1)\right]^{1/4}} \qquad 6.3.2\text{-k}$$

where

$$C_{p_2} = \frac{P_2 - P_1}{q_1}$$

(3) Calculate the total drag coefficient of the interaction phenomena by

$$C_x = 4.75\ C_{p_2} \qquad 6.3.2\text{-}\ell$$

(4) Calculate the normalized effective jet height by

$$\frac{h}{L} = \left(\frac{P_{0_j}\ d_t}{P_1 L}\right)\left(\frac{2\ C_{f_0}}{\gamma C_x M_1^{\ 2} + 2}\right) \qquad 6.3.2\text{-m}$$

(5) Calculate the plateau pressure by

$$P_2 = C_{p_2}\ q_1 + P_1 \qquad 6.3.2\text{-n}$$

(6) Calculate the tangent of the boundary-layer separation angle by

$$\tan \sigma = \left[\frac{5(\xi - 1)}{7\ M_1^{\ 2} - 5(\xi - 1)}\right]\left[\frac{7\ M_1^{\ 2} - (6\xi + 1)}{6\xi + 1}\right]^{1/2} \qquad 6.3.2\text{-o}$$

where

$$\xi = \frac{P_2}{P_1} \qquad 6.3.2\text{-p}$$

(7) Calculate a new value for the normalized effective jet height by

$$\left(\frac{h}{L}\right)_{new} = \left(1 - \frac{R_{\ell_s}}{R_{\ell_L}}\right) \tan \sigma \qquad 6.3.2\text{-q}$$

(8) If $\left(\frac{h}{L}\right)_{new}$ given by equation 6.3.2-q is not equal to $\left(\frac{h}{L}\right)$ given by equation 6.3.2-m, i.e., $\left(\frac{h}{L}\right)_{new} \neq \left(\frac{h}{L}\right)$, choose a new value for R_{ℓ_s} in step 21.a.(1) and iterate until $\left(\frac{h}{L}\right)_{new} = \left(\frac{h}{L}\right)$.

(9) Calculate the normalized center-of-pressure location with respect to the nozzle location by

$$\frac{x_{cp}}{L} = (1 - G) + G \left[1 - \frac{G}{2} \left(\frac{C_{F_c}}{C_{p_2}} \right) \right] \qquad 6.3.2\text{-r}$$

where

$$G \cong 1 - \frac{1}{K} \qquad 6.3.2\text{-s}$$

and C_{p_2} is based on the correct value of $R\ell_s$. (step 21.a.(2))

b. For turbulent flow

(1) Calculate the plateau-pressure coefficient C_{p_2}

For $M_1 \leq 5$

$$C_{p_2} = 0.41 + 0.481\, M_1 - 0.0509\, M_1^2 + 0.0061\, M_1^3 \qquad 6.3.2\text{-t}$$

For $M_1 > 5$

$$C_{p_2} = 0.2257 - 0.0232\, M_1 + 0.0014\, M_1^2 - 0.00003\, M_1^3 \qquad 6.3.2\text{-u}$$

(2) Calculate the normalized center-of-pressure location with respect to the nozzle location by

$$\frac{x_{cp}}{L} = (1 - G) + G \left[1 - \frac{G}{2} \left(\frac{C_{F_c}}{C_{p_2}} \right) \right] \qquad \text{(equation 6.3.2-r)}$$

where

$$G \cong 1 - \frac{1}{K} \qquad \text{(equation 6.3.2-s)}$$

If the calculated value for the center of pressure appears to introduce a significant error into the determination of the required control force in step 2, a new control force should be calculated and the procedure repeated for sizing the nozzle.

Sample Problem

Given: A transverse jet located at the trailing edge of a flat plate

$L = 10.0$ ft $\quad b = 2.0$ ft $\quad \phi = 30^{o} \quad V_e/a_t = 2.0$

$M_e = 2.39 \quad \gamma = 1.2 \quad I_{sp} = 225.0$ sec $\quad c = 0.90$

The sample problem presents a hypothetical case which serves to illustrate the Datcom method. The time-history values of the control force F_c must be calculated or established prior to the application of the Datcom method. For a real problem, the time-history values of the free-stream Mach number M_∞ and the angle of attack α_∞ must also be determined prior to the application of the Datcom method, in order to obtain the time-history values of the local-flow parameters.

TABLE 6.3.2-A

SAMPLE TRANSVERSE-JET SIZING CALCULATIONS

1. Time (sec)	1	2	3	4	5
2. Control Force, F_c (lb)	1000	2000	1000	500	200
3. Local Mach No., M_1	10.0	9.0	8.0	7.0	6.0
4. Reynolds No., $R\ell_L$	1×10^8	5×10^7	1×10^7	5×10^6	1×10^6
5. Local Pressure, P_1 (lb/in.^{2})	1.70	0.65	0.25	0.10	0.04
6. Dynamic Pressure, q_1 (lb/in.^{2})	119	36.8	11.2	3.43	1.01
7. Boundary Layer	turb	turb	turb	turb	lam
8. Control-Force Coeff., $C_{F_c} = F_c/(q_1\, b\, L)$	0.00292	0.0189	0.0310	0.0506	0.0688
9. Corrected Force Coeff., $\left(C_{F_c}\right)_{cr}$	0.00296	0.0192	0.0314	0.0513	0.0698
10. Sonic Amplification Factor, K_o	2.53	2.15	2.10	2.05	2.80
11. Amplification Factor, K	3.44	2.86	2.78	2.70	3.86
12. Vacuum Thrust, F_{j_0} (lb)	291	700	360	185	51.8
13. Min. Pressure Ratio, $(P_{0_j}/P_1)_{min}$	560	510	465	420	375
14. Min. Jet Pressure, $(P_{0_j})_{min}$ (lb/in.^{2})	950	332	116	42	15
15. Jet Pressure, $(P_{0_j})_{trim}$ (lb/in.^{2})	316	760	391	201	56.3
16. Mass-Flow Rate, $\dot{m}$ (lb/sec)	1.29	3.12	1.60	0.82	0.23

With the time-history values of the local-flow parameters completed in items 3 through 7 of table 6.3.2-A, the calculation for the sample problem continues for $t = 1$ second with step 4.

Determine the state of the boundary layer from wind-tunnel test data or as a function of M_1 and $R\ell_L$ from figure 6.3.2-34.

Determine the control-force coefficient

$$C_{F_c} = \frac{F_c}{q_1 bL} \qquad \text{(equation 6.3.2-a)}$$

$$= \frac{1000}{(119)(2)(10)(144)}$$

$$= 0.00292$$

Determine the vacuum-thrust coefficient

$$C_{f_0} = \left(\frac{2}{\gamma + 1}\right)^{\frac{\gamma}{\gamma-1}} (\gamma + 1) \qquad \text{(equation 6.3.2-b)}$$

$$= \left(\frac{2}{1.2 + 1}\right)^{\frac{1.2}{1.2-1}} (1.2 + 1)$$

$$= 1.25$$

Determine the corrected control-force coefficient

$$\left(C_{F_c}\right)_{cr} = \left(\frac{F_c}{q_1 bL}\right)\left(\frac{1.268}{C_{f_0}}\right) \qquad \text{(equation 6.3.2-c)}$$

$$= (0.00292)\left(\frac{1.268}{1.250}\right)$$

$$= 0.00296$$

Determine the sonic amplification factor

$K_o = 2.53$ (figure 6.3.2-40)

Determine the true amplification factor

$K = 3.44$ (figure 6.3.2-41)

Determine the vacuum thrust

$$F_{j_0} = \frac{F_c}{K} \qquad \text{(equation 6.3.2-f)}$$

$$= \frac{1.000}{3.44}$$

$$= 291 \text{ lb}$$

Determine the minimum jet plenum pressure required to induce separation

$$\left(\frac{P_{0_j}}{P_1}\right)_{min} = 560 \qquad \text{(figure 6.3.2-43)}$$

$$\left(P_{0_j}\right)_{min} = \left(\frac{P_{0_j}}{P_1}\right)_{min} P_1 \qquad \text{(equation 6.3.2-g)}$$

$$= (560)\ (1.70)$$

$$= 950 \text{ lb/in.}^2$$

The remaining steps cannot be based on one time segment; i.e., the total time history of the various parameters must be considered.

Determine the throat width

$$d_t = \frac{\left(F_{j_0}\right)_{max} SF}{c\, C_{f_0}\, b \left(P_{0_j}\right)_{max}} \qquad \text{(equation 6.3.2-h)}$$

$$= \frac{(700)\ (1.25)}{(0.9)\ (1.25)\ (24)\ (950)}$$

$$= 0.0341 \text{ in.}$$

The safety factor is determined from the maximum thrust and the maximum jet plenum pressure. The maximum thrust required is 700 lb; however, a value of 900 lb should allow for contingencies. If the design value for the maximum jet pressure required to induce separation is chosen to be 1000 lb/in.^{2} rather than the value of 950 lb/in.^{2} in table 6.3.2-A, the safety factor can be expressed as

$$SF = \frac{\left(F_{j_0}\right)_{max}}{\left(P_{0_j}\right)_{max}}\Bigg|_{design} \frac{\left(P_{0_j}\right)_{max}}{\left(F_{j_0}\right)_{max}}$$

$$= \left(\frac{900}{1000}\right)\left(\frac{950}{700}\right)$$

$$= 1.21, \text{ use } 1.25$$

The jet plenum pressures required to trim the vehicle are calculated based on the throat width by using equation 6.3.2-i. These calculated plenum pressures must always exceed the plenum pressure required to induce separation (950 lb/in.^{2} at the initial time period of one second). The jet plenum pressures required for trim (item 15 in the table) were computed as follows:

$$\left(P_{0_j}\right)_{trim} = \frac{F_{j_0}}{c\, C_{f_0}\, b\, d_t} \qquad \text{(equation 6.3.2-i)}$$

$$= \frac{F_{j_0}}{(0.9)\,(1.25)\,(24)\,(0.0341)}$$

$$= 1.086\, F_{j_0}$$

It is seen that the jet plenum pressures required for trim (item 15) are less than the specified minimum value at the initial time of one second. Two choices are available: either the throat width can be reduced with a corresponding increase in jet pressure or, if this proves to be detrimental to the system weight, then some loss in effectiveness can probably be accepted for a short time period in order to avoid increasing the jet pressure. The proper choice depends upon the sensitivity of the control-system weight to an increase in jet plenum pressure.

The propellant weight required to trim the vehicle is obtained from the integral of the mass-flow rate $\dot{m}$ in item 16. For the sample problem, the required propellant weight to trim the vehicle is 7.06 lb.

In order to arrive at an optimum nozzle design in any particular application, several iterations of the above procedure should be made with systematic variations in the initial assumptions. If extensive sizing studies are required and if suitable computing facilities are available, a computer program, described in reference 1, should be used.

Determine the center-of-pressure location.

Two cases are presented to illustrate the procedure: one where the boundary layer is turbulent and one where the boundary layer is laminar.

Case I t = 4 seconds (turbulent flow)

$M_1 = 7.0$

$C_{F_c} = 0.0506$ } (table 6.3.2-A)

$K = 2.70$

$$C_{p_2} = 0.2257 - 0.0232\, M_1 + 0.0014\, M_1^{\,2} - 0.00003\, M_1^{\,3} \qquad \text{(equation 6.3.2-u)}$$

$$= 0.2257 - 0.0232\,(7) + 0.0014\,(49) - 0.00003\,(343)$$

$$= 0.1216$$

$$G \cong 1 - \frac{1}{K} \qquad \text{(equation 6.3.2-s)}$$

$$= 1 - \frac{1}{2.70} = 0.63$$

$$\frac{x_{cp}}{L} = (1 - G) + G \left[1 - \frac{G}{2}\left(\frac{C_{F_c}}{C_{p_2}}\right)\right] \qquad \text{(equation 6.3.2-r)}$$

$$= (1 - 0.63) + 0.63 \left[1 - \frac{0.63}{2}\left(\frac{0.0506}{0.1216}\right)\right]$$

$$= 0.917$$

$$x_{cp} = (0.917)\, L$$

$$= (0.917)\,(10)$$

$$= 9.17 \text{ ft from leading edge}$$

Case II t = 5 seconds (laminar flow)

$M_1 = 6.0$

$C_{F_c} = 0.0688$ } (table 6.3.2-A)

$K = 3.86$

$P_{0_j} = 56.3$ lb/in.^{2}

$P_1 = 0.04$ lb/in.^{2} } (table 6.3.2-A)

$q_1 = 1.01$ lb/in.^{2}

First iteration (assume $R_{\ell_s} = 1 \times 10^5$)

$$C_{p_2} = \frac{1.60}{\left[R_{\ell_s} (M_1^2 - 1)\right]^{1/4}} \qquad \text{(equation 6.3.2-k)}$$

$$= \frac{1.60}{[10^5 (36 - 1)]^{1/4}}$$

$$= 0.037$$

$$C_x = 4.75\ C_{p_2} \qquad \text{(equation 6.3.2-ℓ)}$$

$$= (4.75)\ (0.037)$$

$$= 0.1758$$

$$\frac{h}{L} = \left[\frac{P_{0_j}\ d_t}{P_1\ L}\right] \left[\frac{2\ C_{f_0}}{\gamma\ C_x\ M_1^2 + 2}\right] \qquad \text{(equation 6.3.2-m)}$$

$$= \left[\frac{(56.3)\ (0.0341)}{(0.04)\ (10)\ (12)}\right] \left[\frac{(2)\ (1.25)}{(1.2)\ (0.1758)\ (36) + 2}\right]$$

$$= (0.400)\ (0.2605)$$

$$= 0.104$$

$$P_2 = C_{p_2}\ q_1 + P_1 \qquad \text{(equation 6.3.2-n)}$$

$$= (0.037)\ (1.01) + 0.04$$

$$= 0.0774 \text{ lb/in.}^2$$

$$\xi = \frac{P_2}{P_1} = \frac{0.0774}{0.04} = 1.93 \qquad \text{(equation 6.3.2-p)}$$

$$\tan \sigma = \left[\frac{5(\xi - 1)}{7 M_1^2 - 5(\xi - 1)}\right]\left[\frac{7 M_1^2 - (6\xi + 1)}{6\xi + 1}\right]^{1/2} \qquad \text{(equation 6.3.2-o)}$$

$$= \left[\frac{5(0.93)}{7(36) - 5(0.93)}\right]\left[\frac{7(36) - [6(1.93) + 1]}{6(1.93) + 1}\right]^{1/2}$$

$$= (0.0188)(4.36)$$

$$= 0.082$$

$$\left(\frac{h}{L}\right)_{new} = \left(1 - \frac{R_{\ell_s}}{R_{\ell_L}}\right)\tan \sigma \qquad \text{(equation 6.3.2-q)}$$

$$= \left(1 - \frac{10^5}{10^6}\right)(0.0819)$$

$$= 0.0738$$

Since $0.0738 \neq 0.104$, try a second iteration.

Second iteration (assume $R_{\ell_s} = 5 \times 10^4$)

$$C_{p_2} = \frac{1.60}{[(5 \times 10^4)(36 - 1)]^{1/4}} = 0.044 \qquad \text{(equation 6.3.2-k)}$$

$$C_x = (4.75)(0.044) = 0.209 \qquad \text{(equation 6.3.2-ℓ)}$$

$$\frac{h}{L} = \left[\frac{(56.3)(0.0341)}{(0.04)(10)(12)}\right]\left[\frac{2(1.25)}{(1.2)(0.209)(36) + 2}\right] \qquad \text{(equation 6.3.2-m)}$$

$$= (0.400)(0.227)$$

$$= 0.0908$$

$$P_2 = (0.044)(1.01) + 0.04 = 0.0844 \text{ lb/in.}^2 \qquad \text{(equation 6.3.2-n)}$$

$$\xi = \frac{P_2}{P_1} = \frac{0.0844}{0.04} = 2.11 \qquad \text{(equation 6.3.2-p)}$$

$$\tan \sigma = \left[\frac{5\,(1.11)}{252 - 5\,(1.11)}\right] \left[\frac{252 - [6\,(2.11) + 1]}{6\,(2.11) + 1}\right]^{1/2} \qquad \text{(equation 6.3.2-o)}$$

$$= (0.0225)\,(4.18)$$

$$= 0.094$$

$$\left(\frac{h}{L}\right)_{new} = \left(1 - \frac{5 \times 10^4}{10^6}\right)(0.094) = 0.0893 \qquad \text{(equation 6.3.2-q)}$$

Since $0.0893 \neq 0.0908$, try a third iteration.

Third iteration (assume $R_{\ell_s} = 4.85 \times 10^4$)

$$C_{p_2} = \frac{1.60}{[(4.85 \times 10^4)\,(36 - 1)]^{1/4}} = 0.0443 \qquad \text{(equation 6.3.2-k)}$$

$$C_x = (4.75)\,(0.0443) = 0.210 \qquad \text{(equation 6.3.2-}\ell\text{)}$$

$$\frac{h}{L} = \left[\frac{(56.3)\,(0.0341)}{(0.04)\,(10)\,(12)}\right] \left[\frac{(2)\,(1.25)}{(1.2)\,(0.210)\,(36) + 2}\right] \qquad \text{(equation 6.3.2-m)}$$

$$= (0.400)\,(0.226)$$

$$= 0.0904$$

$$P_2 = (0.0443)\,(1.01) + 0.04 = 0.0847 \text{ lb/in.}^2 \qquad \text{(equation 6.3.2-n)}$$

$$\xi = \frac{P_2}{P_1} = \frac{0.0847}{0.04} = 2.118 \qquad \text{(equation 6.3.2-p)}$$

$$\tan \sigma = \left[\frac{5\,(1.118)}{252 - 5\,(1.118)}\right] \left[\frac{252 - [6\,(2.118) + 1]}{6\,(2.118) + 1}\right]^{1/2} \qquad \text{(equation 6.3.2-o)}$$

$$= (0.0227)\,(4.17)$$

$$= 0.0947$$

$$\left(\frac{h}{L}\right)_{new} = \left(1 - \frac{4.95 \times 10^4}{10^6}\right)(0.0947) = 0.0901 \qquad \text{(equation 6.3.2-q)}$$

$0.0901 \cong 0.0904$; therefore $R_{\ell_s} = 4.85 \times 10^4$

$C_{p_2} = 0.0443$

$$G \cong 1 - \frac{1}{K} = 1 - \frac{1}{3.86} = 0.741 \qquad \text{(equation 6.3.2-s)}$$

$$\frac{x_{cp}}{L} = (1 - G) + G \left[1 - \frac{G}{2}\left(\frac{C_{F_c}}{C_{p_2}}\right)\right] \qquad \text{(equation 6.3.2-r)}$$

$$= (1 - 0.741) + 0.741 \left[1 - \frac{0.741}{2}\left(\frac{0.0688}{0.0443}\right)\right]$$

$$= 0.574$$

Since the value of $x_{cp}/L = 0.574$ is a conservative estimate of the most extreme forward position for a two-dimensional nozzle, the actual value is probably close to 0.75 or 0.80 (see discussion prior to step 21). Since the center of pressure for t = 5 seconds is not close to the nozzle location, it would be advisable to calculate a new control force based on the approximate value of x_{cp} = 7.5 ft and repeat the sizing calculation for t = 5 seconds.

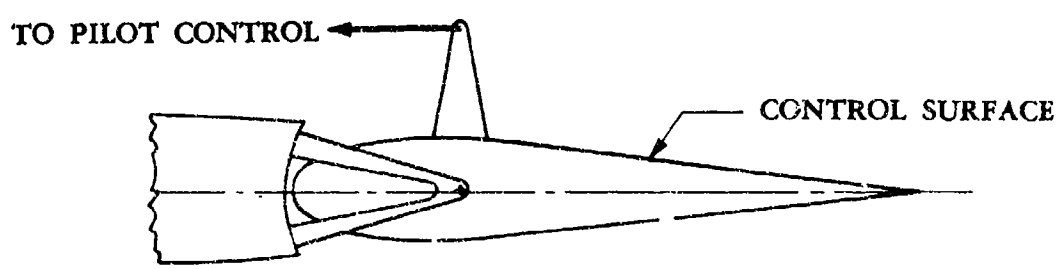
6.3.4 AERODYNAMICALLY BOOSTED CONTROL-SURFACE TABS

Aerodynamically boosted control-surface tabs have been successfully used to reduce the forces on reversible-control systems many years. Linear methods from Reference 1 are presented herein for estimating the stick forces for a variety of the most commonly used control-surface-tab systems. Because of the compressibility effects on tabs at high speeds, the application of these methods should be restricted to subsonic flow; i.e., speeds below the surface critical Mach number or not above a Mach number of 0.90, whichever is least.

In order that the Datcom user may better understand the complex design considerations for a tab system, a general discussion (essentially taken from Reference 1) of pertinent design parameters for control-surface-tab systems is presented. For more details regarding tab systems the reader is referred to References 1 through 6. For a discussion and method of springy tabs or downsprings, the reader is specifically referred to Reference 6.

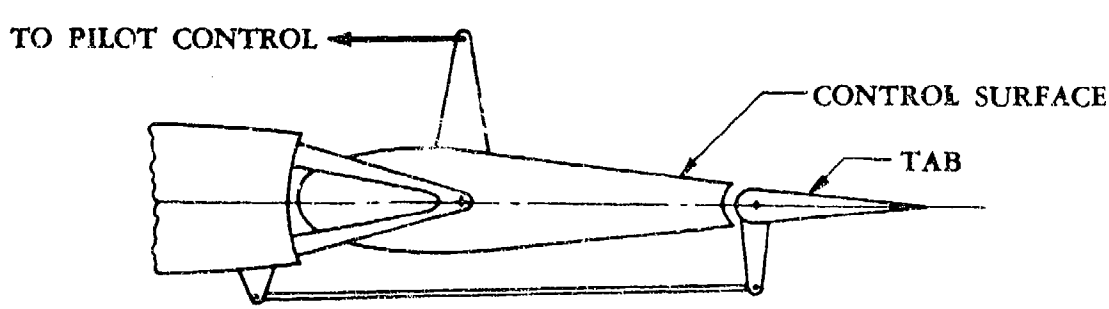
System Description

Aerodynamically boosted control systems can be divided into two distinct classifications: direct-control systems and indirect-control systems. Aerodynamic boost in direct-control systems includes nose aerodynamic balance, internal pressure balance on the main control surface, and may also include a tab "geared" to the main control surface. Sketch (a) illustrates the simple form of direct control without a tab, called "pure direct control."



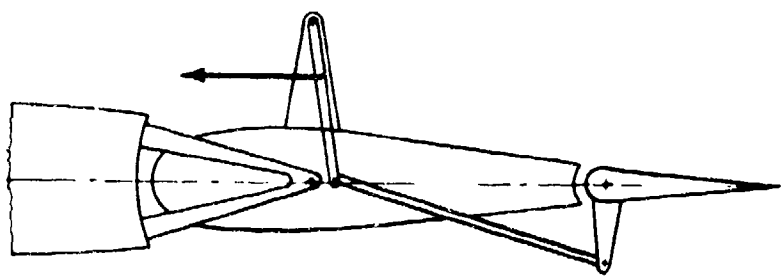
SKETCH (a) PURE DIRECT CONTROL

Sketch (b) illustrates the simple form of direct control with a tab, called a "geared tab."

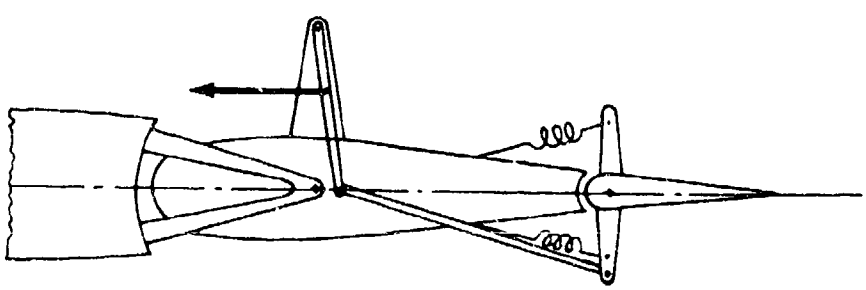


SKETCH (b) GEARED TAB

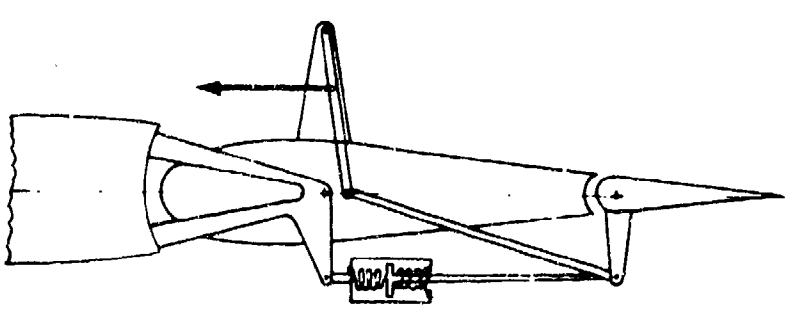
The most commonly used aerodynamically boosted control systems* fall into the indirect-control classification. Indirect-control systems may be subdivided into two types, one in which the pilot has direct control over both the tab and the main control surface and one in which he controls only the tab. Those systems in which the pilot has direct control over both the tab and the main control surface are referred to as link-tab systems. The three types of link-tab systems are plain linked tab, spring tab, and geared spring tab, shown schematically in Sketch (c).



PLAIN LINKED TAB



SPRING TAB



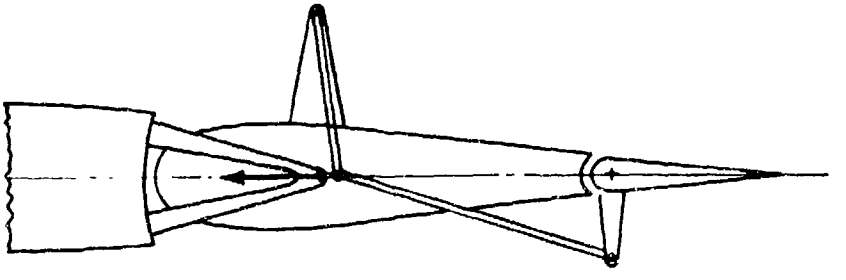
GEARED SPRING TAB

SKETCH (c)

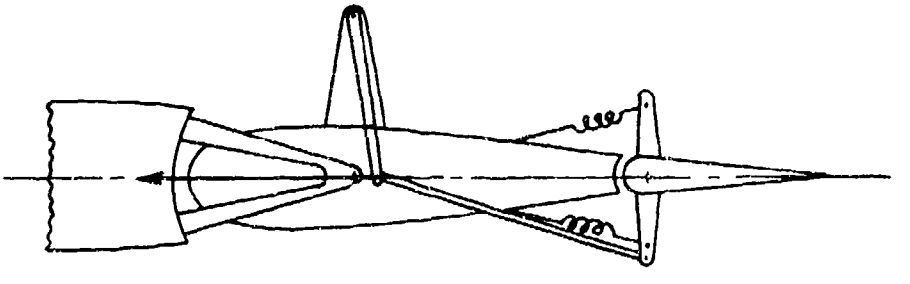
*The control surface may be either an elevator, aileron, or rudder, throughout the discussion.

The fundamental relationship of the three tab systems is depicted in Sketch (c). It is evident that a spring-tab system is a plain linked tab with a spring added. The geared spring tab includes all the components of a spring tab, but with the spring arranged in series with a geared tab link.

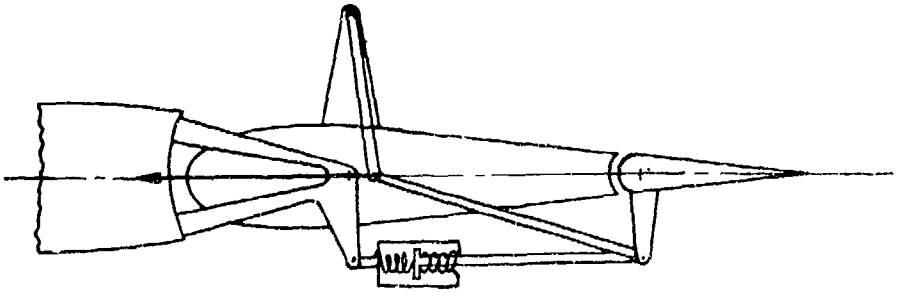
The second type of indirect-control system is distinguished from the link-tab systems in that the pilot controls only the tab and is therefore called the pure-flying-tab system. The three types of flying-tab systems are the pure flying tab, spring flying tab, and the geared flying tab as shown schematically in Sketch (d).



PURE FLYING TAB



SPRING FLYING TAB



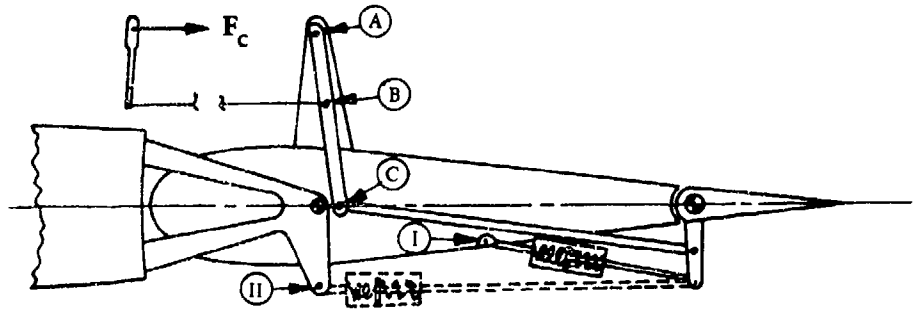
GEARED FLYING TAB

SKETCH (d)

Again, the fundamental relationship of the three tab systems is evident in Sketch (d).

It should be noted that both the plain linked tab and the pure flying tab have been called "servo-tabs" in much of the literature. However, since they are not identical systems, because of the different location of the cockpit control connecting point, it is important to maintain some distinction between the two.

In making any comprehensive analysis of aerodynamically boosted control-surface-tab systems, it is desirable first to reduce the special cases to be considered to the minimum number. Such a study reveals that all of the previously mentioned systems are but special cases of one general system. A schematic illustration of this general tab system is shown in Sketch (e). Table 6.3.4-A which accompanies the generalized control system, describes the specific tab system as a function of the cockpit control connecting point, along with the presence of a spring and its location.



GENERALIZED CONTROL SYSTEM SCHEMATIC DIAGRAM
SKETCH (e)

TABLE 6.3.4-A

Cockpit Control Connecting Point	Tab Spring Configuration	Type of Control System
A	No Spring	Pure Direct Control
A	II	Geared Tab
B	No Spring	Plain Linked Tab
B	I	Spring Tab
B	II	Geared Spring Tab
C	II	Geared Flying Tab
C	I	Spring Flying Tab
C	No Spring	Pure Flying Tab

For a complete understanding of this general control-tab system, it is essential that the system kinematics are clearly understood. The key feature of the tab linkage is the fact that point C in Sketch (e) is not fixed to the control surface; i.e., it is free to translate; whereas, point A in Sketch (e) is fixed to the control surface and can translate only with movement of the control. It should also be noted that the spring configuration I in Sketch (e) corresponds to the case where the tab gearing link is connected to the hinge bracket at the main control-surface hinge line.

Key Linkage Parameters

The tab-system designer determines the type of tab system and the system force characteristics by his selection of three key linkage parameters. These key linkage parameters are:

- o The aerodynamic boost link ratio R_L, which is an index to the relative location of the pilot connecting point (A, B, or C in Sketch (e))
- o The tab spring effectiveness k
- o The tab gearing β, which is determined by the connecting linkage between the tab and the hinge bracket

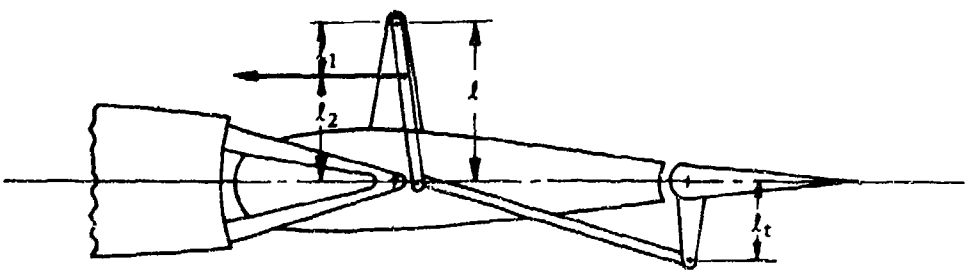
Boost Link Ratio R_L

The boost link ratio R_L is specifically defined as the rate of change of the tab deflection with respect to control-surface deflection with the control column fixed; i.e.,

$$R_L = \left(\frac{\partial \delta_{tc}}{\partial \delta_c} \right)_{\substack{\text{stick} \\ \text{fixed}}} \qquad 6.3.4\text{-a}$$

For a general tab system as shown in Sketch (f), the value of R_L can be approximated by the system geometry by

$$R_L = \frac{\ell_2}{\ell_1} \frac{\ell}{\ell_t} \qquad 6.3.4\text{-b}$$



SKETCH (f)

From this relationship, the value of R_L can be seen as a direct indication of the cockpit control connecting point. Thus, when the value of R_L is zero, the tab system corresponds to a pure flying tab as shown in Sketch (d). Likewise, when the value of R_L is infinite, the tab system becomes a direct-control system (with a free-floating tab).

Tab Spring Effectiveness k

The tab spring effectiveness k is defined as the rate of change of moment on the tab due to the spring with respect to tab deflection, based on the product of tab area and chord; i.e.,

$$k = -\left(\frac{\partial M_{tc}}{\partial \delta_{tc}}\right)_{spring} \frac{1}{S_{tc}\bar{c}_{tc}} \qquad 6.3.4\text{-c}$$

Thus, typical units of k could be lb/ft^2-deg or $lb/in.^2$-deg.

Control Tab Gearing Ratio β

The control-tab-gearing ratio β is specifically defined as the rate of change of the tab deflection with respect to control-surface deflection with $k = \infty$ and the stick free; i.e.,

$$\beta = \left(\frac{\partial \delta_{tc}}{\partial \delta_c}\right)_{\substack{stick \\ free}} \text{ with } k = \infty \qquad 6.3.4\text{-d}$$

So, for a tab system without any connecting linkage between the tab and the hinge bracket, the value of β is zero, i.e., no gearing. For a geared system, the specific value of β is determined by the location of the connecting linkage relative to the control-surface hinge line.

Linkage-Parameter Effects on Forces

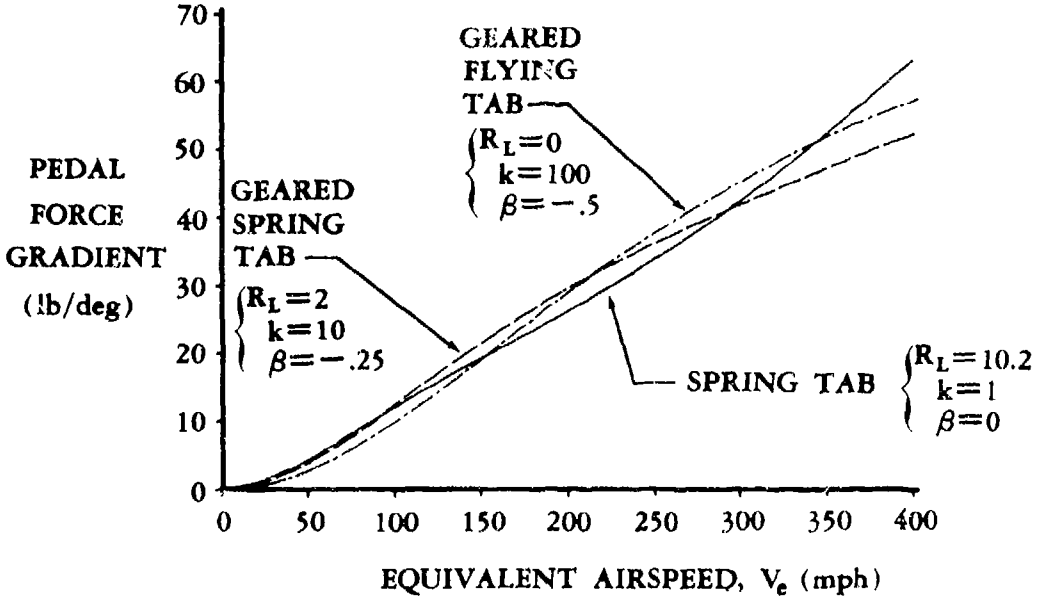
For discussion purposes, consider a plain-linked-tab system on a control surface that requires a pilot force of two hundred pounds to control the main surface, tab free, and a two-pound pilot force for a pure-flying-tab control. By applying one pound of pilot force to the tab, one-half the total work required to move the main surface is performed by the tab itself. Then by applying one hundred pounds of force to the main surface, the remaining one-half of the work is made up by the pilot directly, and the total pilot effort is 100 + 1 or 101 pounds. Thus, the link ratio R_L defines the proportions of the force division. At infinite link ratio, the pilot force will be two hundred pounds; at zero link ratio, two pounds. Therefore, a reduction in link ratio R_L results in a reduction of pilot force.

The use of a spring on the tab increases the tab hinge moments, and therefore increases the forces of a plain-linked-tab system. In the preceding example the force required to move the tab may be increased to, say, twenty pounds. For the same linkage, then, the total pilot force would be 100 + 10 or 110 pounds. Essentially, the spring effect adds an element of locked-tab hinge moment and reduces slightly the free-tab contribution. (This concept may be more clearly understood by referring to Equations 6.3.4-k and -o, which divide the control column force into contributions due to the free-tab, locked-tab, and gearing components.) Since the increase due to the locked-tab element is always greater than the corresponding decrease in the free-tab contribution, the pilot force will increase with increasing tab spring effectiveness.

Tab gearing β in the boost direction always reduces the pilot forces (by an increment rather than by a percentage), although the magnitude of the effect depends upon the values of the tab spring effectiveness k and the link ratio R_L. The effects of the spring and link ratio, however, are not so simply stated. Here both the magnitude and direction of the effect of one depend upon the value of the other and also on the tab gear ratio. In order to understand the interrelations between these parameters, it is necessary first to examine the "aerodynamic" characteristics of a spring. By this is meant the relationship of aircraft speed to the spring effect.

Normal aerodynamic coefficients are of course independent of speed if compressibility and aeroelastic effects are neglected. However, the spring characteristics are represented aerodynamically as (k/q) where q is the local dynamic pressure of the airstream. At zero airspeed the aerodynamic spring characteristic is infinite for all finite values of k. However, at infinite airspeed the aerodynamic spring characteristic is zero for all values of k. Hence, the characteristics of any system incorporating a tab spring correspond to those with the tab locked as in pure direct control (or geared as a geared tab) at zero airspeed, and to a system with no spring at infinite airspeed.

The individual effects of the linkage parameters are interrelated, but are nevertheless independent of the type of system used. It may be surmised that "special tab arrangements" are in themselves not that significant. What is more important is the matter of choosing proper values of the linkage parameters for a design application, rather than choosing a particular type of system. To illustrate this point, Sketch (g) shows three different tab systems for a particular control surface on an aircraft. Each tab system has been adjusted to yield nearly equivalent force characteristics over the speed range considered.



SKETCH (g)

DATCOM METHOD

The Datcom Method presents the fundamental relationship between the pilot forces and the tab and control-surface moments from which the control-column forces are evaluated.

The control-column force equations are presented in such a manner that the individual contributions of the various factors, i.e., tab-free, tab-fixed, and gearing contributions can be readily identified. It should be noted that two control-column force equations are presented, both of which define a general tab control system for an elevator, rudder, aileron, or other control system having linear characteristics. The two equations presented are based on different independent variables for the convenience of the user (they provide identical values of control-column force).

Because of the lengthy control-column force equations, a summary table and shorthand notation has been used to simplify the presentation of equations. In order to facilitate this presentation, the following general notation list is provided.

NOTATION*

SYMBOL		DEFINITION
A_c	=	$\dfrac{S_{tc}\bar{c}_{tc}}{S_c\bar{c}_c}$.
B_1	=	$\left(\partial C_{h_c}/\partial\delta_c\right)_{\delta_{tc},\alpha_s,\delta_{tt}}$
B_2	=	$\left(\partial C_{h_c}/\partial\delta_{tc}\right)_{\delta_c,\alpha_s,\delta_{tt}}$
B_3	=	$\left(\partial C_{h_c}/\partial\alpha_s\right)_{\delta_c,\delta_{tc},\delta_{tt}}$
B_4	=	$\left(\partial C_{h_c}/\partial\delta_{tt}\right)_{\delta_c,\delta_{tc}\alpha_s}$
$\bar{c}_{(\ )}$		surface mean aerodynamic chord (movable surfaces are defined by their area aft of the hinge line, and the MAC is of that area)
C_{h_c}		is the hinge-moment coefficient of the particular control surface, i.e., $H_c/qS_c\bar{c}_c$)(either an elevator, rudder, or aileron)
$C_{h_{tc}}$		is the hinge-moment coefficient of the control tab, i.e., $H_{tc}/qS_{tc}\bar{c}_{tc}$)
C_L		lift coefficient, positive up or to the right

*Units are not specified for derivatives, lengths, or areas. It is up to the user to choose his units and be consistent throughout.

SYMBOL	DEFINITION
C_{L_s}	lift coefficient of surface to which the main control surface is attached, i.e., C_{L_H}, C_{L_V}, or C_{L_W} (total lift, including lift due to control deflection, tab deflection, and angle of attack)
C_{L_H}	is the horizontal-tail lift coefficient (total lift, including lift due to control deflection, tab deflection, and angle of attack)
C_{L_V}	is the vertical-tail lift coefficient (total lift, including lift due to control deflection, tab deflection, and angle of attack)
C_{L_W}	is the wing lift coefficient (total lift, including lift due to control deflection, tab deflection, and angle of attack)
C_{L_α}	airplane lift-curve slope
$C_{L_{\alpha_H}}$	airplane lift-curve slope with respect to the tail angle of attack
$C_1 = \left(\partial C_{L_s}/\partial \delta_c\right)_{\delta_{tc}, \delta_{tt}, \alpha_s}$	
$C_2 = \left(\partial C_{L_s}/\partial \delta_{tc}\right)_{\delta_c, \alpha_s, \delta_{tt}}$	
$C_3 = \left(\partial C_{L_s}/\partial \alpha_s\right)_{\delta_c, \delta_{tc}, \delta_{tt}}$	
$C_4 = \left(\partial C_{L_s}/\partial \delta_{tt}\right)_{\delta_c, \alpha_s, \delta_{tc}}$	
$D_1 = \left(\partial C_{h_{tc}}/\partial \delta_c\right)_{\delta_{tc}, \alpha_s}$	
$D_2 = \left(\partial C_{h_{tc}}/\partial \delta_{tc}\right)_{\delta_c, \alpha_s}$	
$D_3 = \left(\partial C_{h_{tc}}/\partial \alpha_s\right)_{\delta_c, \delta_{tc}}$	
$E_1 = B_1/C_1$	
$E_2 = B_2 - C_2E_1$	
$E_3 = B_3 - C_3E_1$	
$E_4 = B_4 - C_4E_1$	
F_c	control-column force in lb (pull force is positive)

SYMBOL		DEFINITION
F_s		elevator stick force in lb (pull force is positive)
F_p		rudder-pedal force in lb (push on left pedal is positive)
F_1	=	D_1/C_1
F_2	=	$D_2 - C_2F_1$
F_3	=	$D_3 - C_3F_1$
F_4	=	$-C_4F_1$
$G_{(\ )}$		pilot gearing factor (see Equations 6.3.4-f and -f')
$G_{c_{max}}$		maximum stick gearing (see Equation 6.3.4-i)
$H_{(\ )}$		control hinge moment
k		tab spring effectiveness, in lb/ft^2-deg (see Equation 6.3.4-c)
n'		airplane normal acceleration or load factor in g's
q		local dynamic pressure (lb/ft^2)
q_∞		free-stream dynamic pressure (lb/ft^2)
R_1, R_2		shorthand notation for tab and main surface hinge moments and key linkage parameters, obtained from Table 6.3.4-B
R_L		aerodynamic boost link ratio (see Equations 6.3.4-a and -b)
$S_{(\ )}$		surface area (movable surfaces are defined by their area aft of the hinge line)
T_1, T_2		shorthand notation for tab and main surface hinge moments and key linkage parameters, obtained from Table 6.3.4-C
V		airspeed
W		aircraft weight
x_c		fore and aft displacement of control column, positive forward
$x_{c_{max}}$		maximum displacement of control column, positive forward

SYMBOL		DEFINITION
x_p		fore and aft displacement of right rudder pedal, positive forward
α		angle of attack, positive for lift increase
α_s		angle of attack of the surface to which the main control surface is attached, i.e., α_H, α_V, or α_W
α_H		angle of attack of the horizontal tail
α_V		angle of attack of the vertical tail
α_W		angle of attack of the wing
β		control-tab gear ratio (see Equation 6.3.4-d)
ϵ		downwash at the horizontal tail
Δ_r	=	$-\delta_{tc_{max}}/\delta_{c_{max}}$ for a maximum control deflection (the value of Δ_r is positive because $\delta_{tc_{max}}$ and $\delta_{c_{max}}$ will have opposite signs)
$\delta_{c_{max}}$		the maximum deflection of the main control surface, in degrees
$\delta_{(\ )}$		surface deflection, positive for trailing edge down or to the left, in degrees
σ		air density ratio, ρ/ρ_o
ϕ_β		lift efficiency factor for a geared tab system, $1 + \beta C_2/C_1$

SUBSCRIPTS

c	main control surface (elevator, rudder, aileron, etc.)
e	elevator
H	horizontal tail
p	control pedal
r	rudder
s	surface to which the main control surface is attached, i.e., horizontal tail, vertical tail, or wing
tc	control tab
tt	trim tab

The following relationship from Reference 1 is derived from basic considerations of system equilibrium and fundamental laws, giving a relationship between pilot forces and the tab and control surface moments, as

$$F_c = G_c H_c = G_{tc} H_{tc} = -G_c R_L H_{tc} \qquad 6.3.4\text{-e}$$

where the control-surface stick gearing G_c and the tab stick gearing G_{tc} are defined as

$$G_c = \frac{1}{57.3\left(\frac{\partial x_c}{\partial \delta_c}\right)_{tc}} \qquad 6.3.4\text{-f}$$

$$G_{tc} = \frac{1}{57.3\left(\frac{\partial x_c}{\partial \delta_{tc}}\right)_{c}} \qquad 6.3.4\text{-f}'$$

Using Equation 6.3.4-e, the aerodynamic boost link ratio R_L can be expressed as a function of the stick and tab gearing, i.e.,

$$R_L = \frac{-G_{tc}}{G_c}$$

Since the aerodynamic boost link ratio must be positive, it becomes evident that the control surface stick gearing G_c and the tab stick gearing G_{tc} must have opposite signs.

The particular form of Equation 6.3.4-e that is used is dependent upon the value of the boost link ratio; i.e.,

$$F_c = G_c H_c \qquad \text{for} \qquad R_L = \infty$$

$$F_c = G_{tc} H_{tc} \qquad \text{for} \qquad R_L = 0$$

$$F_c = -G_c R_L H_{tc} \qquad \text{for} \qquad 0 < R_L < \infty$$

The control surface moments M_c for a general tab system (see Sketch (e)) can be expressed as*

$$H_c = S_c \bar{c}_c q[B_1 \delta_c + B_2 \delta_{tc} + B_3 \alpha_s + B_4 \delta_{tt} + \frac{k}{q} A_c \beta(\delta_{tc} - \beta\delta_c)] \qquad 6.3.4\text{-g}$$

*These moment equations are applicable for symmetrical, untwisted control surfaces that yield a value of zero for H_c and H_{tc} when δ_c, δ_{tc}, δ_{tt}, and α_s are all zero.

and the tab surface moments M_{t_c} for a general tab system can be expressed as*

$$H_{t_c} = S_{t_c}\bar{c}_{t_c}q[D_1\delta_c + D_2\delta_{t_c} + D_3\alpha_s - \frac{k}{q}(\delta_{t_c} - \beta\delta_c)] \qquad 6.3.4\text{-h}$$

Equation 6.3.4-e is the primary aerodynamic relationship from which the stick forces are evaluated. It defines not only the force-moment relationships, but also the system equilibrium Therefore, analysis of any control system can be made if the control-surface and control-tab hinge-moment characteristics and the system motion characteristics are known.

Another significant parameter is the maximum stick gearing $G_{c_{max}}$ defined by

$$G_{c_{max}} = \frac{1}{57.3\left(\frac{\partial x_c}{\partial \delta_c}\right)_{max}} \qquad 6.3.4\text{-i}$$

The stick gearing G_c is related to the maximum stick gearing by the following:

$$\frac{G_c}{G_{c_{max}}} = \frac{R_L + \Delta_r}{R_L} \qquad 6.3.4\text{-j}$$

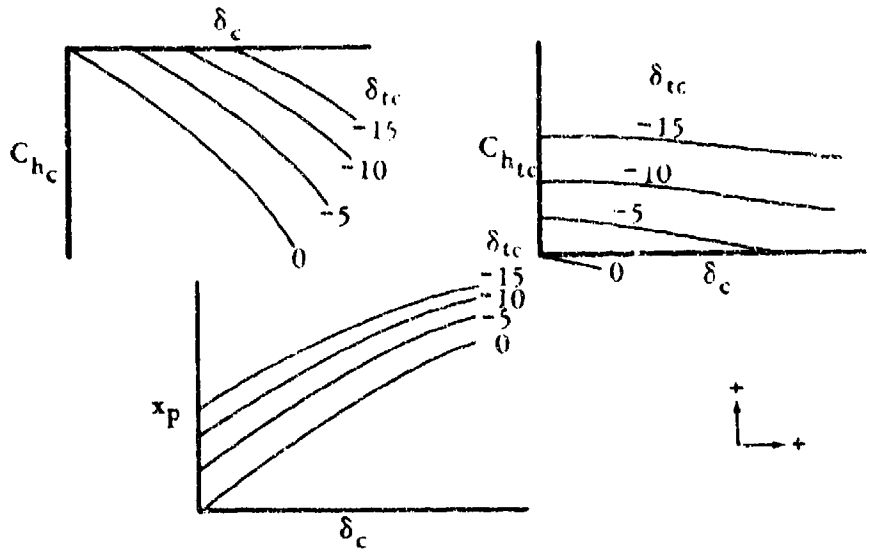
From this equation it is evident that the value of the ratio $G_c/G_{c_{max}}$ is greater than one. This simply means that the cockpit control travel must be greater than that required to bottom the control with the tab fixed. Sufficient control travel must exist to bottom the control surface and the control surface tab simultaneously, while allowing for cable stretch.

Control Column Forces

The analysis of a typical tab system requires detailed knowledge of the tab and control hinge-moment characteristics as a function of the main-control-surface angle of attack. For a particular angle of attack, Sketch (h) illustrates the typical hinge-moment and gearing data required to analyze any tab control system.

These data should preferably be obtained from wind-tunnel-test data or may be estimated by using the hinge-moment methods of Section 6.1.6. Because of the lengthy control-column force equations, a summary table and shorthand notation will be used to simplify the presentation of the equations. The format in which the control-column force equations are presented, i.e., tab-free, tab-fixed, and gearing contributions, is used so that the contribution of the various factors can be more readily identified.

*These moment equations are applicable for symmetrical, untwisted control surfaces that yield a value of zero for H_c and H_{t_c} when δ_c, δ_{t_c}, δ_{t_t}, and α_s are all zero.



SKETCH (h)

The two control-column force equations presented herein are modifications of Equation 6.3.4-e, with the variable δ_{tc} being eliminated. These equations are for a general tab control system on an elevator, rudder, aileron, or other control system having linear aerodynamic characteristics. (For example, when evaluating an elevator tab system, the terms $\bar{c}_c$, δ_c, C_{h_c}, α_s, etc., become $\bar{c}_e$, δ_e, C_{h_e}, α_H, etc., respectively.) The first equation is based on the independent variables δ_c, α_s, and δ_{tt}; while the second equation is based on the independent variables C_L, α_s, and δ_{tt}. Either equation may be used depending upon the preference of the user.

The first equation for estimating the control-column force characteristics, based on the independent variables δ_c, α_s, and δ_{tt}, is

$$F_c = G_{c_{max}} S_c \bar{c}_c q \left[C_{h_{c_{\substack{tab \\ free}}}} R_1 + C_{h_{c_{\substack{tab \\ locked}}}} R_2 + \Delta C_{h_{c_{\substack{tab \\ gearing}}}} R_2 \right] \qquad 6.3.4\text{-k}$$

where

$G_{c_{max}}$ is the maximum stick gearing available as defined by Equation 6.3.4-i. The value of $G_{c_{max}}$ is finite for all tab systems with a finite boost link ratio. However, for flying-tab systems where $R_L = 0$, the value of $G_{c_{max}}$ is zero. To avoid a problem when using Equation 6.3.4-k, the user should realize that the R_1 and R_2 terms for flying-tab systems in Table 6.3.4-B contain the parameter Δ_r. The product of $G_{c_{max}}$ and Δ_r yields $G_{tc_{max}}$ or the maximum gearing of the tab, which has a finite value. Thus, for flying-tab systems a finite value of $G_{c_{max}}$ is not possible; however, Equation 6.3.4-k is still applicable when $G_{tc_{max}}$ is used to replace the product of $G_{c_{max}}$ and Δ_r.

q is the dynamic-pressure ratio. This value must be consistent with whatever value is used to nondimensionalize the hinge-moment coefficients in Equations 6.3.4-ℓ, -m, and -n. If the hinge-moment coefficients are based on wind-tunnel-test data, they are probably nondimensionalized with respect to the free-stream dynamic-pressure ratio. If the Datcom is used to estimate the hinge-moment coefficients, the local dynamic-pressure ratio should be used. (Local dynamic-pressure ratio may be obtained from Section 4.4.1 for an empennage panel.)

$$C_{h_{c_{\substack{tab \\ free}}}} = \left(B_1 - D_1 \frac{B_2}{D_2}\right)\delta_c + \left(B_3 - D_3 \frac{B_2}{D_2}\right)\alpha_s + B_4 \delta_{tt} \qquad 6.3.4\text{-}\ell$$

$$C_{h_{c_{\substack{tab \\ locked}}}} = B_1 \delta_c + B_3 \alpha_s + B_4 \delta_{tt} \qquad 6.3.4\text{-m}$$

$$\Delta C_{h_{c_{gearing}}} = (\beta B_2 + \beta A_c D_1 + \beta^2 A_c D_2)\delta_c + (\beta A_r D_3)\alpha_s \qquad 6.3.4\text{-n}$$

The values for R_1 and R_2 are found from Table 6.3.4-B as a function of the specific type of tab system. This table also summarizes values for the three key linkage parameters R_L, k, and β for each specific type of tab system, using an "F" to denote finite values for the parameters.

The second equation for estimating the control-column force characteristics, based on the independent variables C_{L_s}, α_s, and δ_{tt}, is

$$F_c = G_{c_{max}} S_c \bar{c}_c q \left[C_{h_{c_{\substack{tab \\ free}}}} T_1 + C_{h_{c_{\substack{tab \\ locked}}}} T_2 + \Delta C_{h_{c_{gearing}}} T_2\right] \qquad 6.3.4\text{-o}$$

where

$G_{c_{max}}$ is the maximum stick gearing available as defined by Equation 6.3.4-i. The same comments made about $G_{c_{max}}$ for spring tab systems, when using Equation 6.3.4-k, also apply to the application of Equation 6.3.4-o (see discussion following Equation 6.3.4-k).

q is the dynamic-pressure ratio as defined above for Equation 6.3.4-k. (Consistent with whatever value was used to nondimensionalize the hinge-moment coefficients in Equations 6.3.4-p, -q, and -r.)

*Denotes a finite value.

Tab Lift Loss

In achieving large control-column force reductions, tabs generate loads opposite to those on the main control surface. Thus, the net lift or efficiency of the main control surface is reduced by some amount. A typical value for loss in lift efficiency for a transport-type aircraft is 15%. The majority of the lift losses range from 5 to 20%. The maximum loss will occur for the pure flying-tab system. The efficiency of a control surface employing a tab may be expressed as

$$\eta = 1 - \frac{\Delta C_{L_{tc}} \text{ (lift loss due to tab)}}{\Delta C_{L_c} \text{ (iift increment due to control surface)}} \qquad 6.3.4\text{-s}$$

This can also be expressed as

$$\eta = 1 + \left(\frac{\partial C_{L_c}}{\partial \delta_{tc}}\right)\left(\frac{\partial \delta_c}{\partial C_{L_c}}\right)\frac{\delta_{tc}}{\delta_c} \qquad 6.3.4\text{-t}$$

For most cases, the critical case occurs when the trim tab angle and the angle of attack are zero, allowing δ_{tc}/δ_c to be expressed as

$$\frac{\delta_{tc}}{\delta_c} = \frac{B_1 + R_L A_c D_1 + \frac{k}{q}\beta A_c R_L - \frac{k}{q}A_c \beta^2}{B_2 + R_L A_c D_2 - \frac{k}{q}A_c R_L + \frac{k}{q}A_c \beta} \qquad 6.3.4\text{-u}$$

Thus, the efficiency of a tab system can be evaluated by using Equation 6.3.4-t where Equation 6.3.4-u is used for the relationship of δ_{tc}/δ_c.

Design Criteria

The design of tab boost systems can be a complex iterative process involving many variables. The mechanical limitations vary for various aircraft designs. However, Table 6.3.4-D (from Reference 1) presents a summary of the practical design criteria that will apply to most systems.

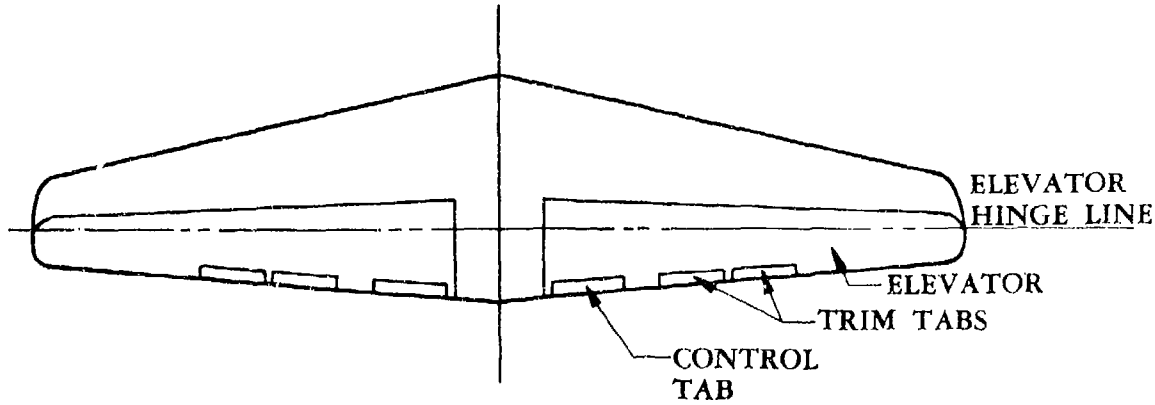
TABLE 6.3.4-D
SUGGESTED DESIGN CRITERIA
FOR AERODYNAMIC BOOST SYSTEMS

Parameter	Maximum Range of Values	Design Limitations
Link Ratio R_L	0, .1 to 10, ∞	Mechanical-Linkage Design
Spring Rate k	Any	Minimum Value Depends on Preload
Gear Ratio β	0 to $-\left(.002+\frac{\partial C_{h_c}}{\partial \delta_c}\right)\left(\frac{\partial C_{h_c}}{\partial \delta_{tc}}\right)$	Nonlinearity and Overbalance
Spring Preload	Min. Value: As required to overcome tab system friction Max. Value: No more than required to obtain desired force level	Good Tab Centering Minimize Variation of Elevator Control Forces with Speed
Tab Size	Minimum: To control main surface to maximum deflection Maximum: To give $\frac{\partial C_{h_c}}{\partial \delta_c} \Big/ \frac{\partial C_{h_c}}{\partial \delta_{tc}} = 0.5$	Adequate Tab Power Overbalance with Free Tab
$\frac{\partial C_{h_c}}{\partial \delta_c} = B_1$	$-B_1 > 0.002$	Overbalance and Nonlinearity

The following sample problem illustrates the use of the control-column force equations as applied to a given elevator spring-tab control system. No attempt is made herein to present a numerical example of the design of a tab boost system.

Sample Problem

Given: An elevator spring-tab control system on a transport-type aircraft.



HORIZONTAL TAIL

Horizontal Tail Characteristics:

$S_e \bar{c}_e G_{e_{max}} = 162.0 \text{ ft}^2$

$\alpha_H = 2.5^o \qquad \delta_{tt} = -3.0^o \qquad \delta_e = 10^o$

$B_1 = \dfrac{\partial C_{h_e}}{\partial \delta_e} = -0.0040 \text{ per deg} \qquad B_2 = \dfrac{\partial C_{h_e}}{\partial \delta_{tc}} = -0.0046 \text{ per deg}$

$B_3 = \dfrac{\partial C_{h_e}}{\partial \alpha_H} = -0.0017 \text{ per deg} \qquad B_4 = \dfrac{\partial C_{h_e}}{\partial \delta_{tt}} = -0.0044 \text{ per deg}$

$\delta_{e_{max}} = 15^o, -30^o \qquad q = 150 \text{ lb/ft}^2 \text{ (sea level)}$

Tab Characteristics:

$R_L = 4.1 \qquad k = 0.244 \text{ lb/ft}^2\text{-deg} \qquad \beta = 0 \qquad \delta_{tc_{max}} = \pm 20^o$

$A_e = \dfrac{S_{tc} \bar{c}_{tc}}{S_e \bar{c}_e} = 0.0169 \qquad D_1 = \dfrac{\partial C_{h_{tc}}}{\partial \delta_e} = -0.0025 \text{ per deg}$

$D_2 = \dfrac{\partial C_{h_{tc}}}{\partial \delta_{tc}} = -0.0085 \text{ per deg} \qquad D_3 = \dfrac{\partial C_{h_{tc}}}{\partial \alpha_H} = -0.0014 \text{ per deg}$

Compute the control-column force required to deflect the elevator 10^o TED at a free-stream dynamic pressure of 150 lb/ft^2.

Determine the values of R_1 and R_2 for a spring-tab system

$$R_1 = \frac{R_L + \Delta_r}{R_L + \dfrac{B_2}{A_e D_2} - \dfrac{k}{qD_2} R_L} \qquad \text{(Table 6.3.4-B)}$$

$$R_1 = \frac{4.1 + \dfrac{20.0}{15.0}}{4.1 + \dfrac{-0.0046}{(0.0169)(-0.0085)} - \dfrac{(0.244)(4.1)}{150.0(-0.0085)}}$$

$$= \frac{5.433}{36.907} = 0.1472$$

$$R_2 = \frac{-\frac{k}{qD_2}(R_L + \Delta_r)}{R_L + \frac{B_2}{A_e D_2} - \frac{k}{qD_2} R_L} = -\frac{k}{qD_2} R_1 \qquad \text{(Table 6.3.4-B)}$$

$$= \frac{-(0.244)}{(150.0)(-0.0085)}(0.1472)$$

$$= 0.02817$$

Determine the tab-free hinge-moment coefficient

$$C_{h_{e_{\substack{tab \\ free}}}} = \left(B_1 - D_1 \frac{B_2}{D_2}\right)\delta_e + \left(B_3 - D_3 \frac{B_2}{D_2}\right)\alpha_H + B_4 \delta_{tt} \qquad \text{(Equation 6.3.4-l)}$$

$$= \left[-0.0040 + 0.0025\left(\frac{-0.0046}{-0.0085}\right)\right]10 + \left[-0.0017 + 0.0014\left(\frac{-0.0046}{-0.0085}\right)\right]2.5$$

$$+ (-0.0044)(-3.0)$$

$$= -0.01563$$

Determine the locked-tab hinge-moment coefficient

$$C_{h_{e_{\substack{tab \\ locked}}}} = B_1 \delta_e + B_3 \alpha_H + B_4 \delta_{tt} \qquad \text{(Equation 6.3.4-m)}$$

$$= (-0.0040)\ 10 + (-0.0017)\ 2.5 + (-0.0044)(-3.0)$$

$$= -0.03105$$

Solution:

$$F_s = G_{e_{max}} S_e \bar{c}_e q \left[C_{h_{e_{\substack{tab \\ free}}}} R_1 + C_{h_{e_{\substack{tab \\ locked}}}} R_2 + \Delta C_{h_{e_{\substack{tab \\ gearing}}}} R_2\right] \qquad \text{(Equation 6.3.4-k)}$$

$$F_s = (162.0)(150)[(-0.01563)(0.1472) + (-0.03105)(0.02817) + 0]$$

$$= (162.0)(150)(-0.003175)$$

$$= -77.16 \text{ lb}$$

Therefore, for the given tab system, a push force of 77.16 lb is required to achieve an elevator deflection of 10^{o} at a free-stream dynamic pressure of 150 lb/ft^2.

7 DYNAMIC DERIVATIVES

Dynamic derivatives are associated with those aerodynamic forces and moments caused by the angular velocities and linear accelerations of the vehicle motion. A detailed discussion of wing, body, and wing-body dynamic derivatives is given in the introduction to each of the subject sections. In most cases the methods presented are based on theories that necessarily assume attached-flow conditions. They are thus limited to low angles of attack except for high-aspect-ratio wings below stall at subsonic speeds.

In general, dynamic derivatives for attached-flow conditions are smaller and of less importance than those for separated-flow conditions. For separated-flow conditions the derivatives become functions of the amplitude and frequency of oscillation. Such conditions exist on low-aspect-ratio wings and bodies at all speeds and at all angles of attack except for a narrow range around zero.

Because of the limited amount of data at high angles of attack and the complexity of deriving adequate generalized methods, particularly for the frequency and amplitude variations, no methods are presented that cover separated-flow conditions. Rather, a literature summary is presented in table 7-A and a bibliography on pages 7-1 through -10.

7.1 WING DYNAMIC DERIVATIVES

The methods presented in this section are to be used for the estimation of pitching, acceleration, rolling, and yawing dynamic derivatives of isolated lifting surfaces. The methods and charts applicable to this section are based on lifting-surface theory for subsonic speeds and on linearized theory for supersonic speeds. The charts are thus limited to conditions for which the flow is essentially attached over the surface of the wing, i.e., the linear lift-curve range. This means that at subsonic speeds the methods are valid for high-aspect-ratio wings up to stall angles of attack but are limited for low-aspect-ratio wings to low angles of attack.

For wings operating under conditions of partially separated flow, such as low-aspect-ratio wings at moderate to high angles of attack, experimental data, e.g., references 1 and 2, show that substantial nonlinearities exist in the dynamic derivatives. In addition, tests made by wind-tunnel oscillating-mode techniques show that the dynamic derivatives are functions of both the amplitude and frequency of oscillation. In general, dynamic derivatives for separated-flow conditions are larger and therefore more significant than for attached-flow conditions. Because of the complexity of the separated-flow case, no quantitative information on these effects is presented in the Datcom. Instead, a qualitative discussion of the characteristics of dynamic derivatives under partially separated-flow conditions is given.

Flow separation on wings at angles of attack below stall is discussed in Sections 4.1.3.3 and 4.1.3.4. The dominant feature of flow over low-aspect-ratio or swept wings, i.e., wings for which flow separation below stall is important, is the leading-edge vortex. The strength of the leading-edge vortex is determined by wing planform and airfoil leading-edge geometry.

In general, large leading-edge sweep angles and sharp airfoil sections are conducive to high vortex strengths. The strength of the leading-edge vortex, in turn, determines the nature and magnitude of the nonlinear static force, moment, and dynamic-derivative characteristics. The effects of geometry on the dynamic derivatives of a triangular wing at low speed are presented in reference 3.

Partially separated flow over a wing causes the dynamic derivatives to be frequency-dependent. The reason is that a change in wing attitude changes the boundary-layer conditions, which, in turn, alter the flow-separation pattern. The time required for the flow to adjust to a change in attitude is appreciable, and the dynamic derivatives become functions of the rate change of attitude (or frequency). The flow about wings with essentially attached flow is less dependent upon the boundary layer and therefore adjusts more rapidly to attitude changes. Hence the dynamic derivatives for these conditions are not frequency-dependent over the practical frequency range.

For wings that exhibit nonlinearities in their static forces and moments (partially separated flow exists), the dynamic derivatives also depend upon the amplitude of the attitude changes. For instance, sketch (a) (reference 2) shows the rolling moment in sideslip for a triangular wing at high angles of attack. It is clear that the rotary derivative C_{l_r} depends upon the amplitude of oscillation about the Z-axis.

7.1.1 WING PITCHING DERIVATIVES

7.1.1.1 WING PITCHING DERIVATIVE C_{L_q}

The wing pitching derivative C_{L_q} is generally small compared to other terms in the equations of motion and is frequently neglected. However, methods are presented for determining C_{L_q} of the wing in subsonic and supersonic speed ranges. The supersonic value of C_{L_q} is used in estimating supersonic values of C_{m_q} in Section 7.1.1.2.

If the wing pitching derivative C_{L_q} is to be used in method 1 of Section 7.3.1.1 to obtain $(C_{L_q})_{WB}$, the exposed wing planform area should be used for all calculations in the Datcom methods. Using the exposed planform area will yield C_{L_q} based on the product of exposed wing area and exposed wing MAC, rather than the product of total wing area and wing MAC as indicated.

DATCOM METHODS

A. SUBSONIC

The equation for estimating the subsonic pitching derivative $C_{L_q}^{*}$ (derived in reference 1), based on the product of wing area and wing MAC $S_W \bar{c}_W$, is given by

$$C_{L_q} = \left(\frac{1}{2} + 2\,\frac{\bar{x}}{\bar{c}}\right) C_{L_\alpha} \qquad 7.1.1.1\text{-a}$$

where $\frac{\bar{x}}{\bar{c}}$ can be expressed as

$$\frac{\bar{x}}{\bar{c}} = \frac{x_{a.c.}}{\bar{c}} - \frac{x_{c.g.}}{\bar{c}} \qquad 7.1.1.1\text{-b}$$

and

$\bar{x}$ is the distance between the center of gravity and the aerodynamic center, positive for aerodynamic center behind center of gravity.

$\frac{x_{a.c.}}{\bar{c}} = \left(\frac{x_{a.c.}}{c_r}\right)_{4.1.4.2} \left(\frac{c_r}{\bar{c}}\right)$, the longitudinal distance from the wing leading-edge vertex to the aerodynamic center measured in mean aerodynamic chords, positive aft.

$\frac{x_{c.g.}}{\bar{c}}$ is the longitudinal distance from the wing leading-edge vertex to the center of gravity measured in mean aerodynamic chords, positive aft.

C_{L_α} is the wing lift-curve slope (Section 4.1.3.2) at the Mach number under consideration, based on the total wing area.

Sample Problem

Given:

$A = 4.0$ $\quad \lambda = 0.68$ $\quad \Lambda_{LE} = 46.3°$ $\quad \frac{c_r}{\bar{c}} = 1.18$

$\frac{x_{c.g.}}{c_r}$ = 1.04 (from planform geometry with c.g. at $\bar{c}/4$) $\quad M = 0.20$

C_{L_α} = 3.20 per rad (Section 4.1.3.2)

Compute:

Calculate $\frac{x_{a.c.}}{c_r}$ using the method of Section 4.1.4.2

$\tan \Lambda_{LE} = 1.046$

$A \tan \Lambda_{LE} = 4.18$

$\beta = 0.98$

$\beta/\tan \Lambda_{LE} = 0.937$

$\frac{x_{a.c.}}{c_r}$ = 1.05 (figures 4.1.4.2-26d, -26e, -26f)

Calculate the distance between the center of gravity and the aerodynamic center

$$\frac{\bar{x}}{\bar{c}} = \frac{x_{a.c.}}{\bar{c}} - \frac{x_{c.g.}}{\bar{c}} \quad \text{(equation 7.1.1.1-b)}$$

$$= \left(\frac{x_{a.c.}}{c_r} - \frac{x_{c.g.}}{c_r} \right) \frac{c_r}{\bar{c}}$$

$= (1.05 - 1.04)\ 1.18$

$= 0.0118$

Solution:

Calculate the wing pitching derivative

$$C_{L_q} = \left(\frac{1}{2} + 2\,\frac{\bar{x}}{\bar{c}}\right) C_{L_\alpha} \quad \text{(equation 7.1.1.1-a)}$$

$$= \left[\frac{1}{2} + 2(0.0118)\right] 3.20$$

$= (0.52)\ (3.20)$

$= 1.66$ per rad (based on $S_W \bar{c}_W$)

B. TRANSONIC

There are few data and no theory available on the derivative C_{L_q} in the transonic region. For the purpose of the Datcom, it is suggested that equation 7.1.1.1-a be applied in the transonic region.

C. SUPERSONIC

The supersonic value of C_{L_q}, based on the product of wing area and wing MAC $S_W \bar{c}_W$, is given by

$$C_{L_q} = C_{L_q}{}' + 2\left(\frac{\bar{x}}{\bar{c}}\right) C_{N_\alpha} \quad \text{(per radian)} \qquad 7.1.1.1\text{-c}$$

where

$$\frac{\bar{x}}{\bar{c}} = \frac{x_{a.c.}}{\bar{c}} - \frac{x_{c.g.}}{\bar{c}} \qquad 7.1.1.1\text{-b}$$

and

C_{L_q} is referred to body axis with the origin at the wing aerodynamic center and is obtained as indicated below, based on the product of total wing area and wing MAC $S_W \bar{c}_W$.

C_{N_α} is the wing normal-force-curve slope (Section 4.1.3.2) at the Mach number under consideration, based on the total wing area (per radian).

Methods of estimating C_{L_q}'

1. Wings with subsonic leading edges ($\beta \cot \Lambda_{LE} < 1.0$)

For wings with subsonic leading edges, C_{L_q}' is obtained by the method of reference 3 for $\lambda = 0$ and by the method of reference 4 for $\lambda = 0.25$ to 1.0. The following methods are not valid if the Mach line from the trailing-edge vertex intersects the leading edge or if the wing-tip Mach lines intersect on the wings or intersect the opposite wing tips.

a. Zero-taper-ratio wings ($\lambda = 0$)

C_{L_q}' is derived in reference 3 as

$$C_{L_q}' = \frac{\pi}{2} A[3G(\beta C) F_3(N) - 2E''(\beta C) F_4(N)] + 2 \frac{(d - x_{a.c.})}{\bar{c}} C_{N_\alpha} \text{ (per radian)}$$

7.1.1.1-d

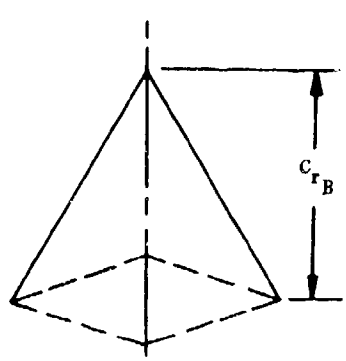
where

$E''(\beta C)$ and $G(\beta C)$ are obtained from figure 7.1.1.1-8.

$F_3(N)$ and $F_4(N)$ are obtained from figure 7.1.1.1-9.

d is two-thirds the basic triangular wing root chord $\left(d = \frac{2}{3} c_{r_B}\right)$. (See sketch (a).)

A is the aspect ratio of the wing.



SKETCH (a)

b. Wings with $\lambda = 0.25$ to 1.0

$C_{L_q}{}'$ is derived in reference 4 as

$$C_{L_q}{}' = C_{L_q}{}'' - 2\left(\frac{x_{a.c.}}{\bar{c}}\right) C_{N_\alpha} \quad \text{(per radian)} \qquad 7.1.1.1\text{-e}$$

where

$C_{L_q}{}''$ is referred to body axis with the origin at the wing leading-edge vertex and is obtained from figures 7.1.1.1-10a, 7.1.1.1-10b, and 7.1.1.1-10c, for $\lambda = 0.25, 0.50$, and 0.75, respectively, and from the equations of reference 4 for $\lambda > 0.75$.

2. Wings with supersonic leading edges ($\beta \cot \Lambda_{LE} > 1.0$)

For wings with supersonic leading edges, $C_{L_q}{}'$ is obtained from figures 7.1.1.1-11a through 7.1.1.1-11k. This method, derived in reference 5, is valid for the range of Mach numbers for which the Mach lines from the leading-edge vertex intersect the trailing edge. An additional limitation is that the foremost Mach line from either wing tip may not intersect the remote half of the wing.

Sample Problem

Given:

$A = 3.46$ $\quad \Lambda_{LE} = 60^\circ$ $\quad \frac{c_r}{\bar{c}} = 1.50$ $\quad M = 1.50$ $\quad \lambda = 0$

$b = 16$ ft $\quad$ c.g. at $\frac{\bar{c}}{4}$ $\quad c_r = 9.25$ ft $\quad \bar{c} = 6.17$ ft

Compute:

$$\beta = \sqrt{M^2 - 1} = 1.12$$

$$\beta \cot \Lambda_{LE} = 0.647 \text{ (subsonic leading edge)}$$

$$N = 1 - \frac{4 \cot \Lambda_{LE}}{A} = 0.333$$

$$\left.\begin{aligned} E''(\beta C) &= 0.770 \\ G(\beta C) &= 0.570 \end{aligned}\right\} \text{ (figure 7.1.1.1-8)}$$

$$\left.\begin{aligned} F_3(N) &= 0.913 \\ F_4(N) &= 1.12 \end{aligned}\right\} \text{ (figure 7.1.1 1-9)}$$

Obtain C_{N_α} from Section 4.1.3.2

$\beta/\tan \Lambda_{LE} = 0.647$

$A \tan \Lambda_{LE} = 6.0$

$\tan \Lambda_{LE}\, C_{N_\alpha} = 5.40$ per rad (figure 4.1.3.2-56a)

$C_{N_\alpha} = 3.12$ per rad

Obtain $\frac{x_{a.c.}}{\bar{c}}$ from Section 4.1.4.2

$\frac{x_{a.c.}}{c_r} = 0.90$ (figure 4.1.4.2-26a)

$$\frac{x_{a.c.}}{\bar{c}} = \left(\frac{x_{a.c.}}{c_r}\right)\left(\frac{c_r}{\bar{c}}\right) = 1.35$$

$x_{a.c.} = 1.35\ \bar{c} = (1.35)(6.17) = 8.33$

Calculate $\frac{\bar{x}}{\bar{c}}$

$\frac{x_{c.g.}}{c_r} = 0.67$ (from planform geometry with c.g. at $\bar{c}/4$)

$$\frac{\bar{x}}{\bar{c}} = \left(\frac{x_{a.c.}}{\bar{c}} - \frac{x_{c.g.}}{\bar{c}}\right) \quad \text{(equation 7.1.1.1-b)}$$

$$= \left(\frac{x_{a.c.}}{c_r} - \frac{x_{c.g.}}{c_r}\right)\frac{c_r}{\bar{c}}$$

$= (0.90 - 0.67)\ 1.50 = 0.345$

Calculate d from the characteristics of the basic triangular wing (see sketch (a))

$$A_B = \frac{b^2}{\frac{1}{2}\, b\, c_{r_b}} = \frac{4}{\tan \Lambda_{LE}} = \frac{4}{1.732} = 2.31$$

$$c_{r_b} = \frac{2b}{A_B} = \frac{2(16)}{2.31} = 13.85 \text{ ft}$$

$$d = \frac{2}{3} c_{r_b} = \frac{2}{3} (13.85) = 9.233 \text{ ft}$$

Solution for C_{L_q}'

$$C_{L_q}' = \frac{\pi A}{2} [3G(\beta C) F_3(N) - 2E''(\beta C) F_4(N)] + 2 \frac{(d - x_{a.c.})}{\bar{c}} C_{N_\alpha}$$

(equation 7.1.1.1-d)

$$= \frac{\pi}{2} (3.46) [3(0.57) (0.913) - 2(0.77) (1.12)] + 2 \frac{(9.233 - 8.33)}{6.17} (3.12)$$

$$= -0.891 + 0.913$$

$$= 0.022 \text{ per rad} \quad (\text{based on } S_W \bar{c}_W)$$

Solution for C_{L_q}

$$C_{L_q} = C_{L_q}' + 2\left(\frac{\bar{x}}{\bar{c}}\right) C_{N_\alpha} \quad \text{(equation 7.1.1.1-c)}$$

$$= 0.022 + 2(0.345)\, 3.12$$

$$= 2.175 \text{ per rad} \quad (\text{based on } S_W \bar{c}_W)$$

7.1.1.2 WING PITCHING DERIVATIVE C_{m_q}

When a wing rotates in pitch about a given center of gravity at an angular velocity θ in a free-stream velocity V_∞, changes in local angle of attack are produced that are proportional to w/V (w is the local vertical disturbance velocity). For wings having sweepback, an additional increment in angle of attack is produced that is a function of spanwise wing station. These local changes in angle of attack produce an effective angle-of-attack increment for the complete wing that results in a pitching-moment increment. This pitching-moment increment is expressed as the wing contribution to the derivative C_{m_q}.

If the wing pitching derivative C_{m_q} is to be used in method 1 of Section 7.3.1.2 to obtain $(C_{m_q})_{WB}$, the exposed wing planform area should be used for all calculations in the Datcom methods. Using the exposed planform area will yield C_{m_q} based on the product of exposed wing area and the square of exposed wing MAC, rather than the product of total wing area and the square of wing MAC as indicated.

DATCOM METHOD

A. SUBSONIC

The low-speed value ($M \approx 0.2$) of C_{m_q}, based on the product of total wing area and the square of wing MAC $S_W \bar{c}_W{}^2$, is given by

$$\left(C_{m_q}\right)_{M \approx 0.2} = -0.7\, c_{\ell_\alpha} \cos \Lambda_{c/4} \left\{ \frac{A\left[\frac{1}{2}\,\frac{\bar{x}}{\bar{c}} + 2\left(\frac{\bar{x}}{\bar{c}}\right)^2\right]}{A + 2\cos\Lambda_{c/4}} + \frac{1}{24}\left(\frac{A^3 \tan^2 \Lambda_{c/4}}{A + 6\cos\Lambda_{c/4}}\right) + \frac{1}{8} \right\} \quad \text{(per radian)} \quad 7.1.1.2\text{-a}$$

where

$\frac{\bar{x}}{\bar{c}}$ is defined in Section 7.1 .1.

c_{ℓ_α} is the wing section lift curve slope from Section 4.1.1 (per radian).

This equation is a modified form of that derived in reference 1. The equation was modified in reference 2 by the empirical factor 0.7. It is strictly applicable to aspect ratios between 1 and 6. For aspect ratios of about 10 or 12 the empirical factor should be approximately 0.9, but there are no experimental data available to show how this empirical factor should vary for intermediate aspect ratios. It is suggested that a smooth fairing be used.

For higher subsonic speeds the derivative C_{m_q}, based on the product of wing area and the square of wing MAC $S_W \bar{c}_W{}^2$, is obtained by applying an approximate compressibility correction derived in reference 3:

$$\left(C_{m_q}\right)_{M>0.2} = \left[\frac{\frac{A^3 \tan^2 \Lambda_{c/4}}{AB + 6\cos\Lambda_{c/4}} + \frac{3}{B}}{\frac{A^3 \tan^2 \Lambda_{c/4}}{A + 6\cos\Lambda_{c/4}} + 3}\right] \left(C_{m_q}\right)_{M\approx 0.2} \quad \text{(per radian)} \qquad 7.1.1.2\text{-b}$$

where

$\left(C_{m_q}\right)_{M\approx 0.2}$ is obtained from equation 7.1.1.2-a.

$B = \sqrt{1 - M^2 \cos^2 \Lambda_{c/4}}$

Sample Problem

Given: Same wing as in sample problem of paragraph A, Section 7.1.1.1.

$A = 4.0 \qquad \lambda = 0.68 \qquad \Lambda_{c/4} = 45^\circ \qquad \frac{c_r}{\bar{c}} = 1.18$

Additional Characteristics:

Airfoil: 64-006 Smooth airfoil surface $M = 0.2, 0.6$

$\frac{\bar{x}}{\bar{c}} = 0.0118$ (sample problem, paragraph A, Section 7.1.1.1)

Compute:

$c_{\ell_\alpha} = 0.109$ per deg (table 4.1.1-B)

$\cos \Lambda_{c/4} = 0.707$; $\tan \Lambda_{c/4} = 1.0$

At $M = 0.6$, $B = \sqrt{1 - M^2 \cos^2 \Lambda_{c/4}} = \sqrt{1 - (0.36)(0.50)} = 0.905$

Solution ($M = 0.2$):

$$\left(C_{m_q}\right)_{M\approx 0.2} = -0.7\, c_{\ell_\alpha} \cos\Lambda_{c/4} \left\{\frac{A\left[\frac{1}{2}\frac{\bar{x}}{\bar{c}} + 2\left(\frac{\bar{x}}{\bar{c}}\right)^2\right]}{A + 2\cos\Lambda_{c/4}} + \frac{1}{24}\left(\frac{A^3 \tan^2 \Lambda_{c/4}}{A + 6\cos\Lambda_{c/4}}\right) + \frac{1}{8}\right\}$$

(equation 7.1.1.2-a)

$$= (-0.7)\,(0.109)\,(57.3)\,(0.707)\left\{\frac{4\left[\frac{1}{2}\,(0.0118) + 2(0.0118)^2\right]}{4 + 2(0.707)}\right.$$

$$\left. + \frac{1}{24}\left[\frac{(4)^3\,(1)}{4 + 6(0.707)}\right] + \frac{1}{8}\right\}$$

$$= -3.090\left[\frac{0.0247}{5.414} + \frac{1}{24}\left(\frac{64}{8.242}\right) + \frac{1}{8}\right]$$

$$= -3.090(0.00456 + 0.3235 + 0.125)$$

$$= -1.400 \text{ per rad } \left(\text{based on } S_W \bar{c}_W{}^2\right)$$

Solution (M = 0.6):

$$\left(C_{m_q}\right)_{M>0.2} = \left[\frac{\frac{A^3 \tan^2 \Lambda_{c/4}}{AB + 6\cos\Lambda_{c/4}} + \frac{3}{B}}{\frac{A^3 \tan^2 \Lambda_{c/4}}{A + 6\cos\Lambda_{c/4}} + 3}\right]\left(C_{m_q}\right)_{M\approx 0.2} \quad \text{(equation 7.1.1.2-b)}$$

$$= \left[\frac{\frac{(4)^3\,(1)}{4(0.905) + 6(0.707)} + \frac{3}{0.905}}{\frac{(4)^3\,(1)}{4 + 6(0.707)} + 3}\right](-1.40)$$

$$= \left[\frac{\frac{64}{7.862} + 3.31}{\frac{64}{8.242} + 3}\right](-1.40)$$

$$= \left(\frac{8.14 + 3.31}{7.77 + 3}\right)(-1.40)$$

$$= -1.49 \text{ per rad } \left(\text{based on } S_W \bar{c}_W{}^2\right)$$

B. TRANSONIC

At transonic speeds the derivative C_{m_q}, based on the product of wing area and the square of wing MAC $S_W \bar{c}_W{}^2$, is estimated by

$$C_{m_q} = \frac{\left(C_{L_\alpha}\right)_M - \left(C_{L_\alpha}\right)_{M_{cr}}}{\left(C_{L_\alpha}\right)_{M=1.2} - \left(C_{L_\alpha}\right)_{M_{cr}}} \left[\left(C_{m_q}\right)_{M=1.2} - \left(C_{m_q}\right)_{M_{cr}}\right] + \left(C_{m_q}\right)_{M_{cr}} \quad \text{(per radian)} \qquad 7.1.1.2\text{-c}$$

where

C_{L_α} is the wing lift-curve slope (Section 4.1.3.2) at the Mach number under consideration, based on the total wing area (per radian).

$\left(C_{m_q}\right)_{M=1.2}$ is obtained from the supersonic method of paragraph C of this section, based on the product of wing area and the square of wing MAC $S_W \bar{c}_W{}^2$ (per radian).

$\left(C_{m_q}\right)_{M_{cr}}$ is obtained from equation 7.1.1.2-b at the critical Mach number, based on the product of wing area and the square of wing MAC $S_W \bar{c}_W{}^2$ (per radian).

For this purpose the critical Mach number M_{cr} is taken equal to the force-break Mach number M_{fb} defined in paragraph B of Section 4.1.3.2.

C. SUPERSONIC

The supersonic value of C_{m_q}, referred to body axis and for any center-of-gravity location and based on the product of wing area and the square of wing MAC $S_W \bar{c}_W{}^2$, is given by

$$C_{m_q} = C_{m_q}{}' - \left(\frac{\bar{x}}{\bar{c}}\right) C_{L_q} \quad \text{(per radian)} \qquad 7.1.1.2\text{-d}$$

where

C_{L_q} is obtained from Section 7.1.1.1, based on the product of wing area and wing MAC (per radian).

$\frac{\bar{x}}{\bar{c}}$ is defined in Section 7.1.1.1.

$C_{m_q}{}'$ is referred to body axis with the origin at the wing aerodynamic center, based on the product of wing area and the square of wing MAC $S_W \bar{c}_W{}^2$, and obtained as indicated below.

Methods for estimating C_{m_q}'

1. Wings with subsonic leading edges ($\beta \cot \Lambda_{LE} < 1.0$)

For wings with subsonic leading edges, C_{m_q}' is obtained by the method of reference 4 for $\lambda = 0$ and by the method of reference 5 for $\lambda = 0.25$ to 1.0. The following methods are not valid if the Mach line from the trailing-edge vertex intersects the leading edge or if the wing-tip Mach lines intersect on the wings or intersect the opposite wing tips.

a. Zero-taper-ratio wings ($\lambda = 0$)

C_{m_q}' is derived in reference 4 as

$$C_{m_q}' = -\frac{3}{16}\pi A \left\{ G(\beta C)\, F_7(N) + \frac{16}{3} E''(\beta C) \left[\frac{F_5(N)}{F_{11}(N)}\right] \right\} - \left(\frac{d - x_{a.c.}}{\bar{c}}\right) C_{L_q}' + 2\left(\frac{d - x_{a.c.}}{\bar{c}}\right)^2 C_{N_\alpha} \quad \text{(per radian)} \qquad 7.1.1.2\text{-e}$$

where

$G(\beta C)$ and $E''(\beta C)$ are obtained from figure 7.1.1.1-8.

$F_5(N)$, $F_7(N)$, and $F_{11}(N)$ are obtained from figure 7.1.1.2-8.

$\frac{x_{a.c.}}{\bar{c}}$ is defined in paragraph A of Section 7.1.1.1.

C_{N_α} is the wing normal-force-curve slope (Section 4.1.3.2) at the Mach number under consideration, based on the total wing area (per radian).

d is defined in paragraph C of Section 7.1.1.1.

C_{L_q}' is obtained from paragraph C of Section 7.1.1.1, based on the product of wing area and wing MAC (per radian).

b. Wings with $\lambda = 0.25$ to 1.0

C_{m_q}' is derived in reference 5 as

$$C_{m_q}' = C_{m_q}'' + \left(\frac{x_{a.c.}}{\bar{c}}\right) C_{L_q}'' \quad \text{(per radian)} \qquad 7.1.1.2\text{-f}$$

where

C_{m_q}'' is referred to body axis with the origin at the wing leading-edge vertex and is obtained from figures 7.1.1.2-9a, 7.1.1.2-9b, and 7.1 1.2-9c, for $\lambda = 0.25$, 0.50, and 0.75, respectively, and from the equations of reference 5 for $\lambda > 0.75$ (per radian).

C_{L_q}'' is obtained from paragraph C of Section 7.1.1.1, based on the product of wing area and wing MAC (per radian).

$\frac{x_{a.c.}}{\bar{c}}$ is defined in paragraph A of Section 7.1.1.1.

2. Wings with supersonic leading edges ($\beta \cot \Lambda_{LE} > 1.0$)

For wings with supersonic leading edges, C_{m_q}' is obtained from figures 7.1.1.2-10a through 7.1.1.2-10k. This method is derived in reference 6 and is valid for the range of Mach numbers for which the Mach lines from the leading-edge vertex intersect the trailing edge. An additional limitation is that the foremost Mach line from either wing tip may not intersect the remote half of the wing.

Sample Problem

Given: Same wing as in sample problem of paragraph C, Section 7.1.1.1.

$A = 3.46$ $\quad \lambda = 0$ $\quad \Lambda_{LE} = 60°$ $\quad \frac{c_r}{\bar{c}} = 1.50$ $\quad b = 16$ ft

c.g. at $\frac{\bar{c}}{4}$ $\quad M = 1.50$ $\quad \bar{c} = 6.17$ ft $\quad c_r = 9.25$ ft

From sample problem of paragraph C, Section 7.1.1.1:

$\beta \cot \Lambda_{LE} = 0.647$ (subsonic leading edge)

$N = 0.333$ $\quad E''(\beta C) = 0.770$ $\quad G(\beta C) = 5.70$ $\quad C_{N_\alpha} = 3.12$ per rad

$C_{L_q}' = 0.022$ per rad $\quad C_{L_q} = 2.175$ per rad $\quad \frac{d - x_{a.c.}}{\bar{c}} = 0.146$ $\quad \frac{\bar{x}}{\bar{c}} = 0.345$

Compute:

$$\left.\begin{aligned} F_5(N) &= 0.133 \\ F_7(N) &= -0.200 \\ F_{11}(N) &= 0.660 \end{aligned}\right\} \text{ (figure 7.1.1.2-8)}$$

Solution:

$$C_{m_q}' = -\frac{3}{16}\pi A\left\{G(\beta C)\,F_7(N) + \frac{16}{3}\,E''(\beta C)\left[\frac{F_5(N)}{F_{11}(N)}\right]\right\}$$

$$-\left(\frac{d - x_{a.c.}}{\bar{c}}\right) C_{L_q}' + 2\left(\frac{d - x_{a.c.}}{\bar{c}}\right)^2 C_{N_\alpha} \quad \text{(equation 7.1.1.2-e)}$$

$$= -\frac{3}{16}\,\pi(3.46)\left[(0.570)\,(-0.200) + \frac{16}{3}\,(0.770)\,\frac{0.133}{0.660}\right]$$

$$-\,(0.146)\,(0.022) + 2(0.146)^2\,(3.12)$$

$$= -2.038(-0.1140 + 0.8276) - 0.0032 + 0.1330$$

$$= -1.325 \text{ per rad}$$

$$C_{m_q} = C_{m_q}' - \left(\frac{\bar{x}}{\bar{c}}\right) C_{L_q} \quad \text{(equation 7.1.1.2-d)}$$

$$= -1.325 - (0.345)\,(2.175)$$

$$= -2.075 \text{ per rad (based on } S_W \bar{c}_W{}^2)$$

7.1.1.3 WING PITCHING DERIVATIVE C_{D_q}

This section presents a method for estimating the wing contribution to the pitching derivative C_{D_q} at subsonic speeds. This derivative is the change in drag coefficient due to a change in pitching velocity at a constant angle of attack and is defined as

$$C_{D_q} = \frac{\partial C_D}{\partial\left(\frac{q\bar{c}}{2V}\right)}, \text{ where } C_D \text{ is based on } S_W.$$

In general, this derivative is small and has a negligible effect on longitudinal stability; hence, it is usually neglected.

A. SUBSONIC

The method presented herein uses the Weissinger method of Reference 1 to calculate the section lift due to angle of attack, twist, and pitch rate. The lift is then rotated through the local downwash angle due to each of these effects to produce a chordwise component of force.

DATCOM METHOD

Design charts for predicting the wing contribution to C_{D_q} are available only at Mach numbers of 0.2 and 0.8. The wing pitching derivative C_{D_q} is given by

$$C_{D_q} = C_{D_{q_0}}(-\theta) + \frac{\partial C_{D_q}}{\partial \alpha_F}\,\alpha_F + \frac{\partial C_{D_q}}{\partial\left(\frac{q\bar{c}}{2V}\right)}\left(\frac{q\bar{c}}{2V}\right) \qquad 7.1.1.3\text{-a}$$

where

$C_{D_{q_0}}$ is the contribution due to zero-angle-of-attack loading obtained from Figures 7.1.1.3-3a through -3f as a function of wing aspect ratio, taper ratio, and sweep.

θ is the wing twist in degrees between the root and tip sections, negative for washout (see Figure 5.1.2.1-30b).

$\frac{\partial C_{D_q}}{\partial \alpha_F}$ is the contribution due to angle of attack obtained from Figures 7.1.1.3- 7a through - 7f as a function of wing aspect ratio, taper ratio, and sweep.

α_F is the fuselage angle of attack in degrees.

$\frac{\partial C_{D_q}}{\partial\left(\frac{q\bar{c}}{2V}\right)}$ is the contribution due to the rate of change of pitch obtained from Figures 7.1.1.3-12a through -12f as a function of wing aspect ratio, taper ratio, and sweep.

q is the pitch rate in degrees per second.

$\bar{c}$ is the wing mean aerodynamic chord.

V is the free-stream velocity.

Sample Problem

Given: The following wing-body configuration

Wing Characteristics:

$A = 7$ $\quad \lambda = 0.25$ $\quad \Lambda_{LE} = 35^{\circ}$

$\bar{c} = 25.0$ ft $\quad S_W = 3500$ ft^2 $\quad \theta = -5.0^{\circ}$

Additional Characteristics:

$M = 0.8$ $\quad \alpha_F = 1^{\circ}$ $\quad q = 5$ deg/sec

$V = 796$ ft/sec $\quad (h = 30{,}000$ ft)

Compute:

$C_{D_{q_0}} = 0.00036$ per deg^2 (interpolated using Figures 7.1.1.3-3d, -3e, and -3f)

$\dfrac{\partial C_{D_q}}{\partial \alpha_F} = 0.000876$ per deg^2 (interpolated using Figures 7.1.1.3- 7d, - 7e, and - 7f)

$\dfrac{\partial C_{D_q}}{\partial \left(\frac{q\bar{c}}{2V}\right)} = 0.00061$ per deg^2 (interpolated using Figures 7.1.1.3-12d, -12e, and -12f)

$\dfrac{q\bar{c}}{2V} = \dfrac{(5)(25)}{2(796)} = 0.0785$ deg

Solution:

$$C_{D_q} = C_{D_{q_0}}(-\theta) + \frac{\partial C_{D_q}}{\partial \alpha_F}\alpha_F + \frac{\partial C_{D_q}}{\partial \left(\frac{q\bar{c}}{2V}\right)}\left(\frac{q\bar{c}}{2V}\right) \qquad \text{(Equation 7.1.1.3-a)}$$

$$= (0.00036)(+5.0) + (0.000876)(1.0) + (0.00061)(0.0785)$$

$$= 0.00272 \text{ per deg}$$

B. TRANSONIC

No method is presented.

C. SUPERSONIC

No method is presented.

7.1.2 WING ROLLING DERIVATIVES

7.1.2.1 WING ROLLING DERIVATIVE C_{Y_p}

This section presents methods for estimating the wing contribution to the rolling derivative C_{Y_p} at subsonic and supersonic speeds. This derivative is the change in side-force coefficient with change in wing-tip helix angle and is expressed as

$$C_{Y_p} = \frac{\partial C_Y}{\partial\left(\frac{pb}{2V_\infty}\right)}$$

A. SUBSONIC

The wing rolling derivative C_{Y_p} results from the angle-of-attack distribution and the tip-suction effects of rolling wings.

The angle-of-attack distribution caused by rolling produces incremental changes in aerodynamic forces. For wings having sweep and/or dihedral, these incremental changes have components in the lateral direction, causing a side force. The contribution to C_{Y_p} due to the angle-of-attack distribution caused by rolling is derived in reference 1, based on simple sweep theory. This result is limited to swept, untapered wings at low lift coefficients. The effect of taper ratio has been derived based on the experimental results presented in reference 2. The effect of dihedral is taken from reference 3. Although the expression for the dihedral effect has been derived specifically for untapered wings, it should be reasonably reliable for wings of any taper ratio over the range of wing dihedral angles of practical interest.

The side force due to rolling of unswept wings is not accounted for by the theory of reference 1. This value is presumed to be caused by tip suction and is given by the empirical expression developed in reference 4. Experimental results show that the tip-suction effect is independent of sweep and varies inversely as the aspect ratio.

The method of reference 5 is applied to extrapolate the potential-flow values to high lift coefficients by using experimental values of the lift and drag at high lift coefficients. If experimental lift and drag data for the particular planform of interest are not available at the chosen Mach number, no attempt should be made to estimate the variation of C_{Y_p} with lift coefficient. The negligible importance of this derivative does not warrant the effort involved in estimating the wing lift and drag variation. Furthermore, no known general method for estimating the variation of drag coefficient will give results reliable enough to use in determining the correction factor for extrapolating the potential-flow values to higher lift coefficients.

DATCOM METHOD

The variation of the wing rolling derivative C_{Y_p} with lift coefficient, based on the product of the wing area and wing span, is given by

$$C_{Y_p} = K\left[\left(\frac{C_{Y_p}}{C_L}\right)_{\substack{C_L=0 \\ M}} C_L\right] + \left(\Delta C_{Y_p}\right)_\Gamma \qquad \text{(per radian)} \qquad 7.1.2.1\text{-a}$$

where

$\left(\frac{C_{Y_p}}{C_L}\right)_{\substack{C_L=0 \\ M}}$ is the slope of the side force due to rolling at zero lift given by

$$\left(\frac{C_{Y_p}}{C_L}\right)_{\substack{C_L=0 \\ M}} = \frac{A + 4\cos\Lambda_{c/4}}{AB + 4\cos\Lambda_{c/4}} \; \frac{AB + \cos\Lambda_{c/4}}{A + \cos\Lambda_{c/4}} \left(\frac{C_{Y_p}}{C_L}\right)_{\substack{C_L=0 \\ M=0}} \qquad 7.1.2.1\text{-b}$$

where $B = \sqrt{1 - M^2\cos^2\Lambda_{c/4}}$ and

$\left(\frac{C_{Y_p}}{C_L}\right)_{\substack{C_L=0 \\ M=0}}$ is the slope of the low-speed side force due to rolling at zero lift, obtained from figure 7.1.2.1-9 as a function of aspect ratio, sweep of the quarter-chord, and taper ratio. This chart has been derived by using the results of references 1, 2, and 4. Equation 7.1.2.1-b modifies the low-speed value by means of the Prandtl-Glauert rule to yield approximate corrections for the first-order three-dimensional effects of compressible flow up to the critical Mach number.

C_L is the wing lift coefficient.

$\left(\Delta C_{Y_p}\right)_\Gamma$ is the increment in C_{Y_p} due to dihedral given by

$$\left(\Delta C_{Y_p}\right)_\Gamma = \left[3\sin\Gamma\left(1 - 2\frac{z}{b/2}\sin\Gamma\right)\right]\left(C_{l_p}\right)_{\substack{\Gamma=0 \\ C_L=0}} \qquad \text{(per radian)} \qquad 7.1.2.1\text{-c}$$

where

Γ is the geometric dihedral angle in degrees, positive for the wing tip above the plane of the root chord.

z is the vertical distance between the c.g and the wing root quarter-chord point, positive for the c.g. above the wing root chord. (This parameter is independent of angle of attack.)

b is the wing span.

$\left(C_{l_p}\right)_{\substack{\Gamma=0 \\ C_L=0}}$ is the roll-damping derivative of the wing without dihedral and at zero lift. This value is obtained from paragraph A of Section 7.1.2.2 and is given by (see equation 7.1.2.2-a)*

$$\left(C_{l_p}\right)_{\substack{\Gamma=0 \\ C_L=0}} = \left(\frac{\beta C_{l_p}}{\kappa}\right)_{C_L=0} \frac{\kappa}{\beta} \quad \text{(per radian)}$$

K is a dimensionless correction factor used to extrapolate the potential-flow values to high lift coefficients. At zero lift this factor is taken as 1.0. At lift coefficients other than zero this factor accounts for the variation of profile drag with lift coefficient and is given by

$$K = \frac{\frac{\partial}{\partial \alpha}\left(C_L \tan\alpha\right) - \frac{\partial}{\partial \alpha}\left(C_D - C_{D_0}\right)}{\frac{\partial}{\partial \alpha}\left(C_L \tan\alpha\right) - \frac{\partial}{\partial \alpha}\left(\frac{C_L{}^2}{\pi A}\right)} \qquad 7.1.2.1\text{-d}$$

Test values of lift and drag at the chosen Mach number for the particular planform of interest must be used in evaluating equation 7.1.2.1-d. The terms of equation 7.1.2.1-d are evaluated by taking the slopes of $C_L \tan\alpha$, $C_D - C_{D_0}$, and $C_L{}^2/(\pi A)$, plotted versus angle of attack.

If reliable values of the static-force coefficients are available, the method should provide results within ±20 percent accuracy throughout the lift-coefficient range to the stall.

Sample Problem

Given: The wing designated 32.6-4-0.6-006 of references 5 and 8.

Wing Characteristics:

$A = 4.0 \qquad \lambda = 0.60 \qquad \Lambda_{c/4} = 32.6^\circ \qquad \Gamma = 0$

$S = 2.25$ sq ft

Additional Characteristics:

$M = 0.7$

The following test values from reference 8 at $M = 0.7$

$C_{D_0} = 0.01$

*The effect of profile drag on the roll damping at zero lift is neglected.

C_L	.05	.1	.2	.3	.4	.5	.6	.7

SKETCH (b)

B. TRANSONIC

No generalized method is available in the literature for estimating transonic values of the rolling derivative C_{Y_p}. Furthermore, no known experimental results are available for this derivative at transonic speeds.

C. SUPERSONIC

At supersonic speeds a design chart based on theoretical calculations is presented for estimating the rolling derivative C_{Y_p} at low values of the lift coefficient. The design chart is based on the results of reference 6 for wings with subsonic leading edges and supersonic trailing edges, and the results of reference 7 for wings with supersonic leading edges and either subsonic or supersonic trailing edges. The results of both references 6 and 7 are based on linearized-supersonic-flow theory and are therefore restricted to thin, swept-back, tapered wings with streamwise tips. The lateral force due to rolling is taken as that arising entirely from suction forces on the wing edges. For wings with supersonic leading edges no suction forces are induced along the leading edges, and the determination of C_{Y_p} involves only the unbalanced suction forces along the wing tips. Therefore, for zero-taper wings with supersonic leading edges the theory gives $C_{Y_p} = 0$.

No experimental data are available for this derivative at supersonic speeds. Therefore, the validity of linearized-supersonic-flow theory for estimating C_{Y_p} cannot be determined.

DATCOM METHOD

The wing contribution to the rolling derivative C_{Y_p} at supersonic speeds and at low values of the lift coefficient is obtained from figure 7.1.2.1-10 as a function of the wing aspect ratio, taper ratio, leading-edge sweep, and Mach number.

Sample Problem

Given: Tapered, swept-back wing.

$A = 3.22 \qquad \lambda = 0.25 \qquad \Lambda_{LE} = 55.2^{o}$

$M = 2.41; \ \beta = 2.19$

Compute:

$\beta A = (2.19)(3.22) = 7.07$

Solution:

$$\frac{C_{Y_p}}{\alpha} = 0.50 \text{ per rad}^2 \text{ (based on } S_W b_W \text{) (figure 7.1.2.1-10)}$$

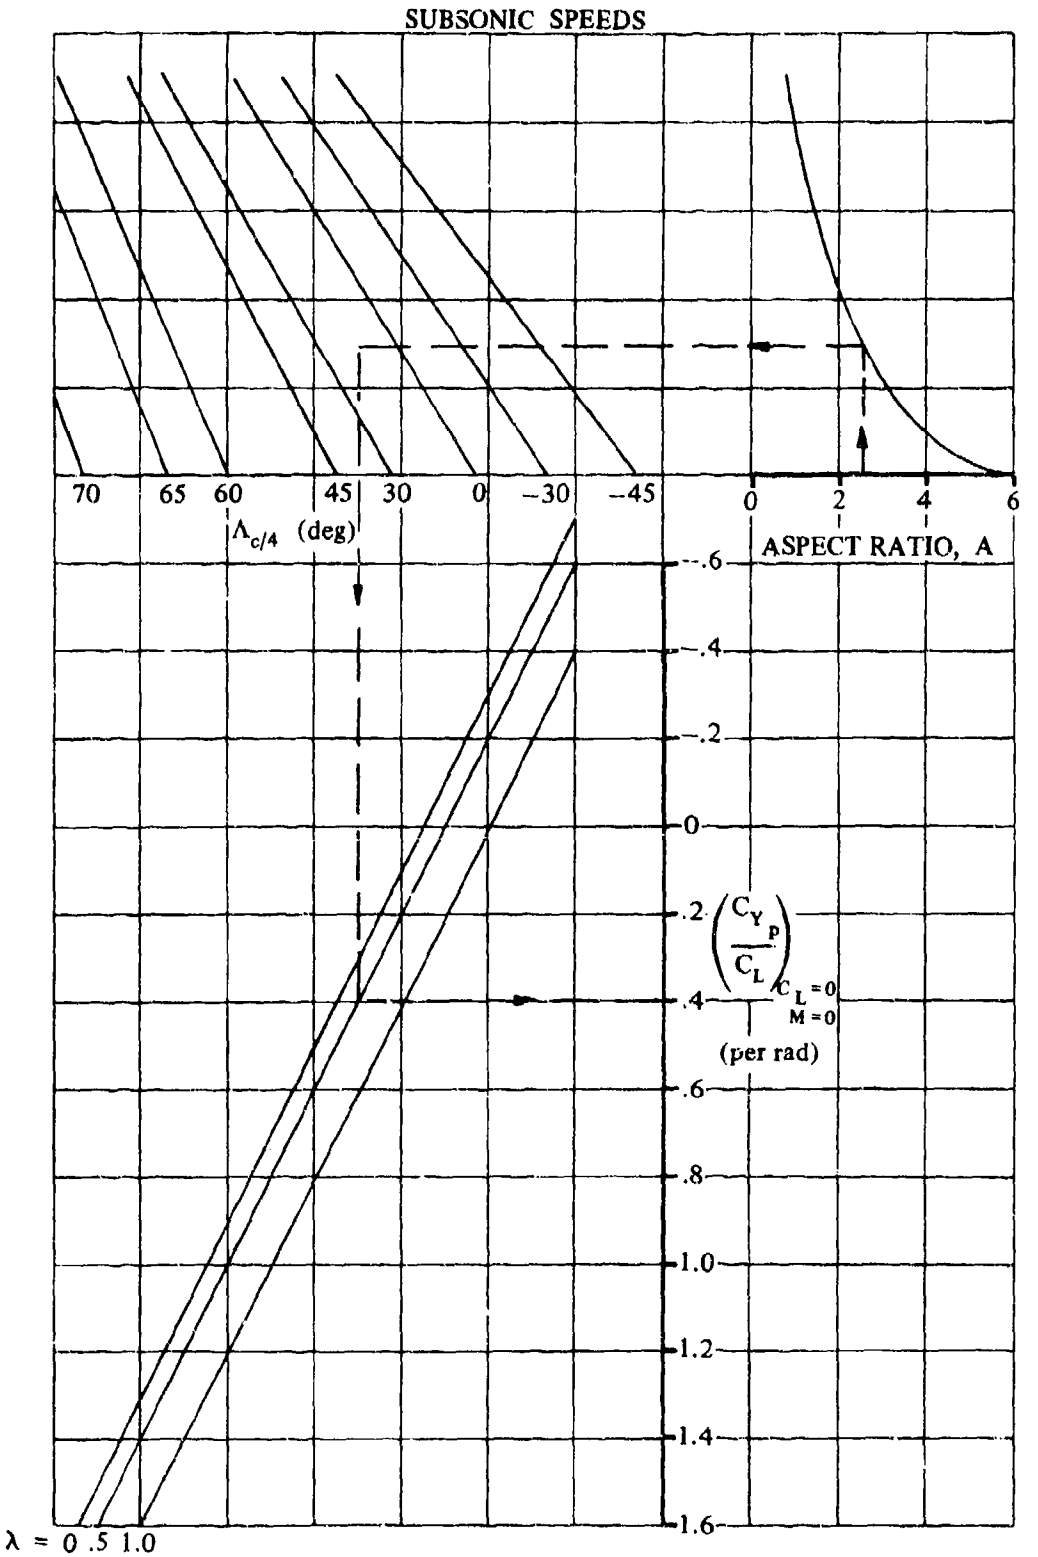

FIGURE 7.1.2.1-9 WING ROLLING DERIVATIVE, C_{Y_p}

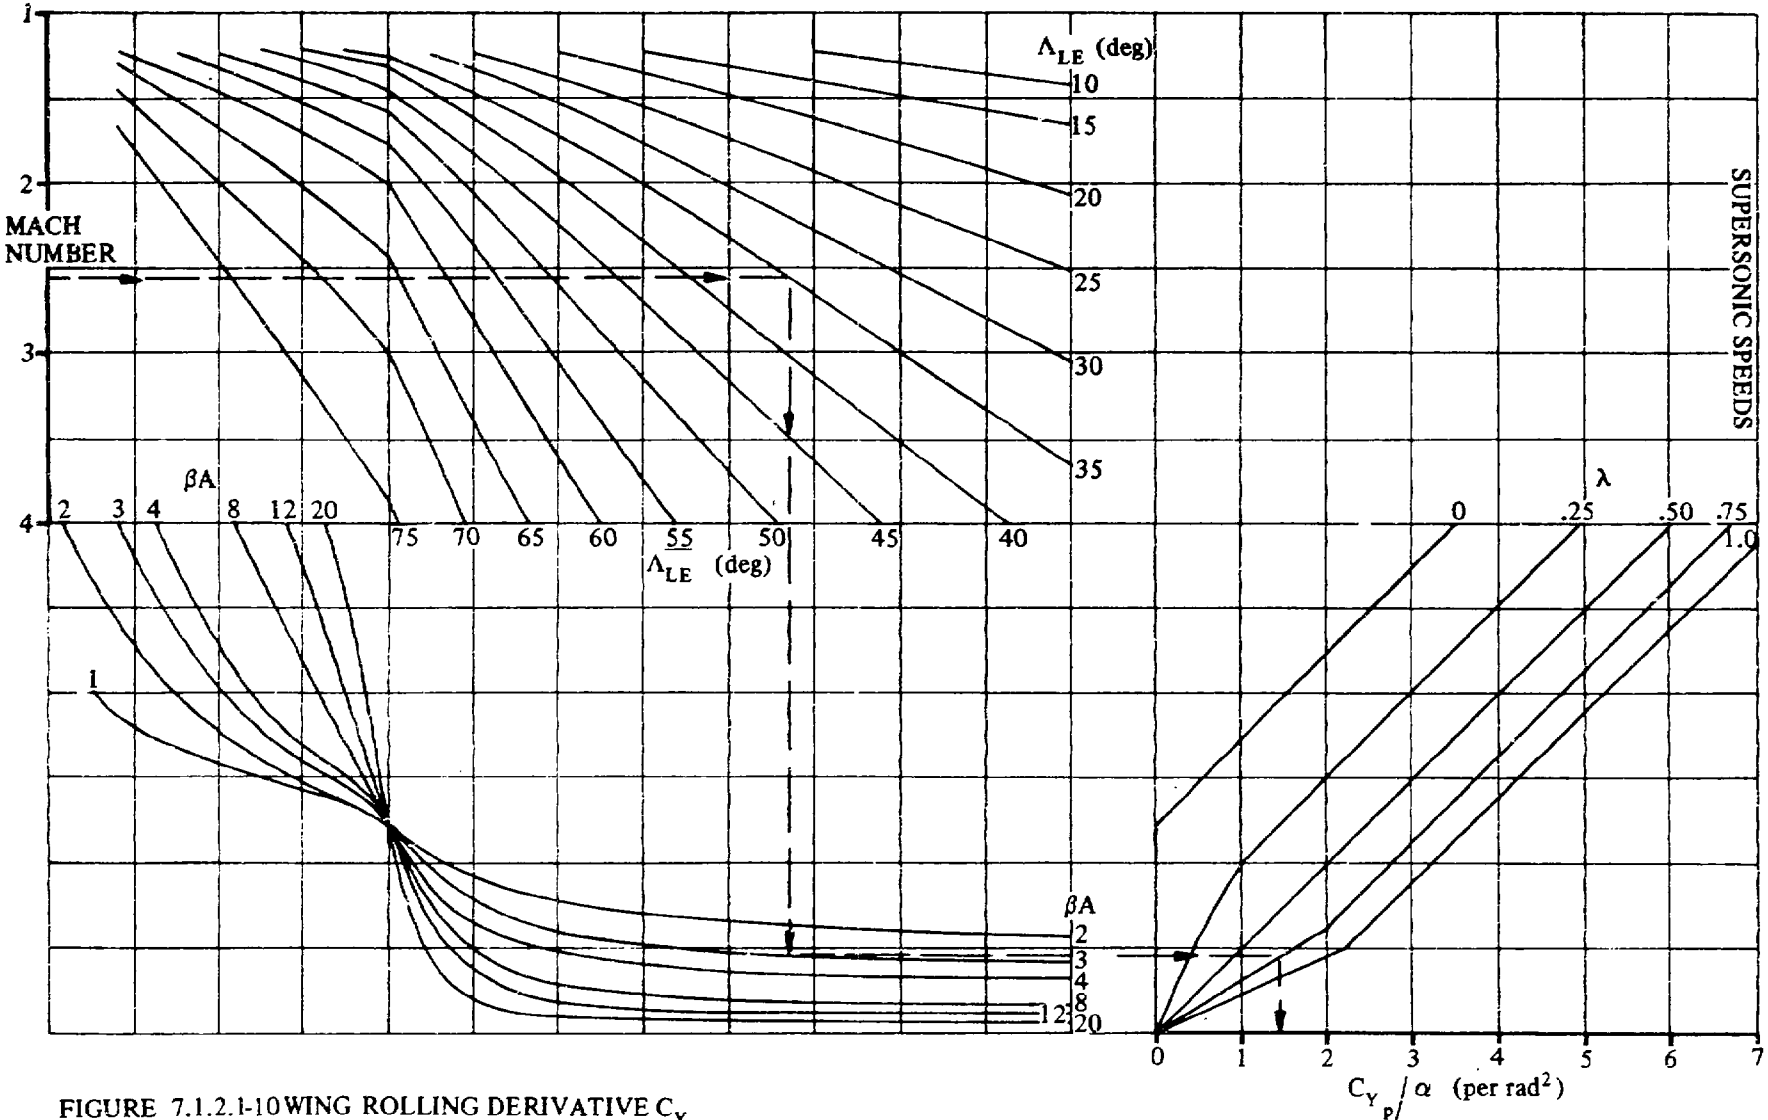

FIGURE 7.1.2.1-10 WING ROLLING DERIVATIVE C_{Y_p}

7.1.2.2 WING ROLLING DERIVATIVE C_{l_p}

This section presents methods for estimating the wing contribution to the rolling derivative C_{l_p} at subsonic and supersonic speeds. This derivative is the change in rolling-moment coefficient with change in wing-tip helix angle and is expressed as

$$C_{l_p} = \frac{\partial C_l}{\partial\left(\frac{pb}{2V_\infty}\right)}$$

A. SUBSONIC

The wing rolling derivative C_{l_p} at subsonic speeds is a function of the wing lift-curve slope, the wing drag, and geometric dihedral. The effects of dihedral become significant when the displacement of the rolling axis from the wing root chord is moderate or large.

For unswept wings of moderately high aspect ratio the lift-curve slope undergoes only small changes throughout the lift-coefficient range, and the drag contribution is relatively unimportant. Therefore, potential flow values of C_{l_p} at zero lift are generally satisfactory at all lift coefficients below the stall for these planforms.

Several methods are available for estimating the potential flow value of C_{l_p}. Reference 1 presents design charts for C_{l_p} at zero lift of unswept wings based on lifting-line theory. An effective edge-velocity correction is applied to the lifting-line theory results of reference 1 in reference 2. Finally the results of reference 2 are modified for the effects of sweep in reference 3. A similar method that accounts for the effects of sweep on the edge-velocity correction is presented in reference 4. Reference 5 presents a more rigorous method of estimating C_{l_p} for wings of arbitrary planform at zero lift, based on the simplified lifting-surface theory of Weissinger for determining the additional span loading due to rolling. The Datcom method for estimating C_{l_p} at zero lift is taken from reference 6. It is essentially that of reference 5 corrected for compressibility effects and extended to a wider range of planform parameters.

For wings of moderate to high aspect ratios and with moderate sweep, the value of C_{l_p} in the nonlinear-lift range is estimated to a first approximation by assuming that variations in the lift-curve slope will affect C_{l_p} in the same proportion as C_{L_α}.

On low-aspect-ratio and/or highly swept wings, the flow separates and forms a stable leading-edge vortex that is responsible for the generation of considerable additional lift on the outer portions of the wing. The drag associated with these high lift coefficients causes significant changes in C_{l_p}. The increment in C_{l_p} due to drag is derived in reference 7, based on the strip-theory procedure of reference 3. Since the effects of drag due to lift and of profile drag on the roll-damping derivative are not of equal importance, they are considered separately in determining the increment due to drag.

The correction for geometric dihedral is considered in detail in reference 8. Although the expression for the dihedral effect has been derived specifically for untapered wings, it should be reasonably reliable for wings of any taper ratio over the range of wing dihedral angles of practical interest.

The Datcom method accounts for the variations in wing lift-curve slope, drag due to lift, and profile

drag, as well as the effect of dihedral. The method requires knowledge of the variation of lift and drag over the angle-of-attack range to the stall for the particular configuration at the appropriate Mach number. Therefore, this method is quite readily applied if experimental lift and drag data are available.

DATCOM METHOD

The value of the wing rolling derivative C_{l_p} at a given lift coefficient at subsonic speeds, based on the product of the wing area and the square of the wing span $S_W b_W^2$, is given by

$$C_{l_p} = \left(\frac{\beta C_{l_p}}{\kappa}\right)_{C_L=0} \left(\frac{\kappa}{\beta}\right) \frac{(C_{L_\alpha})_{C_L}}{(C_{L_\alpha})_{C_L=0}} \frac{(C_{l_p})_\Gamma}{(C_{l_p})_{\Gamma=0}} + (\Delta C_{l_p})_{drag} \quad \text{(per radian)} \qquad 7.1.2.2\text{-a}$$

where

$\left(\frac{\beta C_{l_p}}{\kappa}\right)_{C_L=0}$ is the roll-damping parameter at zero lift, obtained from figure 7.1.2.2-20 as a function of Λ_β and $\beta A/\kappa$.

The parameter κ is the ratio of the two-dimensional lift-curve slope at the appropriate Mach number to $2\pi/\beta$; i.e., $(c_{\ell_\alpha})_M/(2\pi/\beta)$. The two-dimensional lift-curve slope is obtained from Section 4.1.1.2. For wings with airfoil sections varying in a reasonably linear manner with span, the average value of the lift-curve slopes of the root and tip sections is adequate.

The parameter Λ_β is the compressible sweep parameter given as

$$\Lambda_\beta = \tan^{-1}\left(\frac{\tan \Lambda_{c/4}}{\beta}\right), \text{ where } \beta = \sqrt{1 - M^2}\,.$$

$(C_{L_\alpha})_{C_L=0}$ is the wing lift-curve slope at zero lift, obtained from test data or estimated by using the straight-tapered wing method of paragraph A of Section 4.1.3.2 at the appropriate Mach number.

$(C_{L_\alpha})_{C_L}$ is the wing lift-curve slope at any lift coefficient below the stall, obtained from test data or estimated by using the straight-tapered wing method of paragraph A of Section 4.1.3.3 at the appropriate Mach number.

$\frac{(C_{l_p})_\Gamma}{(C_{l_p})_{\Gamma=0}}$ is the dihedral-effect parameter given by

$$\frac{(C_{l_p})_\Gamma}{(C_{l_p})_{\Gamma=0}} = \left[1 - 2\frac{z}{b/2}\sin\Gamma + 3\left(\frac{z}{b/2}\right)^2 \sin^2\Gamma\right] \qquad 7.1.2.2\text{-b}$$

where

Γ is the geometric dihedral angle, positive for the wing tip above the plane of the root chord.

z is the vertical distance between the c.g. and the wing root chord, positive for the c.g. above the root chord.

b is the wing span.

$\left(\Delta C_{l_p}\right)_{drag}$ is the increment in the roll-damping derivative due to drag, given by

$$\left(\Delta C_{l_p}\right)_{drag} = \frac{\left(C_{l_p}\right)_{C_{D_L}}}{C_L^{\,2}} C_L^{\,2} - \frac{1}{8} C_{D_0} \quad \text{(per radian)} \qquad 7.1.2.2\text{-c}$$

where

$\frac{\left(C_{l_p}\right)_{C_{D_L}}}{C_L^{\,2}}$ is the drag-due-to-lift roll-damping parameter obtained from figure 7.1.2.2-24 as a function of A and $\Lambda_{c/4}$.

C_L is the wing lift coefficient below the stall.

C_{D_0} is the profile or total zero-lift drag coefficient. If experimental data are not available, C_{D_0} may be estimated by the method of paragraph A of Section 4.1.5.1 at the appropriate Mach number.

This method includes the effects of compressibility and may be applied up to the critical Mach number. (The drag-due-to-lift term does not include a Mach number correction; however, it is small except at high C_L where the Mach number is generally low.)

The most important factor considered in this method is the variation of the wing lift-curve slope. If reliable values of this parameter are available over the lift-coefficient range, the method will in most cases give satisfactory results over that C_L range for configurations with aspect ratios of approximately 2 or greater.

For wings of low aspect ratio and/or high sweep the accuracy of the method rapidly deteriorates with increasing C_L, even when experimental values of lift and drag are used. The error results from the fact that the high values of $\left(C_{l_p}\right)_{C_{D_L}}$ obtained from figure 7.1.2.2-24 for these configurations are not realized in practice. Therefore, as C_L increases the calculated values of the roll-damping derivative become progressively smaller than those given by experiment.

A comparison of the roll-damping derivative calculated by using this method with test results is presented as table 7.1.2.2-A. Experimental values of lift and drag have been used in evaluating the roll-damping derivative of all the configurations listed in the table. Several additional references containing test results of the damping-in-roll characteristics of straight-tapered wings are listed in table 7-A.

Sample Problem

Given: Model 8 of reference 17.

Wing Characteristics:

$A = 3.0 \qquad \lambda = 0.15 \qquad \Lambda_{c/4} = 36.9^{o} \qquad \Gamma = 0$

Airfoil Characteristics:

NACA 0012 airfoil $\qquad \frac{Y_{90}}{2} = 1.448 \qquad \frac{Y_{99}}{2} = 0.260$

Additional Characteristics:

$M = 0.13; \quad \beta = 0.992 \qquad R_{\ell} = 1.254 \times 10^{6} \qquad C_{D_0} = 0.036$ (test value)

The following test values from reference 17:

C_L	0	.1	.2	.3	.4	.5	.6	.7	.8
C_{L_α}	.0525	.0525	.0525	.053	.053	.054	.054	.050	.030

Compute:

Determine the roll-damping parameter at zero lift $\left(\frac{\beta C_{l_p}}{\kappa}\right)_{C_L = 0}$

$$\tan \frac{1}{2}\phi'_{TE} = \frac{\frac{Y_{90}}{2} - \frac{Y_{99}}{2}}{9} = \frac{1.448 - 0.26}{9} = 0.132$$

$\frac{c_{\ell_\alpha}}{(c_{\ell_\alpha})_{theory}} = 0.768$ (figure 4.1.1.2-8a, extrapolated by plotting vs $\log_{10} R_{\ell}$)

$(c_{\ell_\alpha})_{theory} = 6.88$ (figure 4.1.1.2-8b)

$$(c_{\ell_\alpha})_M = \frac{1.05}{\beta} \frac{c_{\ell_\alpha}}{(c_{\ell_\alpha})_{theory}} (c_{\ell_\alpha})_{theory} \qquad \text{(equation 4.1.1.2-a)}$$

$$= \frac{1.05}{0.992} (0.768)(6.88) = 5.59 \text{ per rad}$$

$$\kappa = \frac{(c_{\ell_\alpha})_M}{2\pi/\beta} = \frac{5.59}{2\pi/0.992} = 0.883$$

$$\frac{\beta A}{\kappa} = \frac{(0.992)\,(3.0)}{0.883} = 3.37$$

$$\Lambda_\beta = \tan^{-1}\left(\frac{\tan \Lambda_{c/4}}{\beta}\right) = \tan^{-1}\left(\frac{0.7508}{0.992}\right) = \tan^{-1} 0.7569 = 37.12^\circ$$

$$\left(\frac{\beta C_{l_p}}{\kappa}\right)_{C_L=0} = -0.251 \text{ per rad} \quad \text{(figure 7.1.2.2-20, interpolated)}$$

Determine the dihedral-effect parameter

$$\frac{(C_{l_p})_\Gamma}{(C_{l_p})_{\Gamma=0}} = 1.0 \quad \text{(equation 7.1.2.2-b at } \Gamma = 0)$$

Determine the increment in roll damping due to drag $(\Delta C_{l_p})_{drag}$

$$\frac{(C_{l_p})_{C_{D_L}}}{C_L^{\,2}} = -0.034 \text{ (figure 7.1.2.2-24)}$$

$$(\Delta C_{l_p})_{drag} = \frac{(C_{l_p})_{C_{D_L}}}{C_L^{\,2}} C_L^{\,2} - \frac{1}{8} C_{D_0} \quad \text{(equation 7.1.2.2-c)}$$

$$= (-0.034) C_L^{\,2} - \frac{1}{8}\, 0.036 \text{ per rad}$$

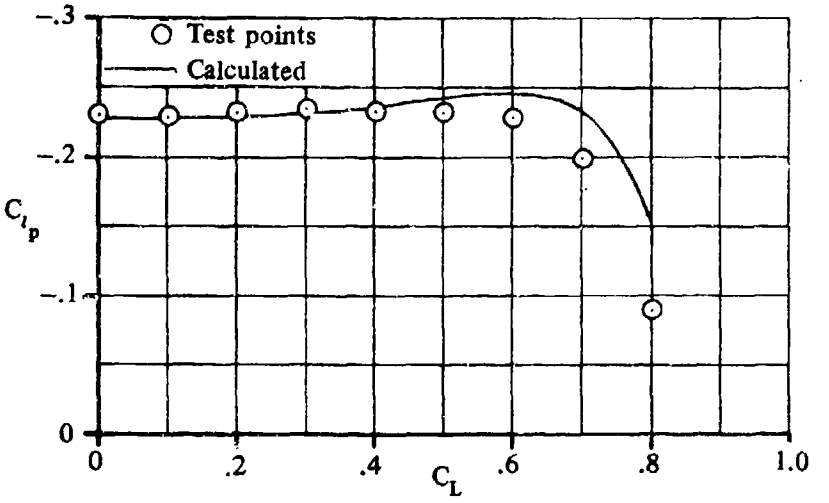
The calculated results are compared with test values in sketch (a) and in table 7.1.2.2-A.



SKETCH (a)

B. TRANSONIC

There are no reliable methods for estimating the derivative C_{l_p} in the transonic region. Although this derivative might be expected to vary with Mach number in the same manner as the lift-curve slope, this trend is not exhibited by experimental data. A considerable quantity of test data is available, however, and reference should be made to table 7-A.

C. SUPERSONIC

At supersonic speeds design charts based on theoretical calculations are presented for estimating the rolling derivative C_{l_p} of wings of vanishing thickness.

The design charts are those of reference 9 and are based on the results presented in the following references:

Reference 10 – in the region of supersonic leading and trailing edges

Reference 11 – in the region of subsonic leading edges and supersonic trailing edges

Reference 12 – for values of $\beta A < 2$

The results presented in references 10 and 11 are based on linearized supersonic-flow theory while those of reference 12 are based on slender-wing theory. The slender-wing-theory value of C_{l_p} for $\beta A = 0$ was used to establish a straight-line relationship between slender-wing theory and the low limit of the linearized supersonic-flow theory. Thin airfoils have been assumed in these theories. Thickness effects are not important except for conditions where the Mach lines lie on or near the wing leading edge. Under these conditions the wing-leading-edge shock position is displaced forward from its theoretical position by the finite thickness effects of the leading edge. This displacement results in substantial losses in normal-force-curve slope and consequently, in roll damping.

The empirical chart presented in Section 4.1.3.2 for determining the leading-edge-thickness effect on the normal-force-curve slope of straight-tapered wings has been adopted in this section to determine the leading-edge-thickness effect on the roll damping. This chart is presented as figure 7.1.2.2-27 in the form

of a ratio of the actual roll-damping derivative to the theoretical roll-damping derivative. For straight-tapered wings with sharp leading edges, the airfoil nose semiwedge angle (measured normal to the wing leading edge) determines the shock position relative to the wing. Experimental data indicate that the parameter corresponding to the nose semiwedge angle is $\Delta y_\perp = \Delta y/\cos \Lambda_{LE}$, where Δy is the difference between the upper-surface ordinates at the 6-percent- and 0.15-percent-chord stations. The parameter Δy is presented for several airfoil shapes in figure 2.2.1-8. For double-wedge and biconvex airfoils there is a linear relationship between $\Delta y_\perp$ and the leading-edge semiwedge angle, given by

$$\Delta y_\perp = 5.85 \tan \delta_\perp$$

Either $\Delta y_\perp$ or $\delta_\perp$ may be used to calculate the thickness effects.

The Datcom method is applicable to straight-tapered wings of arbitrary taper ratio with wing tips parallel to the free stream and with subsonic or supersonic leading edges and supersonic trailing edges. A further restriction is that the foremost Mach line from the tip may not intersect the remote half-wing.

Wings with inverse taper ($\lambda > 1$) have not been considered. Wings with swept-forward leading edges are included through the use of the reversibility theorem (references 13 and 14). The reversibility theorem states that the roll-damping derivative C_{l_p} of the wing in forward flight equals the roll-damping derivative of the same wing in reverse flight.

DATCOM METHOD

The wing contribution to the roll-damping derivative C_{l_p} at supersonic speeds, based on the product of wing area and the square of the wing span $S_W b_W^2$, is given by

$$C_{l_p} = \left[\frac{\left(C_{l_p}\right)_{\text{theory}}}{A}\right] A \; \frac{C_{l_p}}{\left(C_{l_p}\right)_{\text{theory}}} \quad \text{(per radian)} \qquad \text{7.1.2.2-d}$$

where

A is the wing aspect ratio.

$\dfrac{\left(C_{l_p}\right)_{\text{theory}}}{A}$ is the theoretical roll-damping parameter obtained from figures 7.1.2.2-25a through 7.1.2.2-25e.

$\dfrac{C_{l_p}}{\left(C_{l_p}\right)_{\text{theory}}}$ is the empirical thickness correction factor obtained from figure 7.1.2.2-27.

The sonic trailing-edge boundaries on figures 7.1.2.2-25a through 7.1.2.2-25e represent an upper limit for the true theoretical values of the derivatives. Values below the sonic trailing-edge boundary are for wings with subsonic trailing edges and are in violation of one of the basic assumptions of the theory. For configurations with subsonic trailing edges ($\beta \cot \Lambda_{TE} < 1$) the design charts will overestimate the roll-damping derivative.

It should be noted that the "kinks" in the curves of figures 7.1.2.2-25a through 7.1.2.2-25e correspond to the conditions of sonic leading or trailing edges. Experimental evidence shows that these "kinks" do not occur in practice.

Comparisons of the supersonic roll-damping derivative in the linear-lift range calculated by this method with test results are presented in tables 7.1.2.2-B and 7.1.2.2-C. The configurations listed in table 7.1.2.2-B have supersonic leading edges, while those of table 7.1.2.2-C have either sonic or subsonic leading edges. The roll damping is predicted quite accurately by the Datcom method when the wing leading edges are supersonic. However, when the wing leading edges are sonic or subsonic, the calculated roll damping is in almost all cases considerably greater than that given by experiment. Application of the thickness correction factor presented as figure 7.1.2.2-27 improves the agreement between the calculated and experimental values of roll damping in almost all cases presented in table 7.1.2.2-C, since this factor represents a reduction in roll damping. For wings with subsonic leading edges the theoretical results presented in figures 7.1.2.2-25a through 7.1.2.2-25e show the poorest agreement with experiment at the lower values of $\beta \cot \Lambda_{LE}$ for a given value of βA.

Sample Problem

Given: Wing 14 of reference 23.

$\Lambda_{LE} = 60^{\circ}$ $\Lambda_{c/4} = 53.4^{\circ}$ $A = 3.12$ $\lambda = 0.25$

Airfoil: Constant 3/16-in. thickness with symmetrical 5° bevel on all edges in a direction parallel to the root chord.

$\delta_{\perp} = 10^{\circ}$

$M = 2.41$; $\beta = 2.19$

Compute:

$\beta A = (2.19)(3.12) = 6.83$

$A \tan \Lambda_{c/2} = (3.12)(\tan 53.4^{\circ}) = 4.20$

$\dfrac{(C_{l_p})_{theory}}{A} = -0.0716$ per rad (figure 7.1.2.2-25b)

$\beta \cot \Lambda_{LE} = 2.19 (\cot 60^{\circ}) = 1.265$ (supersonic leading edge)

$\dfrac{\tan \Lambda_{LE}}{\beta} = \dfrac{\tan 60^{\circ}}{2.19} = 0.791$

$\dfrac{C_{l_p}}{(C_{l_p})_{theory}} = 0.865$ (figure 7.1.2.2-27)

Solution:

$$C_{l_p} = \left[\frac{\left(C_{l_p}\right)_{\text{theory}}}{A}\right] A \quad \frac{C_{l_p}}{\left(C_{l_p}\right)_{\text{theory}}} \quad \text{(equation 7.1.2.2-d)}$$

$$= (-0.0716)\ (3.12)\ (0.865)$$

$$= -0.193 \text{ per rad} \quad \text{(based on } S_w b_w^2\text{)}$$

This compares with a test result of −0.188 per radian from reference 23.

7.1.2.3 WING ROLLING DERIVATIVE C_{n_p}

This section presents methods for estimating the wing contribution to the rolling derivative C_{n_p} at subsonic and supersonic speeds. This derivative is the change in yawing-moment coefficient with change in wing-tip helix angle and is expressed as

$$C_{n_p} = \frac{\partial C_n}{\partial\left(\frac{pb}{2V_\infty}\right)}$$

A SUBSONIC

The wing rolling derivative C_{n_p} results because the unsymmetrical lift distribution causes a difference in drag between the wing panels when the wing is rolling.

The method for estimating the wing rolling derivative C_{n_p} is derived from an analysis of references 1 through 5. The method is applicable over the lift-coefficient range up to the stall, providing reliable values of lift and drag are available over this range.

The value of C_{n_p} near zero-lift coefficient is the potential-flow value based on simple-sweep theory from reference 1. The effects of linear wing twist and symmetric flap deflection are taken from references 1 and 3. Geometric dihedral also causes an increment in yawing moment that is associated with the increment in lateral force. The empirical results of reference 4 show that this increment is independent of lift coefficient over the low to moderate lift-coefficient range and increases at the higher values of lift coefficient. However, over the range of wing dihedral angles of practical interest the increment in C_{n_p} due to dihedral is very small and may be neglected.

At moderate or high lift coefficients, a comparatively large change in C_{n_p}/C_L occurs, especially for swept wings, due to the rise in drag associated with the increase in lift. In references 2 and 5, methods are presented for evaluating C_{n_p} over the lift-coefficient range up to the stall by using a correction factor to account for the variation of profile drag with lift coefficient. Results obtained by using the methods of both references 2 and 5 for estimating C_{n_p} over the lift-coefficient range have been analyzed and the method of reference 5 selected for the Datcom.

Theoretically, the tip-suction contribution to the lateral force also contributes to the yawing moment. Since this contribution is inversely proportional to aspect ratio, the increment in C_{n_p} due to tip suction becomes quite significant for highly swept and/or low-aspect-ratio planforms. A comparison has been made of C_{n_p} calculated with and without the tip-suction effect of reference 5 with test results. In all cases better agreement was obtained when the tip-suction effects were neglected. The analysis indicates a loss in tip suction particularly at the higher lift coefficients. Therefore, the effect of tip suction has been omitted from the Datcom.

If experimental lift and drag data for the particular planform of interest are not available at the chosen Mach number, no attempt should be made to estimate the variation of C_{n_p} with lift coefficient. No known general method for estimating the variation of drag coefficient will give results reliable enough to use in determining the correction factor for extrapolating the potential-flow values to higher lift coefficients.

DATCOM METHOD

The variation of the wing rolling derivative C_{n_p} with lift coefficient at subsonic speeds, based on the product of the wing area and the square of the wing span $S_W b_W^2$, is given by

$$C_{n_p} = -C_{l_p} \tan\alpha - K\left[-C_{l_p} \tan\alpha - \left(\frac{C_{n_p}}{C_L}\right)_{\substack{C_L=0 \\ M}} C_L\right] + \left(\frac{\Delta C_{n_p}}{\theta}\right)\theta$$

$$+ \left[\frac{\Delta C_{n_p}}{\left(\frac{\partial\alpha}{\partial\delta}\right)_f \delta_f}\right]\left(\frac{\partial\alpha}{\partial\delta}\right)_f \delta_f \qquad \text{(per radian)} \qquad 7.1.2.3\text{-a}$$

where

C_{l_p} is the roll-damping derivative at the appropriate Mach number estimated by using the method of paragraph A of Section 7.1.2.2.

α is the angle of attack in degrees.

C_L is the lift coefficient.

$\left(\frac{C_{n_p}}{C_L}\right)_{\substack{C_L=0 \\ M}}$ is the slope of the yawing moment due to rolling at zero lift given by

$$\left(\frac{C_{n_p}}{C_L}\right)_{\substack{C_L=0 \\ M}} = \left(\frac{A + 4\cos\Lambda_{c/4}}{AB + 4\cos\Lambda_{c/4}}\right)\left[\frac{AB + \frac{1}{2}(AB + \cos\Lambda_{c/4})\tan^2\Lambda_{c/4}}{A + \frac{1}{2}(A + \cos\Lambda_{c/4})\tan^2\Lambda_{c/4}}\right]\left(\frac{C_{n_p}}{C_L}\right)_{\substack{C_L=0 \\ M=0}}$$

7.1.2.3-b

where $B = \sqrt{1-M^2\cos^2\Lambda_{c/4}}$ and

$\left(\frac{C_{n_p}}{C_L}\right)_{\substack{C_L=0 \\ M=0}}$ is the slope of the low-speed yawing moment due to rolling at zero lift given by

$$\left(\frac{C_{n_p}}{C_L}\right)_{\substack{C_L=0 \\ M=0}} = -\frac{1}{6}\,\frac{A + 6(A + \cos\Lambda_{c/4})\left(\frac{\bar{x}}{\bar{c}}\,\frac{\tan\Lambda_{c/4}}{A} + \frac{\tan^2\Lambda_{c/4}}{12}\right)}{A + 4\cos\Lambda_{c/4}}$$

(per radian)
7.1.2.3-c

where $\bar{x}$ is the distance from the center of gravity to the aerodynamic center, positive when the a.c. is aft of the c.g. and c is the wing mean aerodynamic chord. Equation 7.1.2.3-b modifies the low-speed value of equation 7.1.2.3-c by means of the Prandtl-Glauert rule to yield approximate corrections for the first-order three-dimensional effects of compressible flow up to the critical Mach number.

$\frac{\Delta C_{n_p}}{\theta}$ is the effect of linear wing twist obtained from figure 7.1.2.3-12.

θ is the wing twist between the root and tip stations in degrees, negative for washout (see figure 7.1.2.3-12).

$\frac{\Delta C_{n_p}}{\left(\frac{\partial \alpha}{\partial \delta}\right)_f \delta_f}$ is the effect of symmetric flap deflection obtained from figure 7.1.2.3-13.

δ_f is the streamwise flap deflection in degrees.

$\left(\frac{\partial \alpha}{\partial \delta}\right)_f$ is the two-dimensional lift-effectiveness parameter α_δ obtained from Section 6.1.1.1.

K is a dimensionless correction factor used to extrapolate the potential-flow values to high lift coefficients. This is the same correction factor used in Section 7.1.2.1 to account for the variation of profile drag with lift coefficient. At zero lift this factor is taken as 1.0. At lift coefficients other than zero this factor accounts for the variation of profile drag with lift coefficient and is given by

$$K = \frac{\frac{\partial}{\partial \alpha}(C_L \tan \alpha) - \frac{\partial}{\partial \alpha}\left(C_D - C_{D_0}\right)}{\frac{\partial}{\partial \alpha}(C_L \tan \alpha) - \frac{\partial}{\partial \alpha}\left(\frac{C_L^2}{\pi A}\right)} \qquad 7.1.2.3\text{-d}$$

Test values of lift and drag at the chosen Mach number for the particular planform of interest must be used in evaluating equation 7.1.2.3-d. The terms of this equation are evaluated by taking the slopes of $C_L \tan \alpha$, $(C_D - C_{D_0})$, and $C_L^2/(\pi A)$, plotted versus angle of attack.

If reliable values of the static-force coefficients are available, the method should provide results within ±20 percent accuracy throughout the lift-coefficient range to the stall.

Sample Problem

Given: The wing designated 45-4.0-0.6-006 of references 5 and 8.

Wing Characteristics:

$A = 4.0 \quad \lambda = 0.6 \quad \Lambda_{c/4} = 45^o \quad \theta = 0$

$S = 2.25$ sq ft $\quad b = 3.0$ ft

NACA 65A006 Airfoil $\quad \bar{x} = 0$ [origin of moments (c.g.) located at $x_{a.c.}$]

Additional Characteristics:

$M = 0.70; \ \beta = 0.714 \quad R_\ell = 3.1 \times 10^6$

The following values of α and C_D are test results from reference 8. The variation of C_{l_p} with C_L has been calculated using the method of paragraph A of Section 7.1.2.2.

C_L	0	.1	.2	.3	.4	.5	.6	.7	.75
α	0	1.70	3.30	4.90	6.55	8.00	9.60	11.80	13.20

C_{l_p}	−.314	− .314	− .313	− .312	− .326	− .325	− .280	− .181	− .156

Compute:

Determine the slope of the yawing moment due to rolling at zero lift $\left(\frac{C_{n_p}}{C_L}\right)_{\substack{C_L=0 \\ M}}$

$$\left(\frac{C_{n_p}}{C_L}\right)_{\substack{C_L=0 \\ M=0}} = -\frac{1}{6}\,\frac{A + 6(A + \cos\Lambda_{c/4})\left(\frac{\bar{x}}{\bar{c}}\,\frac{\tan\Lambda_{c/4}}{A} + \frac{\tan^2\Lambda_{c/4}}{12}\right)}{A + 4\cos\Lambda_{c/4}} \quad \text{(equation 7.1.2.3-c)}$$

$$= -\frac{1}{6}\,\frac{4.0 + 6\,(4.0 + \cos 45^o)\left(0 + \frac{\tan^2 45^o}{12}\right)}{4.0 + 4\cos 45^o}$$

$$= -\frac{1}{6}\,\frac{4.0 + 6\,(4.7071)\left(0 + \frac{1}{12}\right)}{4.0 + 2.828} = -0.155 \text{ per rad}$$

$$B = \sqrt{1 - M^2 \cos^2 \Lambda_{c/4}} = \sqrt{1 - (0.7)^2 (0.7071)^2} = 0.87$$

$$\frac{A + 4 \cos \Lambda_{c/4}}{AB + 4 \cos \Lambda_{c/4}} = \frac{4.0 + (4.0)(0.7071)}{(4.0)(0.87) + (4.0)(0.7071)} = \frac{6.828}{6.308} = 1.082$$

$$\frac{AB + \frac{1}{2}(AB + \cos \Lambda_{c/4}) \tan^2 \Lambda_{c/4}}{A + \frac{1}{2}(A + \cos \Lambda_{c/4}) \tan^2 \Lambda_{c/4}} = \frac{(4.0)(0.87) + \frac{1}{2}[(4.0)(0.87) + 0.7071](1)}{4.0 + \frac{1}{2}[4.0 + 0.7071](1)}$$

$$= \frac{5.574}{6.354} = 0.877$$

$$\left(\frac{C_{n_p}}{C_L}\right)_{\substack{C_L = 0 \\ M}} = \left(\frac{A + 4 \cos \Lambda_{c/4}}{AB + 4 \cos \Lambda_{c/4}}\right) \left[\frac{AB + \frac{1}{2}(AB + \cos \Lambda_{c/4}) \tan^2 \Lambda_{c/4}}{A + \frac{1}{2}(A + \cos \Lambda_{c/4} \tan^2 \Lambda_{c/4}}\right] \left(\frac{C_{n_p}}{C_L}\right)_{\substack{C_L = 0 \\ M = 0}}$$

(equation 7.1.2.3-b)

$$= (1.082)(0.877)(-0.155) = -0.147 \text{ per rad}$$

Determine the K factor

$$K = \frac{\frac{\partial}{\partial \alpha}(C_L \tan\alpha) - \frac{\partial}{\partial \alpha}(C_D - C_{D_0})}{\frac{\partial}{\partial \alpha}(C_L \tan\alpha) - \frac{\partial}{\partial \alpha}\left(\frac{C_L^2}{\pi A}\right)}$$ (equation 7.1.2.3-d)

SKETCH (b)

B. TRANSONIC

No generalized method is available in the literature for estimating transonic values of the rolling derivative C_{n_p}. Furthermore, no known experimental results are available for this derivative at transonic speeds.

C. SUPERSONIC

At supersonic speeds design charts based on theoretical calculations are presented for estimating the rolling derivative C_{n_p} at low values of the lift coefficient.

The design charts are based on the results of reference 6 for wings with subsonic leading edges and supersonic trailing edges, and on the results of reference 7 for wings with supersonic leading edges and either subsonic or supersonic trailing edges. The results of both references 6 and 7 are based on linearized-supersonic-flow theory and are therefore restricted to thin, swept-back, tapered wings with streamwise tips. The yawing moment due to rolling is taken as that arising entirely from suction forces on the wing edges. For wings with supersonic leading edges no suction forces are induced along the leading edges; consequently, the determination of C_{n_p} involves only the unbalanced suction forces along the wing tips. Therefore, no design chart is presented for zero-taper wings with supersonic leading edges, since the theory gives $C_{n_p} = 0$.

The design charts for wings with subsonic leading edges give values of C_{n_p} that are referred to body axes with the origin located at the wing apex. The design charts for wings with supersonic leading edges give values of C_{n_p} that are referred to body axes with the origin located at the projection of the leading edge of the tip on the wing root chord. The Datcom method presents transformation formulas for conversion from body axes to stability axes with the origin located at an arbitrary distance from the leading edge.

No experimental data are available for this derivative at supersonic speeds. Therefore, the validity of linearized-supersonic-flow theory for estimating C_{n_p} cannot be determined.

DATCOM METHOD

Subsonic Leading Edges ($\beta \cot \Lambda_{LE} < 1$)

For wings with subsonic leading edges the contribution to the rolling derivative C_{n_p} at supersonic speeds, and at low values of the lift coefficient is given by

$$\frac{C_{n_p}}{\alpha} = \left(\frac{C_{n_p}}{\alpha}\right)_{\substack{\text{body}\\ \text{axis}}} + \frac{2\, x_{c.g.}}{A(1+\lambda)} \left(\frac{C_{Y_p}}{\alpha}\right) - \left(C_{l_p} - C_{n_r}\right) \quad \text{(per radian}^2\text{)} \qquad 7.1.2.3\text{-e}$$

where

$\frac{C_{n_p}}{\alpha}$ is the supersonic yawing moment due to rolling referred to stability axes with the origin at the center of gravity.

$\left(\frac{C_{n_p}}{\alpha}\right)_{\substack{body \\ axis}}$ is the supersonic yawing moment due to rolling referred to body axes with the origin at the wing apex, given by

$$\left(\frac{C_{n_p}}{\alpha}\right)_{\substack{body \\ axis}} = \left(\frac{C_{n_p}}{\alpha}\right)_1 + \left(\frac{C_{n_p}}{\alpha}\right)_2 + \left(\frac{C_{n_p}}{\alpha}\right)_3 \quad \text{(per radian}^2\text{)} \qquad 7.1.2.3\text{-f}$$

where

$\left(\frac{C_{n_p}}{\alpha}\right)_1$ is obtained from figure 7.1.2.3-14a through 7.1.2.3-14d as a function of βA, $\beta \cot \Lambda_{LE}$, and taper ratio. For $\lambda = 0$, $(C_{n_p}/\alpha)_1 = 0$.

$\left(\frac{C_{n_p}}{\alpha}\right)_2$ and $\left(\frac{C_{n_p}}{\alpha}\right)_3$ are obtained from figure 7.1.2.3-16 as a function of $\beta \cot \Lambda_{LE}$.

$x_{c.g.}$ is the distance from the wing apex to the center of gravity in root chords, positive when the c.g. is aft of the wing apex.

$\frac{C_{Y_p}}{\alpha}$ is the supersonic side force due to rolling obtained by using the method of paragraph C of Section 7.1.2.1.

C_{l_p} is the supersonic roll-damping derivative obtained by using the method of paragraph C of Section 7.1.2.2.

C_{n_r} is the supersonic yaw-damping derivative. It is negligible except for very low-aspect-ratio wings. References are noted in paragraph C of Section 7.1.3.3 that outline approximate methods that may be used to determine this derivative.

α is the angle of attack in radians.

Supersonic Leading Edges ($\beta \cot \Lambda_{LE} > 1$)

For wings with supersonic leading edges the contribution to the rolling derivative C_{n_p} at supersonic speeds and at low values of the lift coefficient is given by

$$\frac{C_{n_p}}{\alpha} = \left(\frac{C_{n_p}}{\alpha}\right)_{\substack{body \\ axis}} + \left[\frac{2\,x_{c.g.}}{A(1+\lambda)} - \frac{1}{2}\tan \Lambda_{LE}\right] \frac{C_{Y_p}}{\alpha} - C_{l_p} \quad \text{(per radian}^2\text{)}$$

7.1.2.3-g

where

$\frac{C_{n_p}}{\alpha}$ is the supersonic yawing moment due to rolling referred to stability axes with the origin at the center of gravity.

$\left(\frac{C_{n_p}}{\alpha}\right)_{\substack{body \\ axis}}$ is the supersonic yawing moment due to rolling referred to body axes with the origin at the projection of the leading edge of the tip on the wing root chord. It is obtained from figures 7.1.2.3-17a through 7.1.2.3-17d as a function of βA, β cot Λ_{LE}, and taper ratio. No design chart is presented for zero-taper wings since $(C_{n_p}/\alpha)_{\substack{body \\ axis}} = 0$ for these planforms. For wings with taper ratios less than 0.25 ($\lambda < 0.25$) values of $(C_{n_p}/\alpha)_{\substack{body \\ axis}}$ should be obtained by extrapolating values from figures 7.1.2.3-17a through 7.1.2.3-17d.

The remaining terms in equation 7.1.2.3-g are defined under the subsonic-leading-edge case.

Sample Problem

Given: Tapered, swept-back wing

$A = 3.22$ $\lambda = 0.25$ $\Lambda_{LE} = 55.2^o$ $\Lambda_{c/2} = 46.8^o$

$M = 2.41$; $\beta = 2.19$ $x_{c.g.} = 0.742$

Compute:

β cot $\Lambda_{LE} = (2.19)$ (cot 55.2^o) $= 1.522$ (supersonic leading edge)

$\beta A = (2.19)(3.22) = 7.07$

$\frac{C_{Y_p}}{\alpha} = 0.50$ per rad^2 (figure 7.1.2.1-10)

$\left(\frac{C_{n_p}}{\alpha}\right)_{\substack{body \\ axis}} = -0.0114$ per rad^2 (figure 7.1.2.3-17a)

A tan $\Lambda_{c/2} = (3.22)$ (tan 46.8^o) $= 3.433$

$\frac{C_{l_p}}{A} = -0.066$ per rad (figure 7.1.2.2-25b)

$$C_{l_p} = (-0.066)\,(3.22) = -0.213 \text{ per rad}$$

Solution:

$$\frac{C_{n_p}}{\alpha} = \left(\frac{C_{n_p}}{\alpha}\right)_{\substack{\text{body}\\ \text{axis}}} + \left[\frac{2\,x_{c.g.}}{A(1+\lambda)} - \frac{1}{2}\tan\Lambda_{LE}\right]\frac{C_{Y_p}}{\alpha} - C_{l_p} \qquad \text{(equation 7.1.2.3-g)}$$

$$= -0.0114 + \left[\frac{2\,(0.742)}{3.22\,(1+0.25)} - \frac{1}{2}\tan 55.2^{o}\right]0.50 - (-0.213)$$

$$= -0.0114 + [0.3687 - 0.7194]\,0.50 + 0.213$$

$$= 0.026 \text{ per rad}^2 \qquad \text{(referred to stability axes with origin at } x_{c.g.} \text{ and based on } S_W b_W^2\text{)}$$

7.1.3 WING YAWING DERIVATIVES

7.1.3.1 WING YAWING DERIVATIVE C_{Y_r}

This section recommends methods for estimating the wing contribution to the yawing derivative C_{Y_r} at subsonic and supersonic speeds. However, at subsonic, transonic, and supersonic speeds no generalized methods are available for estimating the wing contribution to C_{Y_r}. This derivative is the change in side-force coefficient with variation in yawing velocity and is expressed as

$$C_{Y_r} = \frac{\partial C_Y}{\partial\left(\frac{rb}{2V_\infty}\right)}$$

A. SUBSONIC

The wing contribution to C_{Y_r} is best evaluated from available experimental data (see table 7-A and references 1, 2, 3, and 4), since no generalized method is available in the literature. However, a method is available in reference 1 for wings with a taper ratio of one and moderate sweep at low subsonic speeds. The range and accuracy of this method are limited and generally inadequate for making reliable estimates of the wing contribution.

Since the wing contribution to C_{Y_r} is usually quite small in comparison to the vertical-tail contribution, it is sometimes neglected.

B. TRANSONIC

No generalized method is available in the literature for estimating transonic values of the wing contribution to the yawing derivative C_{Y_r}. Furthermore, there is a scarcity of experimental data for this derivative at transonic speeds.

C. SUPERSONIC

No generalized method is available in the literature for estimating supersonic values of the wing contribution to the yawing derivative C_{Y_r}. A few theoretical methods are available for specific configurations (see table 7-A). Although the use of experimental data for a similar configuration is preferable to theoretical methods, experimental data are so scarce that the use of the limited theoretical methods becomes the only alternative for most configurations.

7.1.3.2 WING YAWING DERIVATIVE C_{l_r}

This section presents a method for estimating the wing contribution to the yawing derivative C_{l_r} at subsonic speeds. No generalized methods are available for estimating C_{l_r} at transonic and supersonic speeds; however, theoretical methods for determining this derivative at supersonic speeds for special classes of wing planforms are discussed. This derivative is the change in rolling-moment coefficient with change in the yawing-velocity parameter and is expressed as

$$C_{l_r} = \frac{\partial C_l}{\partial\left(\frac{rb}{2V_\infty}\right)}$$

A. SUBSONIC

The wing yawing derivative C_{l_r} results from the lift differential between the wing panels when the vehicle is yawed about its vertical axis.

Over the range of lift coefficients for which C_{l_r} is linear with C_L, the derivative C_{l_r} for wings without geometric dihedral, twist, or flaps is based on the lifting-line theory of reference 1 for aspect ratios greater than three and on the experimental data of references 2 and 3 for aspect ratios less than three. The increment in C_{l_r} due to geometric dihedral is taken from reference 4. The effects of symmetric flap deflection and wing twist are taken from reference 1.

In addition to the increments in C_{l_r} due to dihedral, twist, and flaps, an additional increment in C_{l_r} arises due to C_{Y_r} if the center of gravity does not lie at the same height as the quarter-chord point of the wing MAC. This contribution is obtained from the expression

$$(\Delta C_{l_r})_{\text{side force}} = -C_{Y_r}\frac{z}{b}$$

where z is the vertical distance between the center of gravity and the quarter-chord point of the wing MAC, positive for the c.g. above $\bar{c}/4$. The side force due to yawing C_{Y_r} is small except at high angles of attack. Therefore, this increment in C_{l_r} is omitted from the Datcom method.

The fore and aft movement of the center of gravity also affects C_{l_r}, but this effect is neglected because of the questionable accuracy of the basic effect of wing sweep.

The method of reference 5 is applied to extrapolate the potential-flow value of C_{l_r} to higher lift coefficients. The method is semiempirical in that it requires test values to determine the correction factors to be applied to the theory. Analysis of experimental data shows that the discrepancies between theoretical and experimental values of C_{l_r} for wings are similar to the discrepancies between theoretical and experimental values of the static derivative C_{l_β}. Based on this analysis, a correction factor is applied in reference 5, which is the incremental value of C_{l_β} obtained by subtracting the experimental value from the theoretical value.

Experimental data indicate that for unswept wings C_{l_r} is nearly proportional to the lift coefficient until maximum lift occurs. For sweptback wings, a linear variation is obtained over only a limited lift range, which is reduced as sweep increases. At high lift coefficients C_{l_r} decreases, and for sweptback wings may become negative near maximum lift.

If reliable values of the rolling moment due to sideslip C_{l_β} are available, the method should provide results within ±20-percent accuracy over the lift-coefficient range for which C_{l_r} is approximately linear with C_L.

DATCOM METHOD

The variation of the wing yawing derivative C_{l_r} with lift coefficient, based on the product of the wing area and the square of the wing span $S_W b_W^2$, is given by

$$C_{l_r} = C_L\left(\frac{C_{l_r}}{C_L}\right)_{\substack{C_L=0\\M}} + (\Delta C_{l_r})_{C_L} + \left(\frac{\Delta C_{l_r}}{\Gamma}\right)\Gamma + \left(\frac{\Delta C_{l_r}}{\theta}\right)\theta + \left[\frac{\Delta C_{l_r}}{\left(\frac{\partial\alpha}{\partial\delta}\right)_f \delta_f}\right]\left(\frac{\partial\alpha}{\partial\delta}\right)_f \delta_f \quad \text{(per radian)} \qquad 7.1.3.2\text{-a}$$

where

$\left(\frac{C_{l_r}}{C_L}\right)_{\substack{C_L=0\\M}}$ is the slope of the rolling moment due to yawing at zero lift given by

$$\left(\frac{C_{l_r}}{C_L}\right)_{\substack{C_L=0\\M}} = \frac{1 + \frac{A(1-B^2)}{2B(AB+2\cos\Lambda_{c/4})} + \frac{AB+2\cos\Lambda_{c/4}}{AB+4\cos\Lambda_{c/4}}\,\frac{\tan^2\Lambda_{c/4}}{8}}{1 + \frac{A+2\cos\Lambda_{c/4}}{A+4\cos\Lambda_{c/4}}\,\frac{\tan^2\Lambda_{c/4}}{8}}\left(\frac{C_{l_r}}{C_L}\right)_{\substack{C_L=0\\M=0}} \qquad 7.1.3.2\text{-b}$$

where $B = \sqrt{1-M^2\cos^2\Lambda_{c/4}}$ and

$\left(\frac{C_{l_r}}{C_L}\right)_{\substack{C_L=0\\M=0}}$ is the slope of the low-speed rolling moment due to yawing at zero lift, obtained from figure 7.1.3.2-10 as a function of aspect ratio, sweep of the quarter-chord, and taper ratio. This chart has been derived by using the results of references 1, 2, and 3. Equation 7.1.3.2-b modifies the low-speed value by means of the Prandtl-Glauert rule to yield approximate corrections for the first-order three-dimensional effects of compressible flow up to the critical Mach number.

C_L is the wing lift coefficient.

$(\Delta C_{l_r})_{C_L}$ is a semiempirical correction factor used to extrapolate the potential-flow values of C_{l_r} to higher lift coefficients. This parameter is given by

$$(\Delta C_{l_r})_{C_L} = C_L \left(\frac{C_{l_\beta}}{C_L}\right) - \left(C_{l_\beta}\right)_{test} \qquad \text{(per radian)} \qquad 7.1.3.2\text{-c}$$

where

$\frac{C_{l_\beta}}{C_L}$ is the theoretical value of the slope of the rolling moment due to sideslip at zero lift obtained by using the method of paragraph A of Section 5.1.2.1, neglecting the effects of twist and dihedral. In applying this method the compressibility correction to the sweep contribution should be considered.

$\left(C_{l_\beta}\right)_{test}$ is the experimental value of the rolling moment due to sideslip at the appropriate Mach number.

$\frac{\Delta C_{l_r}}{\Gamma}$ is the increment in C_{l_r} due to dihedral, given by

$$\frac{\Delta C_{l_r}}{\Gamma} = \frac{1}{12} \frac{\pi A \sin \Lambda_{c/4}}{A + 4 \cos \Lambda_{c/4}} \qquad \text{(per radian}^2\text{)} \qquad 7.1.3.2\text{-d}$$

Γ is the geometric dihedral angle in radians, positive for the wing tip above the plane of the root chord.

$\frac{\Delta C_{l_r}}{\theta}$ is the increment in C_{l_r} due to wing twist obtained from figure 7.1.3.2-11.

θ is the wing twist between the root and tip sections in degrees, negative for washout (see figure 7.1.3.2-11).

$\frac{\Delta C_{l_r}}{\left(\frac{\partial \alpha}{\partial \delta}\right)_f \delta_f}$ is the effect of symmetric flap deflection obtained from figure 7.1.3.2-12.

δ_f is the streamwise flap deflection in degrees.

$\left(\frac{\partial \alpha}{\partial \delta}\right)_f$ is the two-dimensional lift-effectiveness parameter α_δ obtained from Section 6.1.1.1.

The expression given for the effect of dihedral (equation 7.1.3.2-d) is based on an extension of the simple-sweep theory of reference 6. It has been shown by comparison with test data that the increment in C_{l_Γ} due to dihedral is underestimated by equation 7.1.3.2-d. However, it has not been possible to improve upon the simple-sweep-theory result because of a lack of experimental data.

Furthermore, not enough data are available to examine the validity of the lifting-line-theory results presented for the increments in C_{l_Γ} due to either twist or flap deflection.

A comparison of the slope of the rolling moment due to yawing at zero lift, obtained by using figure 7.1.3.2-10, with test results is presented as table 7.1.3.2-A.

The sample problem illustrates the application of the method over the lift-coefficient range to the stall.

Sample Problem

Given: The sweptback, untapered wing of reference 4.

Wing Characteristics:

$A = 2.61 \qquad \lambda = 1.0 \qquad \Lambda_{c/4} = 45^o \qquad \Lambda_{c/2} = 45^o \qquad \Gamma = 10^o \qquad \theta = 0$

Additional Characteristics:

Low speed; $M \approx 0$

The following test values from reference 4:

C_L	0	.1	.2	.3	.4	.5	.6	.7	.8	.9	1.0	1.1
C_{l_β} (per rad)	−.0458	−.1031	−.140	−.176	−.206	−.235	−.260	−.274	−.260	−.211	−.102	.0287

Compute:

$\left(\frac{C_{l_\Gamma}}{C_L}\right)_{\substack{C_L=0 \\ M=0}}$ = 0.419 per rad (figure 7.1.3.2-10)

Determine the theoretical value of C_{l_β}/C_L (Section 5.1.2.1)

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2}} = -0.0038 \text{ per deg} \qquad \text{(figure 5.1.2.1-27)}$$

$$\left(\frac{C_{l_\beta}}{C_L}\right)_{A} = -0.0044 \text{ per deg} \qquad \text{(figure 5.1.2.1-28b)}$$

$$K_{M_\Lambda} = 1.0 \quad \text{(figure 5.1.2.1-28a for } M \approx 0)$$

$$C_{l_\beta} = C_L\left[\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2}} K_{M_\Lambda} + \left(\frac{C_{l_\beta}}{C_L}\right)_{A}\right] + \Gamma\left(\frac{C_{l_\beta}}{\Gamma} K_{M_\Gamma}\right) + \theta \tan \Lambda_{c/4} \frac{\Delta C_{l_\beta}}{\theta \tan \Lambda_{c/4}}$$

(equation 5.1.2.1-a)

Neglecting the effects of twist and dihedral

$$\frac{C_{l_\beta}}{C_L} = \left[\left(\frac{C_{l_\beta}}{C_L}\right)_{\Lambda_{c/2}} K_{M_\Lambda} + \left(\frac{C_{l_\beta}}{C_L}_{/A}\right)\right]$$

$$= (-0.0038)(1.0) + (-0.0044)$$

$$= -0.0082 \text{ per deg}$$

$$= -0.470 \text{ per rad}$$

$$(\Delta C_{l_r})_{C_L} = C_L\left(\frac{C_{l_\beta}}{C_L}\right) - (C_{l_\beta})_{test} \qquad \text{(equation 7.1.3.2-c)}$$

$$= C_L\,(-0.470) - (C_{l_\beta})_{test} \qquad \text{(see calculation table)}$$

$$\frac{\Delta C_{l_r}}{\Gamma} = \frac{1}{12}\,\frac{\pi A \sin \Lambda_{c/4}}{A + 4\cos \Lambda_{c/4}} \qquad \text{(equation 7.1.3.2-d)}$$

$$= \frac{1}{12}\,\frac{\pi(2.61)(\sin 45^o)}{2.61 + 4\cos 45^o} = \frac{1}{12}\,\frac{\pi(2.61)(0.7071)}{2.61 + 4(0.7071)}$$

$$= 0.0884 \text{ per rad}^2$$

Solution:

$$C_{l_r} = C_L \left(\frac{C_{l_r}}{C_L}\right)_{\substack{C_L = 0 \\ M = 0}} + (\Delta C_{l_r})_{C_L} + \left(\frac{\Delta C_{l_r}}{\Gamma}\right)\Gamma \qquad \text{(equation 7.1.3.2-a)}$$

$$= C_L\,(0.419) + [C_L\,(-0.470) - C_{l_{\beta\ \text{test}}}] + (0.0884)\,\frac{10}{57.3}$$

$$= 0.419\,C_L + [-0.470\,C_L - C_{l_{\beta\ \text{test}}}] + 0.0154$$

FIGURE 7.1.3.2-12 EFFECT OF FLAPS ON C_{l_r}

7.1.3.3 WING YAWING DERIVATIVE C_{n_r}

This section presents a method for estimating the wing contribution to the yawing derivative C_{n_r} at subsonic speeds. No generalized methods are available for estimating C_{n_r} at transonic and supersonic speeds; however, theoretical methods for determining this derivative at supersonic speeds for special classes of wing planforms are discussed. This derivative is the change in yawing-moment coefficient with change in the yawing-velocity parameter. It is commonly referred to as the yaw damping and is expressed as

$$C_{n_r} = \frac{\partial C_n}{\partial\left(\frac{rb}{2V_\infty}\right)}$$

A. SUBSONIC

The wing yawing derivative C_{n_r} is due to the antisymmetrical lift and drag distributions over the wing resulting from the yawing velocity.

The wing contribution to the yaw damping in the range of lift coefficients for which C_{n_r} varies linearly with C_L is composed of two major contributions; namely, that resulting from the drag due to lift and that resulting from the profile drag. The contribution resulting from the drag due to lift is given to a first approximation by the simple-sweep-theory result of reference 1. It is a negative quantity except for highly swept wings in which case it can become positive.

The increment in C_{n_r} due to profile drag is also taken from reference 1. Although the spanwise distribution of profile drag is required for an accurate determination of the effect of profile drag on C_{n_r}, the profile drag has been assumed constant over the wing surface in the analysis reported in reference 1. This approximation greatly simplifies the analysis, since it allows the profile-drag effect to be expressed as a function of only the wing geometry.

Flaps and wing twist will also induce increments in C_{n_r}, primarily as a result of their influencing the lift distribution across the span. However, the technique of the superposition of lift distribution proportional to angle of attack, which was used to determine the effects of either flaps and/or twist on the rotary derivatives C_{n_p} and C_{l_r}, cannot be applied in this case. The contribution of the drag-due-to-lift component to C_{n_r} increases as the square of the angle of attack. Therefore, a breakdown of the lift distribution proportional to angle of attack is not possible. No methods are available in the literature for estimating the effects of flaps or wing twist on the wing contribution to C_{n_r}. Furthermore, not enough test data are available to allow derivation of an empirical method.

The wing side force due to yawing C_{Y_r} will also produce a yawing moment when the center of gravity does not lie at the same longitudinal station as the quarter-chord of the wing MAC. However, the side force due to yawing is small except at high angles of attack; consequently, this increment in C_{n_r} is omitted from the Datcom.

Experimental data indicate that for unswept wings the yaw damping is nearly proportional to the lift coefficient until maximum lift occurs. On the other hand, for sweptback wings linear variations of C_{n_r} are obtained over only a limited lift coefficient range, which is reduced as sweep and/or aspect ratio increase. Experimental data also show that, in general, the yaw damping of a sweptback wing

changes sign and becomes positive at some moderate lift coefficient. The lift coefficient at which this change in sign occurs is reduced as wing sweep and/or aspect ratio increase.

Results obtained by using the Datcom method agree reasonably well with test data over the range of lift coefficients for which C_{n_r} varies linearly with C_L.

Since the wing contribution to the total C_{n_r} of the airplane is small, no method has been developed to account for the effects of compressibility. For the purpose of the Datcom the effects of compressibility are accounted for by evaluating the wing profile-drag coefficient at the desired Mach number.

Experimental data show that the effect of wing dihedral on the yaw damping is negligible.

Because of the insignificance of the wing contribution to the total yaw damping and the approximate nature of the Datcom method, the method is applicable to wings with twist and/or symmetric flap deflection as well as to plain wings.

DATCOM METHOD

The variation of the wing yawing derivative C_{n_r} with lift coefficient at subsonic speeds, based on the product of the wing area and the square of the wing span $S_W b_W^2$, is given by

$$C_{n_r} = \left(\frac{C_{n_r}}{C_L^2}\right) C_L^2 \div \left(\frac{C_{n_r}}{C_{D_0}}\right) C_{D_0} \qquad \text{(per radian)} \qquad 7.1.3.3\text{-a}$$

where

C_L is the wing lift coefficient.

$\frac{C_{n_r}}{C_L^2}$ is the low-speed drag-due-to-lift yaw-damping parameter obtained from figure 7.1.3.3-6 as a function of wing aspect ratio, taper ratio, sweepback, and c.g. position.

$\frac{C_{n_r}}{C_{D_0}}$ is the low-speed profile-drag yaw-damping parameter obtained from figure 7.1.3.3-7 as a function of the wing aspect ratio, sweep-back, and c.g. position.

C_{D_0} is the wing profile drag coefficient evaluated at the appropriate Mach number. For this application C_{D_0} is assumed to be the profile drag associated with the theoretical ideal drag due to lift and is given by

$$C_{D_0} = C_D - \frac{C_L^2}{\pi A}$$

where C_D is the total drag coefficient at a given lift coefficient, obtained from experimental data.

Sample Problem

Given: The delta-wing model of references 5 and 6.

Wing Characteristics:

$A = 2.31 \qquad \lambda = 0 \qquad \Lambda_{c/4} = 52.4^{o} \qquad \theta = 0$

$\bar{x}/\bar{c} = 0$ (c.g. at $\bar{c}/4$)

Additional Characteristics:

$M = 0.13$

7.1.4 WING ACCELERATION DERIVATIVES

7.1.4.1 WING ACCELERATION DERIVATIVE $C_{L_{\dot{\alpha}}}$

Methods are presented for estimating the wing contribution to the derivative $C_{L_{\dot{\alpha}}}$ at low angles of attack for a triangular planform the subsonic and low transonic speed ranges and for planforms with the leading edge swept back and the trailing edge swept back or swept forward in the supersonic speed range. In addition, the supersonic results are directly applicable to wings with sweptforward leading edges, in view of the reversibility theorem (see reference 5). This derivative is used in estimating $C_{m_{\dot{\alpha}}}$ in Section 7.1.4.2.

If the wing acceleration derivative $C_{L_{\dot{\alpha}}}$ is to be used in method 1 of Section 7.3.4.1 to obtain $(C_{L_{\dot{\alpha}}})_{WB}$, the exposed wing planform area should be used for all calculations in the Datcom methods. Using the exposed planform area will yield $C_{L_{\dot{\alpha}}}$ based on the product of the exposed wing area and the exposed wing MAC, rather than the product of wing area and wing MAC as indicated.

DATCOM METHODS

A. SUBSONIC

An equation for estimating the subsonic acceleration derivative $C_{L_{\dot{\alpha}}}$ of a triangular wing (derived in reference 1), based on the product of wing area and wing MAC $S_W \bar{c}_W$, is given by

$$C_{L_{\dot{\alpha}}} = 1.5 \left(\frac{x_{a.c.}}{c_r} \right) C_{L_\alpha} + 3\, C_L(g) \quad \text{(per radian)} \qquad 7.1.4.1\text{-a}$$

where

C_{L_α} is the wing lift-curve slope (Section 4.1.3.2) at the Mach number under consideration, based on the total wing area (per radian).

$\frac{x_{a.c.}}{c_r}$ is obtained from Section 4.1.4.2.

$C_L(g)$ is the lift-coefficient correction term obtained from figure 7.1.4.1-6 (per radian).

Because of the restrictions placed on the lift-coefficient correction term, this method is valid only for $0 < \beta A < 4$.

Explicit expressions for estimating $C_{L_{\dot{\alpha}}}$ of other wing planforms in the subsonic region are not available at this time.

Sample Problem

Given:

$A = 4.0 \qquad \lambda = 0 \qquad \Lambda_{LE} = 45^\circ \qquad C_{L_\alpha} = 4.0$ per rad (Section 4.1.3.2)

$M = 0.6$

Compute:

$\beta = \sqrt{1 - M^2} = 0.80$

$\tan \Lambda_{LE} = 1.0$

$\beta / \tan \Lambda_{LE} = 0.80$

$\beta A = 3.20$

$A \tan \Lambda_{LE} = 4.0$

$\frac{x_{a.c.}}{c_r} = 0.570$ (figure 4.1.4.2-26a)

$\frac{-\beta^2 C_L(g)}{\pi A/2} = 0.1245$ per rad (figure 7.1.4.1-6)

$C_L(g) = -1.22$ per rad

Solution:

$$C_{L_{\dot{\alpha}}} = 1.5 \left(\frac{x_{a.c.}}{c_r} \right) C_{L_\alpha} + 3\, C_L(g) \quad \text{(equation 7.1.4.1-a)}$$

$$= (1.5)\,(0.570)\,(4.0) + (3)\,(-1.22)$$

$$= -0.240 \text{ per rad (based on } S_W \bar{c}_W)$$

B. TRANSONIC

The value of $C_{L_{\dot{\alpha}}}$ of a triangular wing from the critical Mach number to M = 1.0 is given by the method of paragraph A, provided $0 < \beta A < 4$.

There is no general theory available in the literature that gives the transonic values of $C_{L_{\dot{\alpha}}}$, either for additional wing-geometry parameters or for Mach numbers greater than 1.0. Furthermore, there is a scarcity of test data in the transonic region for any wing planform.

C. SUPERSONIC

The supersonic value of $C_{L_{\dot{\alpha}}}$, based on the product of wing area and wing MAC $S_W \bar{c}_W$, is derived in references 2 and 3 for wings with subsonic leading edges and in reference 4 for wings with supersonic leading edges.

1. Wings with subsonic leading edges ($\beta \cot \Lambda_{LE} < 1.0$)

For wings with subsonic leading edges, $C_{L_{\dot{\alpha}}}$ is obtained by the method of reference 2 for $\lambda = 0$ and by the method of reference 3 for $\lambda = 0.25$ to 1.0. The following methods are not valid if the Mach line from the vertex of the trailing edge intersects the leading edge or if the wing-tip Mach lines intersect on the wings or intersect the opposite wing tips.

a. Zero-taper-ratio wings ($\lambda = 0$)

$C_{L_{\dot{\alpha}}}$ is derived in reference 2 as

$$C_{L_{\dot{\alpha}}} = -\frac{\pi A M^2}{2\beta^2}\left[-3G(\beta C)\,F_3(N) + 2E''(\beta C)\,F_2(N) + \frac{1}{M^2}\,E''(\beta C)\,F_1(N)\right] \quad \text{(per radian)} \qquad 7.1.4.1\text{-b}$$

where

$E''(\beta C)$ and $G(\beta C)$ are obtained from figure 7.1.1.1-8.

$F_1(N)$, $F_2(N)$, and $F_3(N)$ are obtained from figure 7.1.4.1-7.

b. Wings with $\lambda = 0.25$ to 1.0

$C_{L_{\dot{\alpha}}}$ is derived in reference 3 as

$$C_{L_{\dot{\alpha}}} = \frac{M^2}{\beta^2}\left(C_{L_{\dot{\alpha}}}\right)_1 - \frac{1}{\beta^2}\left(C_{L_{\dot{\alpha}}}\right)_2 \quad \text{(per radian)} \qquad 7.1.4.1\text{-c}$$

where

$\left(C_{L_{\dot{\alpha}}}\right)_1$ and $\left(C_{L_{\dot{\alpha}}}\right)_2$ are obtained from figures 7.1.4.1-8a through 7.1.4.1-8f for $\lambda = 0.25$, 0.50, and 0.75 and from the equations of reference 3 for $\lambda > 0.75$.

2. Wings with supersonic leading edges ($\beta \cot \Lambda_{LE} > 1.0$)

For wings with supersonic leading edges, $C_{L_{\dot{\alpha}}}$ (derived in reference 4) is given by equation 7.1.4.1-c with $(C_{L_{\dot{\alpha}}})_1$ and $(C_{L_{\dot{\alpha}}})_2$ obtained from figures 7.1.4.1-11a through 7.1.4.1-11o.

Figures 7.1.4.1-11a through 7.1.4.1-11o are valid for the range of Mach numbers for which the Mach lines from the leading-edge vertex intersect the trailing edge. An additional limitation is that the foremost Mach line from either wing tip may not intersect the remote half-wing.

Sample Problem

1. Wing with subsonic leading edge

Given:

$A = 5.80 \qquad \lambda = 0 \qquad \Lambda_{LE} = 60^\circ \qquad M = 1.50$

Compute:

$$\beta = \sqrt{M^2 - 1} = 1.12$$

$$\cot \Lambda_{LE} = 0.5774$$

$$\beta \cot \Lambda_{LE} = 0.647$$

$$N = 1 - \frac{4 \cot \Lambda_{LE}}{A} = 0.602$$

$E''(\beta C) = 0.770$
$G(\beta C) = 0.570$
} (figure 7.1.1.1-8)

$F_1(N) = 0.520$
$F_2(N) = 1.090$
$F_3(N) = 0.907$
} (figure 7.1.4.1-7)

Solution:

$$C_{L_{\dot{\alpha}}} = -\frac{\pi A M^2}{2\beta^2}\left[-3G(\beta C)\,F_3(N) + 2E''(\beta C)\,F_2(N) + \frac{1}{M^2}\,E''(\beta C)\,F_1(N)\right]$$

(equation 7.1.4.1-b)

$$= -\frac{\pi(5.80)(2.25)}{2(1.25)}\left[-3(0.570)(0.907) + 2(0.770)(1.090) + \frac{1}{2.25}(0.770)(0.520)\right]$$

$= -5.22\,\pi(-1.551 + 1.679 + 0.178)$

$= -5.02$ per rad (based on $S_W \bar{c}_W$)

2. Wing with supersonic leading edge

Given:

$A = 4.0$ $\quad \lambda = 0.25$ $\quad \Lambda_{LE} = 45°$ $\quad M = 2.0$

Compute:

$\beta = \sqrt{M^2 - 1} = 1.732$

$\beta A = 6.928$

$\cot \Lambda_{LE} = 1.00$

$\beta \cot \Lambda_{LE} = 1.732$

$\cot^{-1} (\beta \cot \Lambda_{LE}) = 30°$

$\beta \left(C_{L_{\dot{\alpha}}}\right)_1 = -0.390$ per rad (figure 7.1.4.1-11d)

$\left(C_{L_{\dot{\alpha}}}\right)_1 = -0.225$ per rad

$\beta \left(C_{L_{\dot{\alpha}}}\right)_2 = 4.200$ per rad (figure 7.1.4.1-11f)

$\left(C_{L_{\dot{\alpha}}}\right)_2 = 2.425$ per rad

Solution:

$$C_{L_{\dot{\alpha}}} = \frac{M^2}{\beta^2} \left(C_{L_{\dot{\alpha}}}\right)_1 - \frac{1}{\beta^2} \left(C_{L_{\dot{\alpha}}}\right)_2 \text{ (equation 7.1.4.1-c)}$$

$$= \frac{4}{3} (-0.225) - \frac{1}{3} (2.425)$$

$= -1.108$ per rad (based on $S_W \bar{c}_W$)

7.1.4.2 WING ACCELERATION DERIVATIVE $C_{m_{\dot{\alpha}}}$

Methods are presented for estimating the wing contribution to the derivative $C_{m_{\dot{\alpha}}}$ for a triangular planform in the subsonic and low transonic speed ranges and for planforms with the leading edge swept back and the trailing edge swept back or swept forward in the supersonic speed range.

If the wing acceleration derivative $C_{m_{\dot{\alpha}}}$ is to be used in method 1 of Section 7.3.4.2 to obtain $(C_{m_{\dot{\alpha}}})_{WB}$, the exposed wing planform area should be used for all calculations in the Datcom methods. Using the exposed planform area will yield $C_{m_{\dot{\alpha}}}$ based on the product of the exposed wing area and the square of the exposed wing MAC, rather than the product of the wing area and the square of the wing MAC as indicated.

DATCOM METHODS

A. SUBSONIC

The subsonic value of $C_{m_{\dot{\alpha}}}$, based on the product of wing area and the square of wing MAC $S_W \bar{c}_W^{\,2}$, referred to body axis and for any center-of-gravity location is given by

$$C_{m_{\dot{\alpha}}} = C_{m_{\dot{\alpha}}}'' + \left(\frac{x_{c.g.}}{\bar{c}}\right) C_{L_{\dot{\alpha}}} \quad \text{(per radian)} \qquad 7.1.4.2\text{-a}$$

where

$C_{m_{\dot{\alpha}}}''$ is referred to body axis with the origin at the wing leading-edge vertex and is obtained as indicated below (per radian).

$\frac{x_{c.g.}}{\bar{c}}$ is the longitudinal distance from the wing leading-edge vertex to the center of gravity, measure l in mean aerodynamic chords, positive aft.

$C_{L_{\dot{\alpha}}}$ is obtained from Section 7.1.4.1, based on the product of wing area and wing MAC (per radian).

A method of estimating the subsonic acceleration derivative $C_{m_{\dot{\alpha}}}''$ of a triangular wing is derived in reference 1 as

$$C_{m_{\dot{\alpha}}}'' = -\frac{81}{32}\left(\frac{x_{a.c.}}{c_r}\right)^2 C_{L_\alpha} + \frac{9}{2} C_{m_0}(g) \quad \text{(per radian)} \qquad 7.1.4.2\text{-b}$$

where

C_{L_α} is the wing lift-curve slope (Section 4.1.3.2) at the Mach number under consideration, based on the total wing area (per radian).

$\frac{x_{a.c.}}{c_r}$ is obtained from Section 4.1.4.2.

$C_{m_0}(g)$ is the pitching-moment-coefficient correction term obtained from figure 7.1.4.2-8 (per radian).

Because of restrictions placed on the pitching-moment-coefficient correction term, equation 7.1.4.2-b is valid only for $0 < \beta A < 4$.

Explicit expressions for estimating $C_{m_{\dot\alpha}}$ of other wing planforms in the subsonic region are not available. An approximation may be made by subtracting the value of C_{m_q} (Section 7.1.1.2) from the appropriate test value of total pitch damping $\left(C_{m_q} + C_{m_{\dot\alpha}}\right)$ taken from table 7-A. Tests indicate that the relative importance of body damping of a conventional configuration in subsonic flow is small; therefore the use of wing-body test data of total pitch damping in this region is acceptable for an approximation, provided the test data are for a conventional design.

Sample Problem

Given: Same wing as in sample problem of paragraph A, Section 7.1.4.1

$A = 4.0$ $\lambda = 0$ $\Lambda_{LE} = 45°$ $C_{L_\alpha} = 4.0$ per rad (Section 4.1.3.2)

$\frac{x_{c.g.}}{\bar{c}} = 0.75$ (from planform geometry with c.g. at $\bar{c}/4$) $M = 0.6$

From sample problem of paragraph A, Section 7.1.4.1

$\frac{x_{a.c.}}{c_r} = 0.570$ $\beta = 0.8$ $\beta A = 3.20$ $C_{L_{\dot\alpha}} = -0.240$ per rad

Compute:

$\frac{\beta^2 C_{m_0}(g)}{\pi A/2} = 0.071$ per rad (figure 7.1.4.2-8)

$C_{m_0}(g) = 0.697$ per rad

Solution:

$$C_{m_{\dot{\alpha}}}'' = -\frac{81}{32}\left(\frac{x_{a.c.}}{c_r}\right)^2 C_{L_\alpha} + \frac{9}{2} C_{m_0}(g) \quad \text{(equation 7.1.4.2-b)}$$

$$= -\frac{81}{32}(0.570)^2(4.0) + \frac{9}{2}(0.697)$$

$$= -0.153 \text{ per rad}$$

$$C_{m_{\dot{\alpha}}} = C_{m_{\dot{\alpha}}}'' + \left(\frac{x_{c.g.}}{\bar{c}}\right) C_{L_{\dot{\alpha}}} \quad \text{(equation 7.1.4.2-a)}$$

$$= -0.153 + (0.75)(-0.240)$$

$$= -0.333 \text{ per rad (based on } S_W \bar{c}_W^2)$$

B. TRANSONIC

The variation of $C_{m_{\dot{\alpha}}}$ of a triangular wing from the critical Mach number to M = 1.0 is given by the method of paragraph A, provided $0 < \beta A < 4$.

There is no generalized theory available in the literature that gives the transonic values of $C_{m_{\dot{\alpha}}}$, either for additional wing-geometry parameters or for Mach numbers greater than 1.0. An approximation may be made by subtracting the value of C_{m_q} (Section 7.1.1.2) from the appropriate test value of total pitch damping $\left(C_{m_q} + C_{m_{\dot{\alpha}}}\right)$ taken from table 7-A. Although the importance of body damping in this region is unknown because of a lack of experimental data, wing-body test data of total pitch damping will probably have to be utilized if an approximation of $C_{m_{\dot{\alpha}}}$ is to be made, simply because of the lack of sufficient wing-alone test data. This method of analysis gives only a rough approximation and is limited to conventional designs where test data are available.

C. SUPERSONIC

The supersonic value of $C_{m_{\dot{\alpha}}}$, based on the product of wing area and the square of wing MAC $S_W \bar{c}_W^2$, referred to body axis and for any center-of-gravity location, is given by equation 7.1.4.2-a, i.e.,

$$C_{m_{\dot{\alpha}}} = C_{m_{\dot{\alpha}}}'' + \left(\frac{x_{c.g.}}{\bar{c}}\right) C_{L_{\dot{\alpha}}} \qquad \text{(per radian)}$$

where the parameters are defined in paragraph A and the supersonic value of $C_{m_{\dot{\alpha}}}''$ is obtained as indicated below.

Methods for estimating $C_{m_{\dot{\alpha}}}''$

1. Wings with subsonic leading edges ($\beta \cot \Lambda_{LE} < 1.0$)

For wings with subsonic leading edges, $C_{m_{\dot{\alpha}}}''$ is obtained by the method of reference 2 for $\lambda = 0$ and by the method of reference 3 for $\lambda = 0.25$ to 1.0. The following methods are not valid if the Mach line from the vertex of the trailing edge intersects the leading edge or if the wing-tip Mach lines intersect on the wings or intersect the opposite wing tips.

a. Zero-taper-ratio wings ($\lambda = 0$)

$C_{m_{\dot{\alpha}}}''$ is derived in reference 2 as

$$C_{m_{\dot{\alpha}}}'' = -\frac{3\pi AM^2}{16\beta^2}\left[G(\beta C)\, F_7(N) + \frac{16}{3}\, E''(\beta C)\, \frac{F_5(N)}{F_{11}(N)}\right]$$

$$+ \frac{16AM^2}{9\beta^2}\left[E''(\beta C)\, F_8(N)\right] + \frac{\pi A}{16\beta^2}\left[E''(\beta C)\, F_6(N)\right] - \left(\frac{d}{\bar{c}}\right) C_{L_{\dot{\alpha}}}$$

(per radian) 7.1.4.2-c

where

$E''(\beta C)$ and $G(\beta C)$ are obtained from figure 7.1.1.1-8.

$F_5(N)$, $F_7(N)$, and $F_{11}(N)$ are obtained from figure 7.1.1.2-8.

$F_6(N)$ and $F_8(N)$ are obtained from figure 7.1.4.2-9.

d is two-thirds the basic triangular wing root chord, $d = \frac{2}{3} c_{r_B}$ (see sketch (a), Section 7.1.1.1).

$C_{L_{\dot{\alpha}}}$ is obtained from paragraph C of Section 7.1.4.1, based on the product of wing area and wing MAC.

b. Wings with $\lambda = 0.25$ to 1.0

$C_{m_{\dot{\alpha}}}''$ is derived in reference 3 as

$$C_{m_{\dot{\alpha}}}'' = \frac{M^2}{\beta^2}\left(C_{m_{\dot{\alpha}}}\right)_1 - \frac{1}{\beta^2}\left(C_{m_{\dot{\alpha}}}\right)_2 \text{ (per radian)} \qquad 7.1.4.2\text{-d}$$

where

$\left(C_{m_{\dot{\alpha}}}\right)_1$ and $\left(C_{m_{\dot{\alpha}}}\right)_2$ are obtained from figures 7.1.4.2-10a through 7.1.4.2-10f for λ = 0.25, 0.50, and 0.75 and from the equations of reference 3 for $\lambda > 0.75$.

2. Wings with supersonic leading edges ($\beta \cot \Lambda_{LE} > 1.0$)

For wings with supersonic leading edges $C_{m_{\dot{\alpha}}}''$ is derived in reference 4 as

$$C_{m_{\dot{\alpha}}}'' = \frac{M^2}{\beta^2}\left(C_{m_{\dot{\alpha}}}\right)_1 + \left(\frac{M^2}{\beta^2} + 1\right)\left(C_{m_{\dot{\alpha}}}\right)_2 \quad \text{(per radian)} \qquad 7.1.4.2\text{-e}$$

where

$\left(C_{m_{\dot{\alpha}}}\right)_1$ and $\left(C_{m_{\dot{\alpha}}}\right)_2$ are obtained from figures 7.1.4.2-13a through 7.1.4.2-13p.

Figures 7.1.4.2-13a through 7.1.4.2-13p are valid for the range of Mach numbers for which the Mach lines from the leading-edge vertex intersect the trailing edge. An additional limitation is that the foremost Mach line from either wing tip may not intersect the remote half-wing.

Sample Problems

1. Wing with subsonic leading edge

Given: Same wing as in sample problem 1 of paragraph C, Section 7.1.4.1.

$A = 5.80 \quad \lambda = 0 \quad \Lambda_{LE} = 60° \quad$ c.g. at $\frac{\bar{c}}{4} \quad b = 16$ ft $\quad M = 1.50$

$\frac{x_{c.g.}}{\bar{c}} = 1.50$ (from planform geometry with c.g. at $\bar{c}/4$)

From sample problem 1 of paragraph C, Section 7.1.4.1:

$\beta = 1.12 \qquad \beta \cot \Lambda_{LE} = 0.647 \qquad N = 0.602$

$E''(\beta C) = 0.770 \qquad G(\beta C) = 0.570 \qquad C_{L_{\dot{\alpha}}} = -5.02$ per rad

Compute:

$$\left.\begin{aligned} F_5(N) &= 0.251 \\ F_7(N) &= -1.620 \\ F_{11}(N) &= 0.395 \end{aligned}\right\} \text{(figure 7.1.1.2-8)}$$

$$\left.\begin{aligned} F_6(N) &= -2.600 \\ F_8(N) &= 0.880 \end{aligned}\right\} \text{(figure 7.1.4.2-9)}$$

Obtain d from the characteristics of the basic triangular wing (see sketch (a), Section 7.1.1.1).

$$A_B = \frac{4}{\tan \Lambda_{LE}} = 2.31$$

$$c_{r_B} = \frac{2b}{A_B} = 13.85 \text{ ft}$$

$$d = \frac{2}{3} c_{r_B} = 9.233 \text{ ft}$$

$$c_r = \frac{2b}{A} = 5.517 \text{ ft}$$

$$\bar{c} = 3.678 \text{ ft}$$

Solution:

$$C_{m_{\dot{\alpha}}}'' = -\frac{3\pi AM^2}{16\beta^2}\left[G(\beta C)\, F_7(N) + \frac{16}{3} E''(\beta C) \frac{F_5(N)}{F_{11}(N)}\right]$$

$$+ \frac{16AM^2}{9\beta^2}\left[E''(\beta C)\, F_8(N)\right] + \frac{\pi A}{16\beta^2}\left[E''(\beta C)\, F_6(N)\right] - \left(\frac{d}{\bar{c}}\right) C_{L_{\dot{\alpha}}}$$

(equation 7.1.4.2-c)

$$= -\frac{3\pi(5.80)\,(2.25)}{16(1.25)}\left[(0.570)\,(-1.620) + \frac{16}{3}\,(0.770)\,\frac{(0.251)}{(0.395)}\right]$$

$$+ \frac{16(5.80)\,(2.25)}{9(1.25)}\left[(0.770)\,(0.880)\right] + \frac{\pi(5.80)}{16(1.25)}\left[(0.770)\,(-2.600)\right]$$

$$- \frac{(9.233)}{(3.678)}\,(-5.02)$$

$$= -6.15(-0.9234 + 2.610) + 12.576 - 1.824 + 12.602$$

$$= 12.98 \text{ per rad}$$

$$C_{m_{\dot{\alpha}}} = C_{m_{\dot{\alpha}}}'' + \frac{x_{c.g.}}{\bar{c}} C_{L_{\dot{\alpha}}} \quad \text{(equation 7.1.4.2-a)}$$

$$= 12.98 + (1.5)(-5.02)$$

$$= 5.45 \text{ per rad (based on } S_W \bar{c}_W{}^2)$$

2. Wing with supersonic leading edge

Given: Same wing as in sample problem 2 of paragraph C, Section 7.1.4.1.

$$A = 4.0 \qquad \lambda = 0.25 \qquad \Lambda_{LE} = 45° \qquad \text{c.g. at } \frac{\bar{c}}{4} \qquad M = 2.0$$

$$\frac{x_{c.g.}}{\bar{c}} = 0.964 \text{ (from planform geometry with c.g. at } \bar{c}/4)$$

From sample problem 2 of paragraph C, Section 7.1.4.1:

$$\beta = 1.732 \qquad \beta A = 6.928 \qquad \beta \cot \Lambda_{LE} = 1.732$$

$$\cot^{-1}(\beta \cot \Lambda_{LE}) = 30° \qquad C_{L_{\dot{\alpha}}} = -1.108 \text{ per rad}$$

Compute:

$$\beta \left(C_{m_{\dot{\alpha}}}\right)_1 = 11.80 \text{ per rad} \quad \text{(figure 7.1.4.2-13d)}$$

$$\left(C_{m_{\dot{\alpha}}}\right)_1 = 6.813 \text{ per rad}$$

$$\beta \left(C_{m_{\dot{\alpha}}}\right)_2 = -5.530 \text{ per rad} \quad \text{(figure 7.1.4.2-13f)}$$

$$\left(C_{m_{\dot{\alpha}}}\right)_2 = -3.193 \text{ per rad}$$

Solution:

$$C_{m_{\dot{\alpha}}}'' = \frac{M^2}{\beta^2} \left(C_{m_{\dot{\alpha}}}\right)_1 + \left(\frac{M^2}{\beta^2} + 1\right) \left(C_{m_{\dot{\alpha}}}\right)_2 \quad \text{(equation 7.1.4.2-e)}$$

$$= \frac{4}{3}(6.813) + \left(\frac{4}{3} + 1\right)(-3.193)$$

$$= 9.08 - 7.45$$

$$= 1.63 \text{ per rad}$$

$$C_{m_{\dot{\alpha}}} = C_{m_{\dot{\alpha}}}'' + \frac{x_{c.g.}}{\bar{c}} C_{L_{\dot{\alpha}}} \quad \text{(equation 7.1.4.2-a)}$$

$$= 1.63 + (0.964)(-1.108)$$

$$= 0.562 \text{ per rad (based on } S_W \bar{c}_W{}^2)$$

7.1.4.3 WING DERIVATIVE $C_{D_{\dot{\alpha}}}$

This section presents a method for estimating the wing contribution to the derivative $C_{D_{\dot{\alpha}}}$ at subsonic speeds. This derivative is the change in drag coefficient due to a change in $\dot{\alpha}$ at a constant pitch rate and is defined as

$$C_{D_{\dot{\alpha}}} = \frac{\partial C_D}{\partial\left(\frac{\dot{\alpha}\bar{c}}{2V}\right)}, \text{ where } C_D \text{ is based on } S_W.$$

In general, this derivative is small and has a negligible effect on longitudinal stability; hence, it is usually neglected.

A. SUBSONIC

DATCOM METHOD

From the two-dimensional unsteady-flow theory of Garrick (Reference 1), the perturbation section drag coefficient of an oscillating surface can be approximated by

$$c_d = \frac{\pi}{2} c \frac{1}{V} [1 + 2C(k)]\, \alpha\dot{\alpha} \qquad 7.1.4.3\text{-a}$$

where

c_d is the drag coefficient per unit span.

c is the wing chord.

V is the free-stream velocity

$C(k)$ is Theodorsen's function, defined as

$$C(k) = F(k) + iG(k) \qquad 7.1.4.3\text{-b}$$

where

$F(k)$, $G(k)$ are Theodorsen's functions obtained from Table 7.1.4.3-A as a function of the reduced frequency k, where k is defined as

$$k = \frac{\omega c}{2V} \qquad 7.1.4.3\text{-c}$$

where c and V are as defined above, and ω is the angular velocity (rad/sec)

Only one part of the complex equation is needed. It is arbitrary whether to use the real or imaginary part. If the wing oscillation can be defined as

$$\alpha = \alpha_1 e^{i\omega t} = \alpha_1 \cos \omega t + i\alpha_1 \sin \omega t \qquad 7.1.4.3\text{-d}$$

where

α is the complex form of the angle of attack of oscillation

α_1 is the amplitude of the oscillation (radians)

t is the time

then by substitution and expansion the imaginary part of Equation 7.1.4.3-a can be shown to be equal to the following:

$$c_d = \frac{\pi}{2} \frac{c}{V} \alpha_1^2 \omega \left\{(1 + 2F)(\cos^2 \omega t - \sin^2 \omega t) - 4G \sin \omega t \cos \omega t\right\}^* \qquad 7.1.4.3\text{-e}$$

where all the terms are defined above and where the oscillation is given by $\alpha = \alpha_1 \sin \omega t$.

The three-dimensional drag may be obtained by

$$C_D = 2 \int_0^{b/2} \frac{c_d c}{S_W} dy \qquad 7.1.4.3\text{-f}$$

where

c_d is the two-dimensional drag from Equation 7.1.4.3-e.

c is the local wing chord.

S_W is the wing reference area.

If the derivative $C_{D_{\dot{\alpha}}}$ is desired, variations in C_D may be calculated for different values of $\dot{\alpha}$. For α as defined by Equation 7.1.4.3-d, the imaginary part of $\dot{\alpha}$ (to be used in conjunction with Equation 7.1.4.3-e) may be expressed as

$$\dot{\alpha} = \alpha_1 \omega \cos \omega t \qquad 7.1.4.3\text{-g}$$

where the terms are defined above.

*The expression in brackets could also be written as $[(1 + 2F) \cos 2\omega t - 2G \sin 2\omega t]$, which would indicate that c_d varies at twice the angular velocity.

Then $C_{D_{\dot{\alpha}}}$ may be approximated by

$$C_{D_{\dot{\alpha}}} = \frac{\partial C_D}{\partial\left(\frac{\dot{\alpha}\bar{c}}{2V}\right)} = \frac{(C_D)_{t_2} - (C_D)_{t_1}}{[(\dot{\alpha})_{t_2} - (\dot{\alpha})_{t_1}]\frac{\bar{c}}{2V}} \qquad 7.1.4.3\text{-h}$$

where

C_D is the three-dimensional drag coefficient obtained by application of Equation 7.1.4.3-f

$\dot{\alpha}$ is the rate of change of angle of attack obtained by application of Equation 7.1.4.3-g

and the subscript t_n refers to a specified time such that $t_2 - t_1$ is the time interval over which C_D and $\dot{\alpha}$ are evaluated.

Sample Problem

Given: The following wing-body combination

Wing Characteristics:

$A = 4$ $\quad \Lambda = 0$ $\quad \lambda = 1.0$ $\quad S_W = 64.0\ ft^2$ $\quad c = 4.0\ ft$

Additional Characteristics:

$V = 200$ ft/sec $\qquad \omega = 2\pi$ rad/sec

$\alpha = \alpha_1 (\cos \omega t + i \sin \omega t) \qquad \alpha_1 = 1^o$

Compute c_d at $t = 1$ sec:

Find the reduced frequency k

$$k = \frac{\omega c}{2V} \qquad \text{(Equation 7.1.4.3-c)}$$

$$= \frac{(2\pi)(4.0)}{2(200)}$$

$$= 0.0628 \text{ rad}$$

$F = 0.8875$
$G = -0.1451$ } Table 7.1.4.3-A (linear interpolation)

$$c_d = \frac{\pi}{2}\frac{c}{V}\alpha_1^2\,\omega\left\{(1 + 2F)(\cos^2\omega t - \sin^2\omega t) - 4G \sin \omega t \cos \omega t\right\} \qquad \text{(Equation 7.1.4.3-e)}$$

$$= \frac{\pi}{2}\left(\frac{4.0}{200}\right)\left(\frac{1}{57.3}\right)^2 2\pi\left\{[1 + 2(0.8876)](1.0 - 0) - 4(-0.1451)(0)(1)\right\}$$

$$= \frac{\pi}{2}\left(\frac{4.0}{200}\right)\left(\frac{1}{57.3}\right)^2 2\pi\left\{[1 + 2(0.8876)]\ 1.0\right\}$$

$$= 0.000167$$

$\dot{\alpha} = \alpha_1 \omega \cos \omega t$ (Equation 7.1.4.3-g)

$$= \frac{1}{57.3}\ (2\pi)(1)$$

$$= 0.110$$

$C_D = 2\int_0^{b/2} \frac{c_d c}{S_W}\, dy$ (Equation 7.1.4.3-f)

$= 2\frac{c_d c}{S_W}\frac{b}{2} = 2\frac{c_d c}{bc}\frac{b}{2} = c_d$ (Rect wing $S_W = bc$)

$C_D = 0.000167$

Compute c_d for t = 1.1 sec:

$c_d = \frac{\pi}{2}\frac{c}{V}\alpha_1^2\ \omega\left\{(1 + 2F)(\cos^2 \omega t - \sin^2 \omega t) - 4G \sin \omega t \cos \omega t\right\}$ (Equation 7.1.4.3-e)

$$= \frac{\pi}{2}\left(\frac{4.0}{200}\right)\left(\frac{1}{57.3}\right)^2 2\pi\left\{[1 + 2(0.8876)]\,[(0.8090)^2 - (0.5878)^2]\right.$$
$$\left. - 4(-0.1451)(0.8090)(0.5878)\right\}$$

$$= 0.0000681$$

$\dot{\alpha} = \alpha_1 \omega \cos \omega t$ (Equation 7.1.4.3-g)

$$= \frac{1}{57.3}\ 2\pi(0.809)$$

$$= 0.0887$$

$$C_D = 2 \int_0^{b/2} \frac{c_d c}{S_W} \, dy \qquad \text{(Equation 7.1.4.3-f)}$$

$$= 2 \frac{c_d c}{S_W} \frac{b}{2} = .2 \frac{c_d c}{bc} \frac{b}{2} = c_d \qquad \text{(Rect Wing } S_W = bc\text{)}$$

$$C_D = 0.0000681$$

Solution:

$$C_{D_{\dot{\alpha}}} = \frac{\partial C_D}{\partial \left(\frac{\dot{\alpha} \bar{c}}{2V} \right)} = \frac{(C_D)_{t_2} - (C_D)_{t_1}}{[(\dot{\alpha})_{t_2} - (\dot{\alpha})_{t_1}] \frac{\bar{c}}{2V}} \qquad \text{(Equation 7.1.4.3-h)}$$

$$= \frac{(0.0000681 - 0.000167)}{(0.0887 - 0.110) \frac{4.0}{2(200)}}$$

$$= 0.464 \text{ per rad}$$

$$= 0.0081 \text{ per deg}$$

B. TRANSONIC

No method is presented.

C. SUPERSONIC

No method is presented.

7.2 BODY DYNAMIC DERIVATIVES

The methods presented in this section are for estimating pitching and acceleration dynamic derivatives of isolated bodies. The methods and charts of the subsonic, transonic, and supersonic speed ranges are based on a combination of slender-body theory and the theories used in predicting the body-lift-curve slope and pitching-moment-curve slope in Sections 4.2.1.1 and 4.2.2.1, respectively. Newtonian impact theory is used in the hypersonic speed range. The methods are restricted to angles of attack near zero and should yield values suitable for first approximations to dynamic stability.

No test data are available on body dynamic derivatives. Therefore, all theoretical methods must be considered tentative until compared with experimental results. A brief discussion of available theoretical methods is presented.

The starting point of almost all theories is the well-known linearized potential equation. Various methods based on linear theory have been developed for obtaining the flow field about bodies in supersonic flow. The problem of determining the dynamic stability derivatives for bodies has been treated principally within the assumptions of slender-body theory. The application of Munk's slender-body theory to the calculation of the aerodynamic coefficients describing steady motion has been made by a number of authors (see references 1 through 4). In reference 5, slender-body values of the aerodynamic coefficients associated with nonsteady angle of attack have been obtained as a by-product of a linear analysis of the potential equation for nonsteady supersonic flow. However, approximations made in the analysis effectively limit its application to bodies of vanishingly small thickness. The problem of determining the dynamic derivatives for a smooth slender body of arbitrary cross section performing slow maneuvers is treated within the assumptions of slender-body theory by Sacks in reference 6. This approach is novel in slender-body theory in that the squared terms in the pressure relation for slender configurations are retained and all motions of the configuration are treated simultaneously. However, the derivatives are obtained in terms of the mapping functions of the cross sections and are too complex for inclusion in the Datcom.

A method is developed for estimating aerodynamic loads on slender, symmetrical configurations performing small lateral oscillations of limited reduced frequency in sonic and supersonic flow in references 7 and 8, respectively. This method is an extension of an iterative technique originally proposed by Adams and Sears in reference 9, and is a combination of first-order and second-order cross-flow solutions. The results consist of slender-body-theory terms plus higher-order effects of fineness ratio. For sonic flow about a body of revolution, reference 7 shows that by retaining only the first-order terms in reduced frequency the pitching derivatives are given by simple slender-body theory; whereas the acceleration derivatives are influenced by the second-order terms and contain logarithms of the reduced frequency. Under certain limitations on the rapidity of the oscillations, all derivatives in supersonic flow prove to be independent of changes in reduced frequency; consequently the method can be applied to slow time-dependent motions. At present this method is limited to slender bodies of revolution, and in most cases requires a considerable amount of mathematical manipulation to obtain a solution. This method can be applied to bodies of more general cross section; however, the practicality of such an analysis would depend on the possibility of solving the integrals that appear.

In reference 10 an attempt has been made to overcome the slender-body limitation by adapting hybrid theory to the calculation of the body dynamic derivatives. (This method, derived by Van Dyke in reference 11, has proved successful in calculations for the static aerodynamic derivatives.) This method is used to predict the dynamic derivatives of a cone, and the results are consistent with those obtained by impact theory at the higher Mach numbers. In order to extend this method to bodies of more general shape, it is necessary to satisfy the boundary conditions corresponding to the specified body. Unfortunately, the analytical expressions required to do so have been found only for the cone.

The application of simple slender-body theory appears to be the only method of solution warranted at the present time, in view of the large effects of viscosity on the forces acting over slender bodies, the mathematical complexity involved in solution of the linearized equations for general planforms, and the lack of test data.

Since extensive use is made of slender-body-theory results throughout this section, the term "slender" is clarified.* Tsien, in reference 2, pointed out that slender-body theory applies to the flow about inclined, pointed projectiles at supersonic speeds. Subsequently, Jones, in reference 12, indicated that his slender-wing theory (slender-body theory extended to wings) applies to both subsonic and supersonic speeds, at least for pointed planforms. Actually, the meaning of the term "slender" is somewhat different in the various speed regimes. For supersonic Mach numbers "slender" implies that the body lies well within the Mach cone from the body apex. This leads directly to the limitation to pointed bodies. It also leads to the conclusion that relatively blunt bodies may qualify as "slender" at low supersonic speeds; while for hypersonic speeds the method must fail for practical shapes. At subsonic speeds the term "slender" becomes less restrictive as the Mach number increases from 0 to 1, until at sonic speed all bodies become slender. Thus, slender-body theory is seen to apply to at least some body shapes throughout the speed range from low subsonic to hypersonic.

7.2.1 BODY PITCHING DERIVATIVES

7.2.1.1 BODY PITCHING DERIVATIVE C_{L_q}

The pitching derivative C_{L_q} is a measure of the lift produced by rotational motion of the airframe about a spanwise axis. This derivative is generally small compared to other terms in the equations of motion and is frequently neglected. However, methods are presented for determining the body contribution to C_{L_q} in the subsonic, transonic, supersonic, and hypersonic speed ranges. The value of C_{N_q} in the hypersonic speed range is used to obtain the value of C_{m_q} in the hypersonic speed range in Section 7.2.1.2.

In the subsonic, transonic, and supersonic speed ranges the Datcom methods are based on the relatively simple results derived from slender-body theory and the assumption that a relationship of corresponding slender-body derivatives may be employed with reasonable accuracy to the case of steady pitching in a manner similar to that of reference 1. This approach to the calculation of body dynamic derivatives has been applied with reasonable success by Walker and Wolowicz in reference 2. It was shown in reference 1 that, although slender-body theory alone does not accurately predict the characteristics of nonslender configurations, the ratio of corresponding slender-body derivatives may be employed with reasonable accuracy in predicting the static forces on nonslender configurations. The body contribution to C_{L_q} is thus given as the product of the lift-curve slope C_{L_α} and the ratio of slender-body derivatives, i.e.,

$$C_{L_q} = C_{L_\alpha}\left(\frac{C_{L_q}}{C_{L_\alpha}}\right)_{\text{slender-body theory}}$$

Slender-body theory states that body force characteristics are independent of Mach number. The effect of Mach number is taken into account by the static force coefficient. Therefore, the limitations of these methods are determined by the limitations of the methods employed in determining the static derivative C_{L_α} in the various speed regimes. Experimental data should be used for the body lift-curve slope when available.

A. SUBSONIC

There is no explicit method available in the literature for obtaining the body dynamic derivatives for general planforms.

The method presented is based on the application of the results of slender-body theory in the manner previously discussed.

DATCOM METHOD

The body contribution to C_{L_q}, based on body base area and body length and referred to the center of rotation, is given by

$$C_{L_q} = 2\,C_{L_\alpha}\left(1 - \frac{x_m}{\ell_B}\right) \quad \text{(per radian)} \qquad 7.2.1.1\text{-a}$$

where

C_{L_α} is the body lift-curve slope from paragraph A of Section 4.2.1.1 multiplied by $\left(V_B^{2/3}/S_b\right)$ (per radian).

x_m is the longitudinal distance from the body vertex to the center of rotation, positive aft.

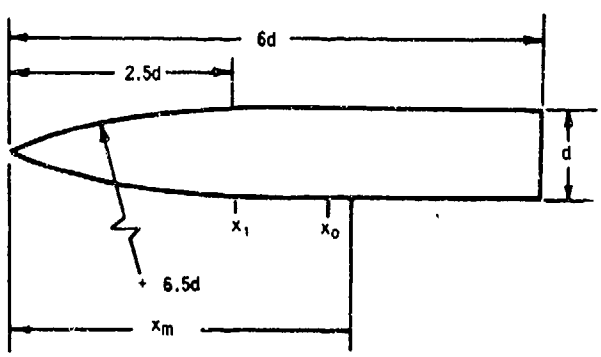
ℓ_B is the length of the body.

V_B is the total body volume from Section 2.3.

S_b is the body base area.

Sample Problem

Given:



d = 1.0 ft $\quad \ell_B$ = 6.0 ft $\quad$ Fineness Ratio = 6.0 $\quad x_m$ = 3.8 ft

C_{L_α} = 0.548 per rad (based on $V_B^{2/3}$) (Section 4.2.1.1)

$V_B^{2/3}$ = 2.47 sq ft (Section 2.3) $\quad S_b$ = 0.785 sq ft

Compute:

$$C_{L_\alpha} = (0.548)\frac{(V_B)^{2/3}}{S_b} = (0.548)\left(\frac{2.47}{0.785}\right) = 1.724 \text{ per rad (based on } S_b)$$

$$\left(1 - \frac{x_m}{\ell_B}\right) = \left(1 - \frac{3.8}{6}\right) = 0.367$$

Solution:

$$C_{L_q} = 2\, C_{L_\alpha} \left(1 - \frac{x_m}{\ell_B}\right) \quad \text{(equation 7.2.1.1-a)}$$

$$= 2(1.724)\,(0.367)$$

$$= 1.265 \text{ per rad (based on } S_b \ell_B)$$

B. TRANSONIC

The linearization of the transonic flow problem has been accomplished by Landahl, in reference 3, by introducing a small amount of unsteadiness into the motion. This theoretical method is briefly discussed in Section 7.2. By neglecting the second-order effects of reduced frequency the pitching derivatives of a slender body of revolution are those given by slender-body theory. Since slender-body theory does not predict a dependence on configuration parameters, this method cannot be expected to give reasonable approximations for the pitching derivatives of nonslender configurations. Therefore, the method of paragraph A is applied throughout the transonic speed range.

C. SUPERSONIC

Several of the theoretical methods that have been developed for estimating the body pitching derivative C_{N_q} in the supersonic speed range are briefly discussed in Section 7.2. The available theoretical methods are limited to simple slender-body theory, theories treated within the assumptions of slender-body theory, and hybrid theory. The method presented here is based on simple slender-body theory. Theories treated within the assumption of slender-body theory are mathematically complex and restricted to specific body shapes; therefore, no general quantitative results are presented.

The supersonic C_{N_q} for cones can be estimated by the hybrid theory solutions presented in reference 4.

DATCOM METHOD

The method presented here for determining the body contribution to C_{N_q}, based on the cone-cylinder or ogive-cylinder maximum frontal area and body length and referred to the center of rotation, is the same as that of paragraph A and is given by equation 7.2.1.1-a, i.e.,

$$C_{N_q} = 2\, C_{N_\alpha} \left(1 - \frac{x_m}{\ell_B}\right) \quad \text{(per radian)}$$

where C_{N_α} is the body normal-force-curve slope from paragraph C of Section 4.2.1.1, evaluated at the appropriate Mach number and based on the cone-cylinder or ogive-cylinder maximum frontal area (per radian).

D. HYPERSONIC

Simple Newtonian theory is used in this section to estimate the contribution of cone frustum bodies, with or without spherical noses, to the derivative C_{N_q}. Newtonian theory is discussed in paragraph D, Section 4.2.1.1.

DATCOM METHOD

Charts taken from reference 5, based on simple Newtonian theory, are presented for determining C_{N_q} of spherical segments and cone frustums at small angles of attack.

The coefficients of these charts are referred to the body base area and base diameter and to a moment center at the forward face of the segment. By proper use of the data presented, the total C_{N_q} may be determined for bodies composed of multiple cone frustums with or without spherically blunted noses.

The Newtonian value of the derivative C_{N_q} for a complex body is obtained as follows:

Step 1. Compute $C_{N_q}{}'$ for each body segment about its front face using figures 7.2.1.1-9a and 7.2.1.1-9b.

Step 2. Transfer the individual derivatives $C_{N_q}{}'$ to a common reference axis by applying the following transfer equation to each body segment

$$C_{N_q} = C_{N_q} - 2\left(\frac{n}{d}\right)C_{N_\alpha} \qquad 7.2.1.1\text{-b}$$

where

C_{N_α} is the normal-force-curve slope for each segment based on individual base areas from paragraph D, Section 4.2.1.1.

C_{N_q} is the pitching derivative for each segment based on individual base areas and base diameters and referred to a moment center at the forward face of the segment, from figures 7.2.1.1-9a and 7.2.1.1-9b.

n is the distance from the face of a given frustum to the desired moment reference axis of the configuration, positive aft.

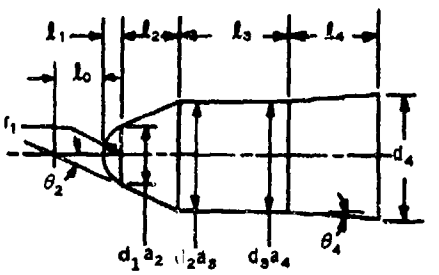
d is the base diameter of a given frustum.

Step 3. The transferred derivatives of the individual body segments are converted to a common reference area and diameter and added. The total derivative is given by

$$C_{N_q} = \sum_{n=1}^{m} (C_{N_q})_n \left(\frac{d_n}{d_b}\right)^3 \qquad 7.2.1.1\text{-c}$$

Sample Problem

Given: Same multiple-segment body as sample problem of paragraph D of Sections 4.2.1.1 and 4.2.2.1.



ℓ_0 = 0.55 ft (distance from moment reference center to body nose)

Spherical segment

ℓ_1 = 0.18 ft

r_1 = 0.36 ft

d_1 = 0.62 ft

Forward cone frustum

a_2 = 0.62 ft

d_2 = 1.20 ft

ℓ_2 = 0.72 ft

θ_2 = 22.5°

Cylinder

a_3 = 1.20 ft

d_3 = 1.20 ft

ℓ_3 = 1.20 ft

θ_3 = 0

Rear cone frustum

a_4 = 1.20 ft

d_4 = 1.368 ft

ℓ_4 = 0.96 ft

θ_4 = 5°

Compute:

Spherical segment

$2\ell_1/d_s = \ell_1/r_1 = 0.50$

$C_{N_{q_1}}' = 0.865$ per rad (figure 7.2.1.1-9b)

$n_1 = -\ell_0 = -0.55$ ft

$d_1 = a_2 = 0.62$ ft

$C_{N_{\alpha_1}} = 0.75$ per rad (figure 4.2.1.1-23)

$$C_{N_{q_1}} = C_{N_{q_1}}' - 2\left(\frac{n_1}{d_1}\right)C_{N_{\alpha_1}} \quad \text{(equation 7.2.1.1-b)}$$

$$= 0.865 - 2\left(\frac{-0.55}{0.62}\right)0.75$$

$$= 2.195 \text{ per rad } \left(\text{based on } \frac{\pi d_1^{\,3}}{4}\right)$$

Forward cone frustum

$a_2/d_2 = \lambda_2 = 0.517$

$C_{N_{q_2}}' = 1.22$ per rad (figure 7.2.1.1-9a)

$n_2 = -(\ell_0 + \ell_1) = -0.73$

$C_{N_{\alpha_2}} = 1.250$ per rad (figure 4.2.1.1-26)

$$C_{N_{q_2}} = C_{N_{q_2}}' - 2\left(\frac{n_2}{d_2}\right)C_{N_{\alpha_2}} \quad \text{(equation 7.2.1.1-b)}$$

$$= 1.22 - 2\left(\frac{-0.73}{1.20}\right)1.250$$

$$= 2.74 \text{ per rad} \left(\text{based on } \frac{\pi d_2{}^3}{4}\right)$$

Cylinder

$$a_3/d_3 = \lambda_3 = 1.0$$

$$C_{N_{q_3}}{}' = 0 \text{ (figure 7.2.1.1-9a)}$$

$$n_3 = -(\ell_0 + \ell_1 + \ell_2) = -1.45$$

$$C_{N_{\alpha_3}} = 0 \text{ (figure 4.2.1.1-26)}$$

$$C_{N_{q_3}} = C_{N_{q_3}}{}' - 2\left(\frac{n_3}{d_2}\right)C_{N_{\alpha_3}} \quad \text{(equation 7.2.1.1-b)}$$

$$= 0$$

Rear cone frustum

$$a_4/d_4 = \lambda_4 = 0.877$$

$$C_{N_{q_4}}{}' = 0.36 \text{ per rad} \quad \text{(figure 7.2.1.1-9a)}$$

$$n_4 = -(\ell_0 + \ell_1 + \ell_2 + \ell_3) = -2.65$$

$$C_{N_{\alpha_4}} = 0.450 \text{ per rad} \quad \text{(figure 4.2.1.1-26)}$$

$$C_{N_{q_4}} = C_{N_{q_4}}{}' - 2\left(\frac{n_4}{d_4}\right)C_{N_{\alpha_4}} \quad \text{(equation 7.2.1.1-b)}$$

$$= 0.36 - 2\left(\frac{-2.65}{1.368}\right)0.45$$

$$= 2.10 \text{ per rad} \left(\text{based on } \frac{\pi d_4{}^3}{4}\right)$$

Solution:

Converting the derivative for each segment to a common reference area and diameter, the base area and diameter of the rear cone frustum, and adding

$$C_{N_q} = \sum_{n=1}^{m} \left(C_{N_q}\right)_n \left(\frac{d_n}{d_b}\right)^3 \qquad \text{(equation 7.2.1.1-c)}$$

$$C_{N_q} = C_{N_{q_1}} \left(\frac{d_1}{d_4}\right)^3 + C_{N_{q_2}} \left(\frac{d_2}{d_4}\right)^3 + C_{N_{q_3}} \left(\frac{d_3}{d_4}\right)^3 + C_{N_{q_4}}$$

$$= 2.195 \left(\frac{0.62}{1.368}\right)^3 + 2.74 \left(\frac{1.20}{1.368}\right)^3 + 0 + (2.10)$$

$$= 0.2043 + 1.8494 + 2.10$$

$$= 4.154 \text{ per rad} \quad \left(\text{based on } \frac{\pi d_4{}^3}{4}\right)$$

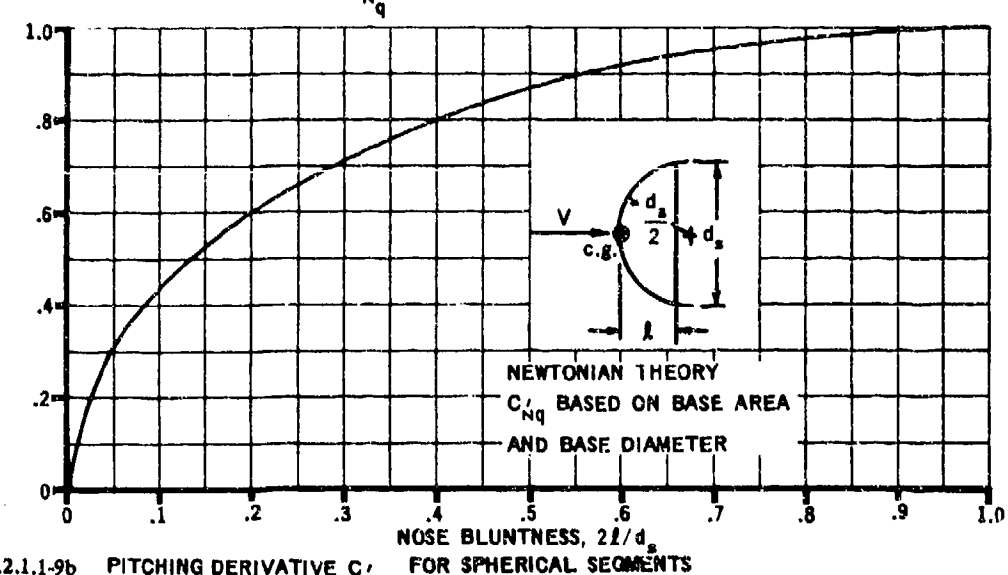

FIGURE 7.2.1.1-9b PITCHING DERIVATIVE C'_{N_q} FOR SPHERICAL SEGMENTS

7.2.1.2 BODY PITCHING DERIVATIVE C_{m_q}

The derivative C_{m_q} is a measure of the pitching moment produced by rotational motion of the airframe about a spanwise axis and is commonly referred to as the pitch-damping derivative. Methods are presented for determining the body contribution to this derivative in the subsonic, transonic, supersonic, and hypersonic speed ranges.

In the subsonic, transonic, and supersonic speed ranges the Datcom methods are based on the same assumption that was made in regard to the body contribution to the derivative C_{L_q}, and the general discussion of Section 7.2.1.1 is directly applicable here.

The body contribution to C_{m_q} is expressed as

$$C_{m_q} = C_{m_\alpha}\left(\frac{C_{m_q}}{C_{m_\alpha}}\right)_{\text{slender-body theory}}$$

The limitations of these methods are determined by the limitations of the methods employed in determining the static derivative C_{m_α} in the various speed regimes. Experimental data should be used for the body pitching-moment-curve slope when available.

A. SUBSONIC

The comments of paragraph A of Section 7.2.1.1 are directly applicable here.

DATCOM METHOD

The body contribution to C_{m_q}, based on body base area and the square of body length and referred to the center of rotation, is given by

$$C_{m_q} = 2\,C_{m_\alpha}\left[\frac{\left(1-\frac{x_m}{\ell_B}\right)^2 - \frac{V_B}{S_b \ell_B}\left(\frac{x_c}{\ell_B}-\frac{x_m}{\ell_B}\right)}{\left(1-\frac{x_m}{\ell_B}\right)-\frac{V_B}{S_b \ell_B}}\right] \qquad 7.2.1.2\text{-a}$$

where

C_{m_α} is the body pitching-moment-curve slope from paragraph A of Section 4.2.2.1, multiplied by $V_B/(S_b \ell_B)$.

V_B is the total body volume from Section 2.3.

S_b is the body base area.

x_c is the longitudinal distance from the vertex to the centroid of the volume and is given by

$$x_c = \frac{\int_0^{\ell_B} S(x)\, x\, dx}{V_B} \qquad 7.2.1.2\text{-b}$$

where

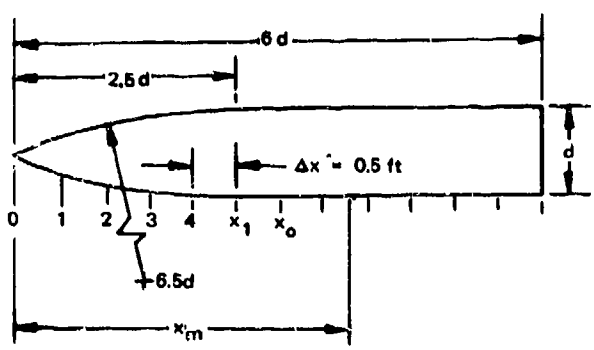
$S(x)$ is the body cross-sectional area at any station. It is not feasible to present generalized design charts of x_c, but the equation can be integrated for any arbitrary body of revolution.

ℓ_B is the length of the body.

x_m is the longitudinal distance from the body vertex to the center of rotation, positive aft.

Sample Problem

Given: Same ogive-cylinder configuration as sample problem of paragraph A of Section 7.2.1.1.



$d = 1.0$ ft $\quad \ell_B = 6.0$ ft $\quad$ Fineness Ratio $= 6.0$ $\quad x_m = 3.8$ ft

$x_1 = 2.5$ ft
$x_o = 3.6$ ft
$(k_2 - k_1) = 0.863$
} (Section 4.2.1.1)

$S_b = 0.785$ sq ft $\quad V_B = 3.88$ cu ft

Compute:

12	1.00	0.785	5.75	2.2570

$$\sum_{x=0}^{\ell_B} S(x)x\,\Delta x = 13.775$$

$$x_c = \frac{\int_0^{\ell_B} S(x)\,x\,dx}{V_B} \quad \text{(equation 7.2.1.2-b)}$$

$$= \frac{13.775}{3.88} = 3.55 \text{ ft}$$

$$\frac{V_B}{S_b \ell_B} = \frac{(3.88)}{(0.785)\,(6.0)} = 0.824$$

$$\left(1 - \frac{x_m}{\ell_B}\right) = 1 - \frac{3.8}{6.0} = 0.367$$

Solution:

$$C_{m_q} = 2\,C_{m_\alpha} \left[\frac{\left(1 - \frac{x_m}{\ell_B}\right)^2 - \frac{V_B}{S_b \ell_B}\left(\frac{x_c}{\ell_B} - \frac{x_m}{\ell_B}\right)}{\left(1 - \frac{x_m}{\ell_B}\right) - \frac{V_B}{S_b \ell_B}} \right] \quad \text{(equation 7.2.1.2-a)}$$

*x is taken to be at the center of volume of each body segment.

$$= (2)(0.781)\left[\frac{(0.367)^2 - (0.824)\left(\frac{3.55}{6.0} - \frac{3.8}{6.0}\right)}{0.367 - 0.824}\right]$$

$$= 1.562\left[\frac{0.135 - (0.824)(-0.0417)}{-0.457}\right]$$

$$= 1.562\left[\frac{0.1693}{-0.457}\right]$$

$$= -0.579 \text{ per rad (based on } S_b \ell_B{}^2)$$

B. TRANSONIC

The comments of paragraph B of Section 7.2.1.1 are directly applicable here. The method of paragraph A is applicable throughout the transonic speed range.

C. SUPERSONIC

The theoretical methods applicable for the estimation of the body contribution to the derivative C_{m_q} parallel those of the body contribution to the derivative C_{L_q}.

Therefore, the general comments of paragraph C of Section 7.2.1.1 are also applicable here.

The supersonic C_{m_q} for cones can be estimated from the hybrid theory solutions presented in reference 1.

DATCOM METHOD

The method presented here for the body contribution to C_{m_q}, based on body base area and the square of body length and referred to the center of rotation, is the same as that of paragraph A and is given by equation 7.2.1.2-a, i.e.,

$$C_{m_q} = 2\,C_{m_\alpha}\left[\frac{\left(1 - \frac{x_m}{\ell_B}\right)^2 - \frac{V_B}{S_b \ell_B}\left(\frac{x_c}{\ell_B} - \frac{x_m}{\ell_B}\right)}{\left(1 - \frac{x_m}{\ell_B}\right) - \frac{V_B}{S_b \ell_B}}\right]$$

where C_{m_α} is the body pitching-moment-curve slope from paragraph C of Section 4.2.2.1 evaluated at the appropriate Mach number.

D. HYPERSONIC

Simple Newtonian theory is used in this section to estimate the derivative C_{m_q} of cone frustum bodies with or without spherical noses. Newtonian theory is discussed in paragraph D, Section 4.2.1.1.

DATCOM METHOD

Charts based on simple Newtonian theory (reference 2) are presented for determining C_{m_q} of spherical segments and cone frustums at small angles of attack. The coefficients of these charts are referred to the base area and the square of the base diameter and to a moment center at the forward face of the segment. By proper use of the data presented, the total C_{m_q} may be determined for bodies composed of multiple cone frustums with or without spherically blunted noses.

The Newtonian value of the stability derivative C_{m_q} for a complex body is obtained as follows:

Step 1. Compute $C_{m_q}{}'$ for each body segment about its own front face using figures 7.2.1.2-12 and 7.2.1.2-13b if the body has a spherically blunted nose, and figures 7.2.1.2-12 and 7.2.1.2-13a if the body nose is a cone frustum.

Step 2. Transfer the individual derivatives $C_{m_q}{}'$ to a common moment center by applying the following axis transfer equation to each body segment:

$$C_{m_q} = C_{m_q}{}' - 2\frac{n}{d} C_{m_\alpha}{}' + \frac{n}{d} C_{N_q}{}' - 2\left(\frac{n}{d}\right)^2 C_{N_\alpha} \qquad 7.2.1.2\text{-c}$$

where

C_{N_α} is the normal-force-curve slope for each segment based on individual base areas from Section 4.2.1.1.

$C_{N_q}{}'$ is the pitching derivative for each segment based on individual base areas and base diameters and referred to a moment center at the forward face of the segment. This derivative is obtained from paragraph D of Section 7.2.1.1.

$C_{m_\alpha}{}'$ is the pitching-moment-curve slope for each segment based on individual base areas and base diameters and referred to a moment center at the forward face of the segment. This derivative is obtained from paragraph D of Section 4.2.2.1.

$C_{m_q}{}'$ is the pitching derivative for each body segment based on individual base areas and the square of base diameters and referred to a moment center at

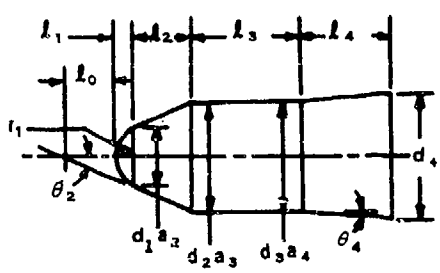
the forward face of the segment. If a complex body consists of combinations of cone frustums, the derivative for the first frustum must be obtained from figure 7.2.1.2-13a, which accounts for the front face being exposed to the air stream. If the body has a spherically blunted nose, the derivative of the nose is obtained from figure 7.2.1.2-13b. For subsequent frustums the derivatives are obtained from figure 7.2.1.2-12.

Step 3. The transferred derivatives of the individual body segments are added after being converted to a common reference area and squared diameter. The total derivative of the individual body segments is given by

$$C_{m_q} = \sum_{n=1}^{m} \left(C_{m_q}\right)_n \left(\frac{d_n}{d_b}\right)^4 \qquad 7.2.1.2\text{-d}$$

Sample Problem

Given: Same multiple-segment body as sample problems of paragraph D of Sections 4.2.1.1, 4.2.2.1, and 7.2.1.1.



ℓ_0 = 0.55 ft (distance from moment reference center to body nose)

Spherical segment

ℓ_1 = 0.18 ft

r_1 = 0.36 ft

d_1 = 0.62 ft

Forward cone frustum

a_2 = 0.62 ft

d_2 = 1.20 ft

ℓ_2 = 0.72 ft

θ_2 = 22.5°

Cylinder

$a_3 = 1.20$ ft

$d_3 = 1.20$ ft

$\ell_3 = 1.20$ ft

$\theta_3 = 0$

Rear cone frustum

$a_4 = 1.20$ ft

$d_4 = 1.368$ ft

$\ell_4 = 0.96$ ft

$\theta_4 = 5°$

Compute:

Spherical segment

$2\ell_1/d_s = \ell_1/r_1 = 0.50$

$C_{m_{q_1}}' = -0.50$ per rad (figure 7.2.1.2-13b)

$n_1 = -\ell_0 = -0.55$ ft

$d_1 = a_2 = 0.62$ ft

$C_{N_{\alpha_1}} = 0.75$ per rad (figure 4.2.1.1-23)

$C_{m_{\alpha_1}}' = -0.430$ per rad (figure 4.2.2.1-20b)

$C_{N_{q_1}}' = 0.865$ per rad (figure 7.2.1.1-9b)

$$C_{m_{q_1}} = C_{m_{q_1}} - 2\frac{n_1}{d_1} C_{m_{\alpha_1}}' + \frac{n_1}{d_1} C_{N_{q_1}}' - 2\left(\frac{n_1}{d_1}\right)^2 C_{N_{\alpha_1}} \quad \text{(equation 7.2.1.2-c)}$$

$$= -0.50 - (-1.774)(-0.43) + (-0.887)(0.865) - (1.574)(0.75)$$

$$= -0.50 - 0.763 - 0.767 - 1.180$$

$$= -3.210 \text{ per rad} \left(\text{based on } \frac{\pi d_1^4}{4}\right)$$

Forward cone frustum

$a_2/d_2 = \lambda_2 = 0.517$

$C_{m_{q_2}}' = -0.68$ per rad (figure 7.2.1.2-12)

$n_2 = -(\ell_0 + \ell_1) = -0.73$

$C_{N_{\alpha_2}} = 1.250$ per rad (figure 4.2.1.1-26)

$C_{m_{\alpha_2}}' = -0.590$ per rad (figure 4.2.2.1-20a)

$C_{N_{q_2}}' = 1.22$ per rad (figure 7.2.1.1-9a)

$$C_{m_{q_2}} = C_{m_{q_2}}' - 2\frac{n_2}{d_2} C_{m_{\alpha_2}}' + \frac{n_2}{d_2} C_{N_{q_2}}' - 2\left(\frac{n_2}{d_2}\right)^2 C_{N_{\alpha_2}} \quad \text{(equation 7.2.1.2-c)}$$

$$= -0.68 - (-1.217)(-0.590) + (-0.608)(1.22) - (0.74)(1.25)$$

$$= -0.68 - 0.718 - 0.742 - 0.925$$

$$= -3.065 \text{ per rad} \left(\text{based on } \frac{\pi d_2^4}{4}\right)$$

Cylinder

$a_3/d_3 = \lambda_3 = 1.0$

$C_{m_{q_3}}' = 0$ (figure 7.2.1.2-12)

$n_3 = -(\ell_0 + \ell_1 + \ell_2) = -1.45$

$C_{N_{\alpha_3}} = 0$ (figure 4.2.1.1-26)

$C_{m_{\alpha_3}} = 0$ (figure 4.2.2.1-20a)

$C_{N_{q_3}}' = 0$ (figure 7.2.1.1-9a)

$C_{m_{q_3}} = 0$

Rear cone frustum

$a_4/d_4 = \lambda_4 = .0.877$

$C_{m_{q_4}}' = -0.250$ per rad (figure 7.2.1.2-12)

$n_4 = -(\ell_0 + \ell_1 + \ell_2 + \ell_3) = -2.65$

$C_{N_{\alpha_4}} = 0.450$ per rad (figure 4.2.1.1-26)

$C_{m_{\alpha_4}}' = -0.19$ per rad (figure 4.2.2.1-20a)

$C_{N_{q_4}}' = 0.36$ per rad (figure 7.2.1.1-9a)

$$C_{m_{q_4}} = C_{m_{q_4}}' - 2\frac{n_4}{d_4} C_{m_{\alpha_4}}' + \frac{n_4}{d_4} C_{N_{q_4}}' - 2\left(\frac{n_4}{d_4}\right)^2 C_{N_{\alpha_4}} \quad \text{(equation 7.2.1.2-c)}$$

$$= -0.25 - (-3.87)(-0.19) + (-1.94)(0.36) - (7.53)(0.45)$$

$$= -0.25 - 0.735 - 0.698 - 3.388$$

$$= -5.072 \text{ per rad} \left(\text{based on } \frac{\pi d_4^4}{4}\right)$$

Solution:

Converting the derivative for each segment to a common reference area and square of the diameter, the base area and diameter of the rear cone frustum, and adding gives

$$C_{m_q} = C_{m_{q_1}}\left(\frac{d_1}{d_4}\right)^4 + C_{m_{q_2}}\left(\frac{d_2}{d_4}\right)^4 + C_{m_{q_3}}\left(\frac{d_3}{d_4}\right)^4 + C_{m_{q_4}} \quad \text{(equation 7.2.1.2-d)}$$

$$= -3.210\left(\frac{0.62}{1.368}\right)^4 - 3.065\left(\frac{1.20}{1.368}\right)^4 + 0 + (-5.072)$$

$$= -0.1354 - 1.8148 - 5.072$$

$$= -7.022 \text{ per rad} \left(\text{based on } \frac{\pi d_4^4}{4}\right)$$

7.2.2 BODY ACCELERATION DERIVATIVES

7.2.2.1 BODY ACCELERATION DERIVATIVE $C_{L_{\dot{\alpha}}}$

Methods are presented for determining the body contribution to the derivative $C_{L_{\dot{\alpha}}}$ in the subsonic, transonic, and supersonic speed ranges.

Datcom methods are based on the relatively simple results derived from slender-body theory in a manner similar to that used to predict the body pitching derivatives. It is assumed that a relationship of corresponding slender-body derivatives may be applied with reasonable accuracy to the case of vertical acceleration in a manner similar to that of reference 1. This approach to the calculation of body dynamic derivatives has been applied with reasonable success by Walker and Wolowicz in reference 2. It was shown in reference 1 that, although slender-body theory alone does not accurately predict the characteristics of nonslender bodies, the ratio of corresponding slender-body derivatives may be used with reasonable accuracy to predict the static forces on nonslender configurations. The body contribution to $C_{L_{\dot{\alpha}}}$ is then given as the product of the lift-curve slope C_{L_α} and the ratio of slender-body derivatives, i.e.,

$$C_{L_{\dot{\alpha}}} = C_{L_\alpha}\left(\frac{C_{L_{\dot{\alpha}}}}{C_{L_\alpha}}\right)_{\text{slender-body theory}}$$

Since slender-body theory states that body force characteristics are independent of Mach number, the limitations of these methods are determined by the limitations of the methods used in determining the derivative C_{L_α} in the various speed regimes. Experimental data should be used for the body lift-curve slope when available.

A. SUBSONIC

There is no explicit method available in the literature for the estimation of body acceleration derivatives in the subsonic speed range. The method presented below is based on the application of slender-body theory in the manner previously discussed.

DATCOM METHOD

The body contribution to $C_{L_{\dot{\alpha}}}$, based on body base area and body length, is given by

$$C_{L_{\dot{\alpha}}} = 2\,C_{L_\alpha}\left(\frac{V_B}{S_b \ell_B}\right) \quad \text{(per radian)} \qquad 7.2.2.1\text{-a}$$

where

C_{L_α} is the body lift-curve slope from paragraph A of Section 4.2.1.1 multiplied by $(V_B{}^{2/3}/S_b)$, based on S_b (per radian).

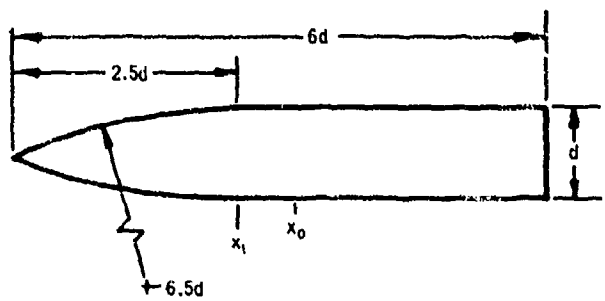
V_B is the total body volume from Section 2.3.

S_b is the body base area.

ℓ_B is the length of the body.

Sample Problem

Given: Same ogive-cylinder configuration as sample problem of paragraph A of Section 7.2.1.1.



$d = 1$ ft $\quad \ell_B = 6.0$ ft $\quad$ Fineness Ratio $= 6.0$

$V_B = 3.88$ cu ft (Section 2.3) $\quad S_b = 0.785$ sq ft

$C_{L_\alpha} = 1.724$ per rad (based on S_b, Section 7.2.1.1)

Compute:

$$\frac{V_B}{S_b \ell_B} = \frac{(3.88)}{(0.785)\,(6.0)} = 0.824$$

Solution:

$$C_{L_{\dot{\alpha}}} = 2\, C_{L_\alpha} \left(\frac{V_B}{S_b \ell_B}\right) \quad \text{(equation 7.2.2.1-a)}$$

$$= 2(1.724)\,(0.824)$$

$$= 2.84 \text{ per rad (based on } S_b \ell_B)$$

B. TRANSONIC

The only available method for determining the body dynamic stability derivatives at transonic speeds is that of Landahl in reference 3. However, Landahl's results for the acceleration derivatives are frequency-dependent and no quantitative information is presented. Since slender-body theory states that body force characteristics are independent of Mach number, the method of paragraph A is applicable throughout the transonic speed range.

C. SUPERSONIC

Several of the theoretical methods available for estimating the body acceleration derivatives in the supersonic speed range are briefly discussed in Section 7.2. These include simple slender-body theory, theories treated within the assumptions of slender-body theory, and hybrid theory. The method presented here is based on the results of simple slender-body theory. Theories treated within the assumptions of slender-body theory are mathematically complex and restricted to specific planforms; therefore, no general quantitative information of their results is presented.

The supersonic $C_{N_{\dot{\alpha}}}$ of cones may be obtained from the hybrid theory solution of reference 4.

DATCOM METHOD

The method presented here for determining the body contribution to $C_{N_{\dot{\alpha}}}$, based on body base area and body length, is the same as that of paragraph A and is given by equation 7.2.2.1-a, i.e.,

$$C_{N_{\dot{\alpha}}} = 2\, C_{N_{\alpha}} \left(\frac{V_B}{S_b \ell_B} \right)$$

where $C_{N_{\alpha}}$ is the body normal-force-curve slope from paragraph C of Section 4.2.1.1, evaluated at the appropriate Mach number. The other parameters are defined in paragraph A of this section.

D HYPERSONIC

The body contribution to the derivative $C_{N_{\dot{\alpha}}}$ in the hypersonic speed range is shown in reference 5 to be zero when determined by the Newtonian impact theory.

7.2.2.2 BODY ACCELERATION DERIVATIVE $C_{m_{\dot{\alpha}}}$

Methods are presented for determining the body contribution to the acceleration derivative $C_{m_{\dot{\alpha}}}$ in the subsonic, transonic, and supersonic speed ranges.

Datcom methods are based on the same assumptions that were made in regard to the estimation of the body contribution to the derivative $C_{L_{\dot{\alpha}}}$, and the general discussion of Section 7.2.2.1 is directly applicable here. The body contribution to $C_{m_{\dot{\alpha}}}$ is expressed as

$$C_{m_{\dot{\alpha}}} = C_{m_\alpha}\left(\frac{C_{m_{\dot{\alpha}}}}{C_{m_\alpha}}\right)_{\text{slender-body theory}}$$

The limitations of these methods are determined by the limitations of the methods used in estimating the static derivative C_{m_α} in the various speed regimes. Experimental data should be used for the body pitching-moment-curve slope when available.

A. SUBSONIC

The comments of Paragraph A of Section 7.2.2.1 are directly applicable here.

DATCOM METHOD

The body contribution to $C_{m_{\dot{\alpha}}}$, based on body base area and the square of the body length and referred to an arbitrary moment center, is given by

$$C_{m_{\dot{\alpha}}} = 2\,C_{m_\alpha}\frac{\left[\frac{V_B}{S_b \ell_B}\left(\frac{x_c}{\ell_B} - \frac{x_m}{\ell_B}\right)\right]}{\left[\left(1 - \frac{x_m}{\ell_B}\right) - \frac{V_B}{S_b \ell_B}\right]} \qquad 7.2.2.2\text{-a}$$

where

C_{m_α} is the body pitching-moment-curve slope from Paragraph A of Section 4.2.2.1, multiplied by $V_B/(S_b \ell_B)$.

x_c is the longitudinal distance from the vertex to the centroid of the volume and is given by Equation 7.2.1.2-b, i.e.,

$$x_c = \frac{\int_0^{\ell_B} S(x)\, x\, dx}{V_B}$$

x_m is the longitudinal distance from the body vertex to the center of rotation, positive aft.

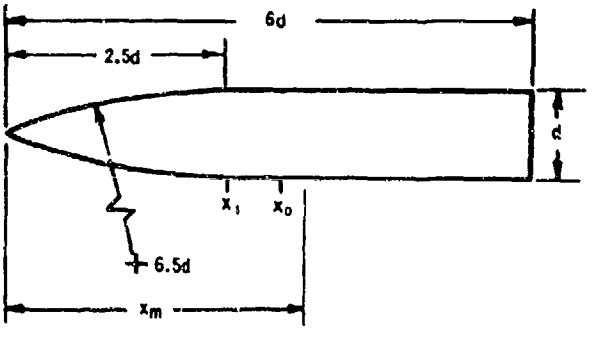
ℓ_B is the length of the body.

V_B is the total body volume from Section 2.3.

S_b is the body base area.

Sample Problem

Given: Same ogive-cylinder configuration as sample problems of Paragraph A of Sections 7.2.1.2 and 7.2.2.1.



$d = 1$ ft $\quad \ell_B = 6.0$ ft $\quad$ Fineness Ratio $= 6.0$ $\quad x_m = 3.8$ ft

$$\frac{V_B}{S_b \ell_B} = 0.824 \text{ (Section 7.2.2.1)}$$

$$\left.\begin{aligned} C_{m_\alpha} &= 0.781 \text{ per rad} \\ x_c &= 3.55 \text{ ft} \end{aligned}\right\} \text{ (Section 7.2.1.2)}$$

Solution:

$$\left(1 - \frac{x_m}{\ell_B}\right) = \left(1 - \frac{3.8}{6.0}\right) = 0.367$$

$$C_{m_{\dot{\alpha}}} = 2\,C_{m_\alpha} \frac{\left[\frac{V_B}{S_b \ell_B}\left(\frac{x_c}{\ell_B} - \frac{x_m}{\ell_B}\right)\right]}{\left[\left(1 - \frac{x_m}{\ell_B}\right) - \frac{V_B}{S_b \ell_B}\right]} \quad \text{(Equation 7.2.2.2-a)}$$

$$= 2(0.781)\left[\frac{0.824\left(\frac{3.55}{6.0} - \frac{3.8}{6.0}\right)}{0.367 - 0.824}\right]$$

$$= 1.562\left(\frac{-0.0343}{-0.457}\right)$$

$$= 0.117 \text{ per rad (based on } S_b \ell_B^2)$$

B. TRANSONIC

The comments of Paragraph B of Section 7.2.2.1 are directly applicable here. The method of Paragraph A is applicable throughout the transonic speed range.

C. SUPERSONIC

The theoretical methods applicable for the estimation of the body contribution to the derivative $C_{m_{\dot{\alpha}}}$ parallel those of the body contribution to the derivative $C_{L_{\dot{\alpha}}}$. Therefore, the general comments of Paragraph C of Section 7.2.2.1 are also applicable here.

The supersonic $C_{m_{\dot{\alpha}}}$ for a cone can be estimated by the hybrid theory solutions presented in Reference 1.

DATCOM METHOD

The method presented here for the body contribution to $C_{m_{\dot{\alpha}}}$, based on body base area and the square of the body length and referred to an arbitrary moment center, is the same as that of Paragraph A and is given by Equation 7.2.2.2-a, i.e.,

$$C_{m_{\dot{\alpha}}} = 2\,C_{m_\alpha} \frac{\left[\frac{V_B}{S_b \ell_B}\left(\frac{x_c}{\ell_B} - \frac{x_m}{\ell_B}\right)\right]}{\left[\left(1 - \frac{x_m}{\ell_B}\right) - \frac{V_B}{S_b \ell_B}\right]}$$

where C_{m_α} is the body pitching-moment-curve slope from Paragraph C of Section 4.2.2.1, evaluated at the appropriate Mach number. The other parameters are defined in Paragraph A of this section.

D. HYPERSONIC

The body contribution to the derivative $C_{m_{\dot{\alpha}}}$ in the hypersonic speed range is shown in Reference 1 to be zero when determined by the Newtonian impact theory.

7.3 WING-BODY DYNAMIC DERIVATIVES

7.3.1 WING-BODY PITCHING DERIVATIVES

7.3.1.1 WING-BODY PITCHING DERIVATIVE C_{L_q}

The information contained in this section is for estimating the pitching derivative C_{L_q} of wing-body configurations at low angles of attack. In general, it consists of a synthesis of material presented in other sections; however, the method of application is new.

The Datcom methods are based on the assumption that the mutual interferences that occur between components for angle-of-attack variations, determined in references 1 and 2 and presented in Section 4.3.1.2, may be employed with reasonable accuracy to the case of steady pitching. This approach to the calculation of wing-body pitching derivatives has been used with reasonable success by Walker and Wolowicz in reference 3.

A. SUBSONIC

Two methods are presented for determining the pitching derivative C_{L_q} of a wing-body configuration, differing only in their treatment of the mutual interference effects.

DATCOM METHODS

Method 1

For wing-body configurations similar to sketch (d) of Section 4.3.1.2, the pitching derivative C_{L_q}, based on the area and mean aerodynamic chord of the total panel and referred to a moment center at the assumed center of gravity or center of rotation, is given by

$$\left(C_{L_q}\right)_{WB} = \left[K_{W(B)} + K_{B(W)}\right]\left(\frac{S_e}{S}\right)\left(\frac{\bar{c}_e}{\bar{c}}\right)\left(C_{L_q}\right)_e + \left(C_{L_q}\right)_B\left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right) \qquad 7.3.1.1\text{-a}$$

where

$K_{W(B)}$ and $K_{B(W)}$ are the appropriate wing-body interference factors obtained from Section 4.3.1.2.

$\left(C_{L_q}\right)_e$ is the contribution of the exposed panel to the pitching derivative C_{L_q}, obtained from Section 7.1.1.1. (See Section 4.3.1.2 for the definition of exposed surfaces.)

$\left(C_{L_q}\right)_B$ is the contribution of the body to the pitching derivative C_{L_q}, obtained from Section 7.2.1.1.

$\frac{S_e}{S}$ is the ratio of the exposed to the total panel area.

$\frac{S_b}{S}$ is the ratio of the body base area to the total panel area.

$\frac{\bar{c}_e}{\bar{c}}$ is the ratio of the mean aerodynamic chord of the exposed panel to the mean aerodynamic chord of the total panel.

$\frac{\ell_B}{\bar{c}}$ is the ratio of the body length to the mean aerodynamic chord of the total panel.

Moment transfer calculations are included as an integral part of the wing and body derivative estimation methods of Sections 7.1.1.1 and 7.2.1.1, respectively.

Method 2

For wing-body configurations similar to sketch (c) of Section 4.3.1.2, the pitching derivative C_{L_q}, based on the area and mean aerodynamic chord of the total panel and referred to a moment center at the assumed center of gravity or center of rotation, is given by

$$\left(C_{L_q}\right)_{WB} = K_{(WB)}\left(C_{L_q}\right)_W + \left(C_{L_q}\right)_B \left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right) \qquad 7.3.1.1\text{-b}$$

where

$K_{(WB)}$ is the wing-body interference factor, obtained from figure 4.3.1.2-12c of Section 4.3.1.2.

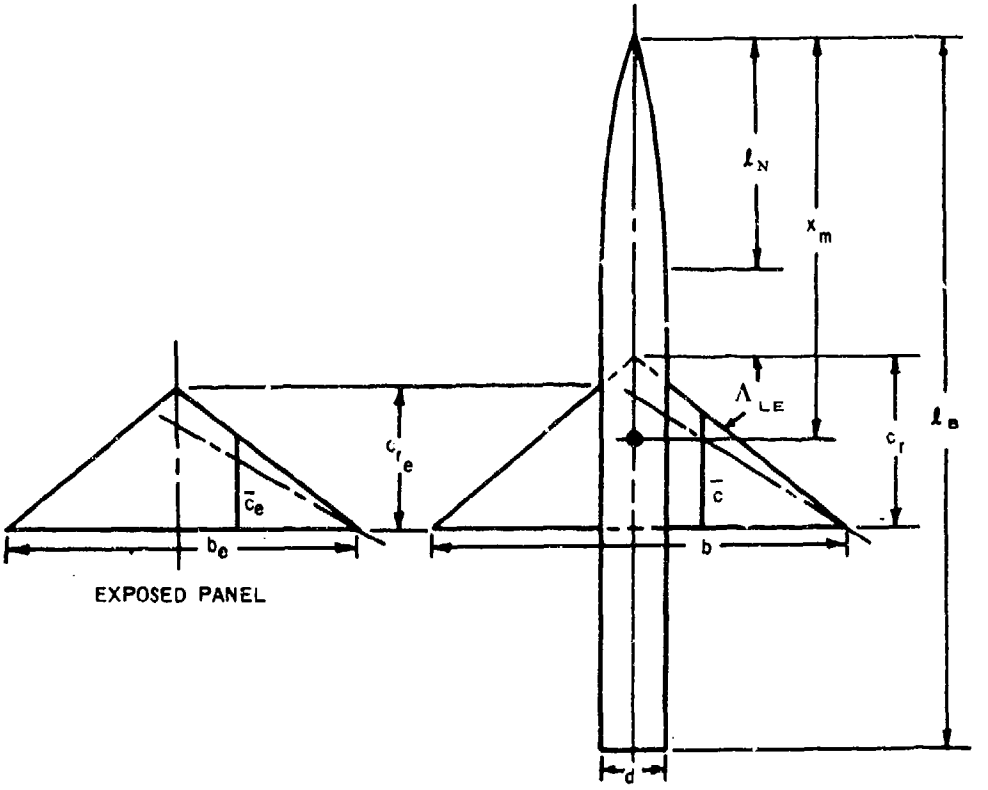
$\left(C_{L_q}\right)_W$ is the contribution of the total panel to the pitching derivative C_{L_q}, obtained from Section 7.1.1.1.

The remaining terms are defined in method 1 above. Moment transfer calculations are included as an integral part of the wing and body derivative estimation methods of Sections 7.1.1.1 and 7.2.1.1, respectively.

Sample Problem

Method 1

Given: An ogive-cylinder-body–triangular-wing configuration



Wing Characteristics:

Total Panel		Exposed Panel	
$A = 5.0$	$\lambda = 0$	$A_e = 5.0$	$\lambda_e = 0$
$\Lambda_{LE} = 38.67°$	$S = 414.0$ sq ft	$b_e = 38.37$ ft	$S_e = 294.50$ sq ft
$i_W = 0$	$c_r = 18.20$ ft	$\Lambda_{c/2} = 21.8°$	$c_{r_e} = 15.375$ ft
$b = 45.50$ ft	$\bar{c} = 12.133$ ft		$\bar{c}_e = 10.25$ ft

NACA 66-206 airfoil section

Body Characteristics:

$\ell_N = 25.0$ ft $\qquad \ell_B = 77.20$ ft $\qquad d = 7.127$ ft

The following ratios based on total panel dimensions:

$\frac{S_e}{S} = 0.7113 \qquad \frac{\bar{c}_e}{\bar{c}} = 0.845 \qquad \frac{S_b}{S} = 0.0963 \qquad \frac{\ell_B}{\bar{c}} = 6.363$

Additional Characteristics:

$M = 0.60$ $\qquad x_m = 43.70$ ft (moment center at $\bar{c}/4$ of total panel)

$\beta = 0.80$ $\qquad \frac{d}{b} = 0.157$

Compute:

Step 1. Pitching derivative C_{L_q} for exposed panel (Section 7.1.1.1)

$c_{\ell_\alpha} = 6.19$ per rad (table 4.1.1-B)

$$\kappa = \frac{c_{\ell_\alpha}}{2\pi} = 0.985$$

$$\frac{A_e}{\kappa}\left[\beta^2 + \tan^2 \Lambda_{c/2}\right]^{1/2} = \frac{5.0}{0.985}\left[0.64 + 0.16\right]^{1/2} = 4.54$$

$$\frac{\left(C_{L_\alpha}\right)_e}{A_e} = 0.90 \text{ per rad} \quad \text{(figure 4.1.3.2-49)}$$

$$\left(C_{L_\alpha}\right)_e = 4.50 \text{ per rad}$$

$$\frac{\tan \Lambda_{LE}}{\beta} = 1.0$$

$$A_e \tan \Lambda_{LE} = 4.0$$

$$\left(\frac{x_{a.c.}}{c_r}\right)_e = 0.560 \quad \text{(figure 4.1.4.2-26a)}$$

$$\left(\frac{x_{c.g.}}{c_r}\right)_e = 0.408 \quad \text{(from planform geometry of exposed panel with c.g. at } \bar{c}/4 \text{ of total panel)}$$

$$\left(\frac{\bar{x}}{\bar{c}}\right)_e = \left(\frac{x_{a.c.}}{\bar{c}} - \frac{x_{c.g.}}{\bar{c}}\right)_e \quad \text{(equation 7.1.1.1-b)}$$

$$= \left(\frac{x_{a.c.}}{c_r} - \frac{x_{c.g.}}{c_r}\right)_e \left(\frac{c_r}{\bar{c}}\right)_e = (0.560 - 0.408)\ 1.50 = 0.228$$

$$\left(C_{L_q}\right)_e = \left(\frac{1}{2} + 2\frac{\bar{x}}{\bar{c}}\right)_e \left(C_{L_\alpha}\right)_e \quad \text{(equation 7.1.1.1-a)}$$

$$= (0.956)\ (4.50)$$

$$= 4.30 \text{ per rad (based on } S_e \bar{c}_e)$$

Step 2. Wing-body interference factors (Section 4.3.1.2)

$$\left.\begin{aligned} K_{W(B)} &= 1.125 \\ K_{B(W)} &= 0.215 \end{aligned}\right\} \text{(figure 4.3.1.2-10)}$$

Step 3. Pitching derivative C_{L_q} for body (Section 7.2.1.1)

$$\frac{\ell}{d} = \frac{77.20}{7.127} = 10.83$$

$$(k_2 - k_1) = 0.947 \quad \text{(figure 4.2.1.1-20a)}$$

$$x_1 = \ell_N = 25.0 \text{ ft}$$

$$\frac{x_1}{\ell_B} = \frac{25.0}{77.2} = 0.324$$

$$\frac{x_o}{\ell_B} = 0.55 \quad \text{(extrapolated using figure 4.2.1.1-20b)}$$

$$x_o = 42.46 \text{ ft}$$

$$S_o = S_1 = 39.88 \text{ sq ft}$$

$$\frac{\ell_N}{d} = \frac{25.0}{7.127} = 3.508$$

$$\frac{V_N}{S_o \ell_N} = 0.535 \quad \text{(figure 2.3-5, ogive)}$$

$$V_N = (0.535)\ (39.88)\ (25.0) = 533.4 \text{ cu ft}$$

$$V_B = (\ell_B - \ell_N)\, S_1 + V_N$$

$$= (77.2 - 25.0)\,(39.88) + 533.4$$

$$= 2615.1 \text{ cu ft}$$

$$V_B^{2/3} = 189.8 \text{ sq ft}$$

$$\left(C_{L_\alpha}\right)_B = \frac{2(k_2 - k_1)\, S_o}{V_B^{2/3}} \quad \text{(equation 4.2.1.1-a)}$$

$$= \frac{2(0.947)\,(39.88)}{189.8}$$

$$= 0.398 \text{ per rad} \quad \text{(based on } V_B^{2/3}\text{)}$$

$$\left(C_{L_\alpha}\right)_B = 0.398\, \frac{V_B^{2/3}}{S_b} = 0.398 \left(\frac{189.8}{39.88}\right) = 1.894 \text{ per rad} \quad \text{(based on } S_b\text{)}$$

$$\left(1 - \frac{x_m}{\ell_B}\right) = \left(1 - \frac{43.70}{77.20}\right) = 0.434$$

$$\left(C_{L_q}\right)_B = 2\left(C_{L_\alpha}\right)_B \left(1 - \frac{x_m}{\ell_B}\right) \quad \text{(equation 7.2.1.1-a)}$$

$$= 2(1.894)\,(0.434)$$

$$= 1.644 \text{ per rad} \quad \text{(based on } S_b \ell_B\text{)}$$

Solution:

$$\left(C_{L_q}\right)_{WB} = \left[K_{W(B)} + K_{B(W)}\right]\left(\frac{S_e}{S}\right)\left(\frac{\bar{c}_e}{\bar{c}}\right)\left(C_{L_q}\right)_e + \left(C_{L_q}\right)_B \left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right) \quad \text{(equation 7.3.1.1-a)}$$

$$= (1.175 + 0.215)\,(0.7113)\,(0.845)\,(4.30) + (1.644)\,(0.0963)\,(6.363)$$

$$= 3.46 + 1.007$$

$$= 4.467 \text{ per rad} \quad \text{(based on the area and mean aerodynamic chord of the total panel and referred to a moment center at } \bar{c}/4 \text{ of the total panel)}$$

B. TRANSONIC

The aerodynamic interference effects for slender wing-body configurations are relatively insensitive to Mach number; consequently, the slender-body interference factors of Section 4.3.1.2 should give reasonable results. For nonslender configurations, transonic interference effects can become quite large and sensitive to minor changes in local contour.

DATCOM METHODS

It is recommended that the methods presented in paragraph A for estimating the pitching derivative C_{L_q} of a wing-body configuration be applied to the transonic speed regime. Care should be taken to estimate the contributions of the lifting panel and body at the appropriate Mach number. The interference factors should be obtained from paragraph C, Section 4.3.1.2.

C. SUPERSONIC

The information included in the Datcom accounts for most of the mutual interferences that occur between components of a wing-body configuration at supersonic speeds. These interference effects have been accounted for by the slender-body interference factors of Section 4.3.1.2.

DATCOM METHODS

The methods presented in paragraph A for estimating the pitching derivative C_{L_q} of a wing-body configuration are also applicable to the supersonic speed range. Care should be taken to estimate the contributions of the lifting panel and body at the appropriate Mach number.

Sample Problem

Method 1

Given: Same configuration as sample problem of paragraph A

$M = 1.4 \qquad \beta = 0.98$

Compute:

Step 1. Pitching derivative C_{L_q} for exposed panel (Section 7.1.1.1)

$$\frac{\tan \Lambda_{LE}}{\beta} = 0.816$$

$$A_e \tan \Lambda_{LE} = 4.0$$

$$\beta \left(C_{N_\alpha}\right)_e = 4.0 \text{ per rad} \quad \text{(figure 4.1.3.2-56a)}$$

$\left(C_{N_\alpha}\right)_e$ = 4.08 per rad

$\left(\frac{x_{a.c.}}{c_r}\right)_e$ = 0.67 (figure 4.1.4.2-26a)

$\left(\frac{x_{c.g.}}{c_r}\right)_e$ = 0.408 (from planform geometry of exposed panel with c.g. at $\bar{c}/4$ of total panel)

$\left(\frac{\bar{x}}{\bar{c}}\right)_e = \left(\frac{x_{a.c.}}{\bar{c}} - \frac{x_{c.g.}}{\bar{c}}\right)_e$ (equation 7.1.1.1-b)

$= \left(\frac{x_{a.c.}}{c_r} - \frac{x_{c.g.}}{c_r}\right)_e \left(\frac{c_r}{\bar{c}}\right)_e$ = (0.67 – 0.408) 1.50 = 0.393

$\beta \cot \Lambda_{LE}$ = 1.225 (supersonic leading edge)

βA_e = 4.90

$\cot^{-1} (\beta \cot \Lambda_{LE})$ = 39.23°

$\left(C_{L_q}'\right)_e$ = 0 (figure 7.1.1.1-11a)

$\left(C_{L_q}\right)_e = \left(C_{L_q}'\right)_e + 2\left(\frac{\bar{x}}{\bar{c}}\right)_e \left(C_{N_\alpha}\right)_e$ (equation 7.1.1.1-c)

= 0 + 2(0.393) (4.08)

= 3.21 per rad (based on $S_e \bar{c}_e$)

Step 2. Wing-body interference factors (Section 4.3.1.2)

$K_{W(B)}$ = 1.125 (figure 4.3.1.2-10)

$\frac{\beta d}{c_{r_e}} = \frac{(0.98)\ (7.127)}{15.375}$ = 0.455

$K_{B(W)}\left[\beta \left(C_{N_\alpha}\right)_e (\lambda_e + 1)\left(\frac{b}{d} - 1\right)\right]$ = 3.90 (figure 4.3.1.2-11a)

$$\left[\beta \left(C_{N_\alpha}\right)_e (\lambda_e + 1) \left(\frac{b}{d} - 1\right)\right] = (0.98)\,(4.08)\,(1)\,(6.38 - 1) = 21.51$$

$$K_{B(W)} = \frac{3.90}{21.51} = 0.181$$

Step 3. Pitching derivative C_{L_q} for body (Section 7.2.1.1)

$$f_A = \frac{\ell_A}{d} = \frac{77.2 - 25.0}{7.127} = 7.32$$

$$f_N = \frac{\ell_N}{d} = \frac{25.0}{7.127} = 3.51$$

$$f_A / f_N = 2.09$$

$$\frac{\beta}{f_N} = \frac{0.98}{3.51} = 0.279$$

$\left(C_{N_\alpha}\right)_B$ = 2.74 per rad (figure 4.2.1.1-21a, extrapolated)

$\left(1 - \frac{x_m}{\ell_B}\right)$ = 0.434 (sample problem, paragraph A)

$$\left(C_{L_q}\right)_B = 2\left(C_{N_\alpha}\right)_B \left(1 - \frac{x_m}{\ell_B}\right) \quad \text{(equation 7.2.1.1-a)}$$

$$= 2(2.74)\,(0.434)$$

$$= 2.378 \text{ per rad (based on } S_b \ell_B)$$

Solution:

$$\left(C_{L_q}\right)_{WB} = \left[K_{W(B)} + K_{B(W)}\right] \left(\frac{S_e}{S}\right) \left(\frac{\bar{c}_e}{\bar{c}}\right) \left(C_{L_q}\right)_e + \left(C_{L_q}\right)_B \left(\frac{S_b}{S}\right) \left(\frac{\ell_B}{\bar{c}}\right)$$

(equation 7.3.1.1-a)

$$= (1.125 + 0.181)\,(0.7113)\,(0.845)\,(3.21) + (2.378)\,(0.0963)\,(6.363)$$

$$= 2.520 + 1.457$$

= 3.977 per rad (based on the area and mean aerodynamic chord of the total panel and referred to a moment center at $\bar{c}/4$ of the total panel)

7.3.1.2 WING-BODY PITCHING DERIVATIVE C_{m_q}

The information contained in this section is for estimating the pitching derivative C_{m_q} of wing-body configurations at low angles of attack. The derivative C_{m_q} is a measure of the pitching moment produced by rotational motion about a spanwise axis and is commonly referred to as the pitch-damping derivative.

The Datcom methods are based on the same assumption that was made in regard to the pitching derivative C_{L_q} of a wing-body configuration, and the general discussion of Section 7.3.1.1 is directly applicable here.

A. SUBSONIC

Two methods are presented for determining the pitching derivative C_{m_q} of a wing-body configuration, differing only in their treatment of the mutual interference effects.

DATCOM METHODS

Method 1

For wing-body configurations similar to sketch (d) of Section 4.3.1.2, the pitching derivative C_{m_q}, based on the area and the square of the mean aerodynamic chord of the total panel and referred to a moment center at the assumed center of gravity or center of rotation, is given by

$$\left(C_{m_q}\right)_{WB} = \left[K_{W(B)} + K_{B(W)}\right]\left(\frac{S_e}{S}\right)\left(\frac{\bar{c}_e}{\bar{c}}\right)^2\left(C_{m_q}\right)_e + \left(C_{m_q}\right)_B\left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right)^2 \qquad 7.3.1.2\text{-a}$$

where

$\left(C_{m_q}\right)_e$ is the contribution of the exposed panel to the pitching derivative C_{m_q}, obtained from Section 7.1.1.2. (See Section 4.3.1.2 for the definition of exposed surfaces.)

$\left(C_{m_q}\right)_B$ is the contribution of the body to the pitching derivative C_{m_q}, obtained from Section 7.2.1.2.

The remaining terms are defined in paragraph A of Section 7.3.1.1. Moment transfer calculations are included as an integral part of the wing- and body-derivative estimation methods of Sections 7.1.1.2 and 7.2.1.2, respectively.

Method 2

For wing-body configurations similar to sketch (c) of Section 4.3.1.2, the pitching derivative C_{m_q}, based on the area and the square of the mean aerodynamic chord of the total panel and referred to a moment center at the assumed center of gravity or center of rotation, is given by

$$\left(C_{m_q}\right)_{WB} = K_{(WB)}\left(C_{m_q}\right)_W + \left(C_{m_q}\right)_B \left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right)^2 \qquad 7.3.1.2\text{-b}$$

where

$\left(C_{m_q}\right)_W$ is the contribution of the total panel to the pitching derivative C_{m_q}, obtained from Section 7.1.1.2.

The remaining terms are defined in method 1 above and paragraph A of Section 7.3.1.1. Moment transfer calculations are included as an integral part of the wing- and body-derivative estimation methods of Sections 7.1.1.2 and 7.2.1.2, respectively.

Sample Problem

Method 1

Given: Same configuration as sample problem of paragraph A, Section 7.3.1.1. The characteristics are repeated below.

Wing Characteristics:

Total Panel		Exposed Panel	
$A = 5.0$	$\lambda = 0$	$A_e = 5.0$	$\lambda_e = 0$
$\Lambda_{LE} = 38.67°$	$S = 414.0$ sq ft	$b_e = 38.37$ ft	$S_e = 294.50$ sq ft
$i_W = 0$	$c_r = 18.20$ ft	$\Lambda_{c/4} = 30.96°$	$c_{r_e} = 15.375$ ft
$b = 45.50$ ft	$\bar{c} = 12.133$ ft		$\bar{c}_e = 10.25$ ft

NACA 66-206 airfoil section

Body Characteristics:

$\ell_N = 25.0$ ft $\qquad \ell_B = 77.20$ ft $\qquad d = 7.127$ ft

The following ratios based on total panel dimensions:

$$\frac{S_e}{S} = 0.7113 \qquad \left(\frac{\bar{c}_e}{\bar{c}}\right)^2 = 0.7140$$

$$\frac{S_b}{S} = 0.0963 \qquad \left(\frac{\ell_B}{\bar{c}}\right)^2 = 40.49$$

Additional Characteristics:

$M = 0.60$ $\qquad$ $x_m = 43.70$ ft (moment center at $\bar{c}/4$ of total panel)

$\beta = 0.80$ $\qquad$ $\frac{d}{b} = 0.157$

Compute:

Step 1. Pitching derivative C_{m_q} for exposed panel (Section 7.1.1.2)

$$\left.\begin{array}{l} c_{\ell_\alpha} = 6.19 \text{ per rad} \\ \left(\frac{\bar{x}}{\bar{c}}\right)_e = 0.228 \end{array}\right\} \text{ (sample problem, paragraph A, Section 7.3.1.1)}$$

$$\cos \Lambda_{c/4} = 0.8576$$

$$\tan \Lambda_{c/4} = 0.600$$

$$B = \sqrt{1 - M^2 \cos^2 \Lambda_{c/4}} = 0.8575$$

$$\left[\left(C_{m_q}\right)_{M \approx 0.2}\right]_e = -0.7\, c_{\ell_\alpha} \cos \Lambda_{c/4} \left\{ \frac{A_e \left[\frac{1}{2}\frac{\bar{x}}{\bar{c}} + 2\left(\frac{\bar{x}}{\bar{c}}\right)^2\right]_e}{A_e + 2\cos \Lambda_{c/4}} + \frac{1}{24}\left(\frac{A_e^3 \tan^2 \Lambda_{c/4}}{A_e + 6\cos \Lambda_{c/4}}\right) + \frac{1}{8}\right\} \text{ (equation 7.1.1.2-a)}$$

$$= -0.7(6.19)(0.8576)\left\{ \frac{5\left[\frac{1}{2}(0.228) + 2(0.228)^2\right]}{5 + 2(0.8576)} + \frac{1}{24}\left[\frac{(5)^3 (0.6)^2}{5 + 6(0.8576)}\right] + \frac{1}{8}\right\}$$

$$= -3.72\left[\frac{1.090}{6.715} + \frac{1}{24}\left(\frac{45}{10.146}\right) + \frac{1}{8}\right]$$

$$= -3.72(0.4721)$$

$$= -1.76 \text{ per rad (based on } S_e \bar{c}_e{}^2)$$

$$\left(C_{m_q}\right)_e = \left[\frac{\frac{A_e{}^3 \tan^2 \Lambda_{c/4}}{A_e B + 6\cos\Lambda_{c/4}} + \frac{3}{B}}{\frac{A_e{}^3 \tan^2 \Lambda_{c/4}}{A_e + 6\cos\Lambda_{c/4}} + 3}\right]\left[\left(C_{m_q}\right)_{M\approx 0.2}\right]_e \quad \text{(equation 7.1.1.2-b)}$$

$$= \left[\frac{\frac{(5)^3\,(0.6)^2}{(5)\,(0.8575) + 6(0.8576)} + \frac{3}{0.8575}}{\frac{(5)^3\,(0.6)^2}{5 + 6(0.8576)} + 3}\right](-1.76)$$

$$= \left(\frac{4.77 + 3.499}{4.435 + 3}\right)(-1.76)$$

$$= \left(\frac{8.269}{7.435}\right)(-1.76)$$

$$= -1.96 \text{ per rad (based on } S_e \bar{c}_e{}^2)$$

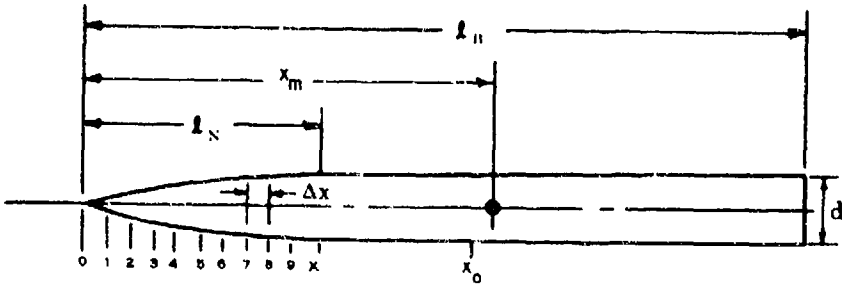
Step 2. Wing-body interference factors (Section 4.3.1.2)

$K_{W(B)} = 1.125$

$K_{B(W)} = 0.215$

} (sample problem, paragraph A, Section 7.3.1.1)

Step 3. Pitching derivative C_{m_q} for body (Section 7.2.1.2)



$\Delta x = 2.5$ ft

From sample problem, paragraph A, Section 7.3.1.1:

$(k_2 - k_1) = 0.947$ $\quad V_B = 2615.1$ cu ft $\quad S_b = 39.88$ sq ft

$x_1 = 25.0$ ft $\quad x_o = 42.46$ ft

Determine $\left(C_{m_\alpha}\right)_B$

Station	d ft	S_x sq ft	$\Delta S_x \approx \frac{dS_x}{dx} \Delta x$	$(x_m - x)^*$	$\frac{dS_x}{dx} (x_m - x) \Delta x$
1	1.137	1.016	1.016	42.033	42.71
2	2.600	5.309	4.293	39.787	170.81
3	3.725	10.898	5.589	37.376	208.89
4	4.650	16.982	6.084	34.904	212.36
5	5.450	23.328	6.346	32.417	205.72
6	6.150	29.706	6.378	29.925	190.86
7	6.625	34.472	4.766	27.425	130.71
8	6.950	37.937	3.405	24.940	86.42
9	7.100	39.592	1.655	22.446	37.15
x_1	7.127	39.800	0.288	19.949	5.74
x_o	7.127	39.880	0	9.970	0

$$\sum_{x=0}^{x_o} \frac{dS_x}{dx} (x_m - x) \Delta x = 1291$$

$$\left(C_{m_\alpha}\right)_B = \frac{2(k_2 - k_1)}{V_B} \sum_{x=0}^{x_o} \frac{dS_x}{dx} (x_m - x) \Delta x \quad \text{(equation 4.2.2.1-a)}$$

$$= \frac{2(0.947)\,(1291)}{2615.1} = 0.935 \text{ per rad (based on } V_B)$$

$$\left(C_{m_\alpha}\right)_B = (0.935) \frac{V_B}{S_b \ell_B} = 0.935 \frac{(2615.1)}{(39.88)\,(77.2)} = 0.794 \text{ per rad (based on } S_b \ell_B)$$

*x is taken to be at the center of volume of each body segment.

Determine x_c

Station	d ft	S(x) sq ft	x*	S(x) x Δx
1	1.137	1.016	1.667	4.23
2	2.600	5.309	3.913	51.94
3	3.725	10.898	6.324	172.30
4	4.650	16.982	8.796	373.43
5	5.450	23.328	11.283	658.02
6	6.150	29.706	13.775	1023.00
7	6.625	34.472	16.275	1402.58
8	6.950	37.937	18.760	1779.24
9	7.100	39.592	21.254	2103.72
10	7.127	39.880	23.751	2367.97
ℓ_B	7.127	39.880	51.100	106,377.

$$\sum_{x=0}^{\ell_B} S(x) \times \Delta x = 116{,}313$$

$$x_c = \frac{\int_0^{\ell_B} S(x) \times dx}{V_B} = \frac{116{,}313}{2615.1} = 44.48 \text{ ft} \quad \text{(equation 7.2.1.2-b)}$$

$$\frac{V_B}{S_b \ell_B} = \frac{2615.1}{(39.88)(77.2)} = 0.849$$

$$\left(1 - \frac{x_m}{\ell_B}\right) = 0.434 \quad \text{(sample problem, paragraph A, Section 7.3.1.1)}$$

$$\left(C_{m_q}\right)_B = 2\left(C_{m_\alpha}\right)_B \left[\frac{\left(1 - \frac{x_m}{\ell_B}\right)^2 - \frac{V_B}{S_b \ell_B}\left(\frac{x_c}{\ell_B} - \frac{x_m}{\ell_B}\right)}{\left(1 - \frac{x_m}{\ell_B}\right) - \frac{V_B}{S_b \ell_B}}\right] \quad \text{(equation 7.2.1.2-a)}$$

$$= 2(0.794)\left[\frac{(0.434)^2 - 0.849\left(\frac{44.48 - 43.70}{77.20}\right)}{0.434 - 0.849}\right]$$

*x is taken to be at the center of volume of each body segment.

$$= 1.59\left[\frac{0.1884 - 0.849\,(0.0101)}{-0.415}\right]$$

$$= 1.59\left(\frac{0.1798}{-0.415}\right)$$

$$= -0.689 \text{ per rad (based on } S_b \ell_B{}^2)$$

Solution:

$$\left(C_{m_q}\right)_{WB} = [K_{W(B)} + K_{B(W)}]\left(\frac{S_e}{S}\right)\left(\frac{\bar{c}_e}{\bar{c}}\right)^2 \left(C_{m_q}\right)_e + \left(C_{m_q}\right)_B \left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right)^2$$

(equation 7.3.1.2-a)

$$= (1.125 + 0.215)\,(0.7113)\,(0.7140)\,(-1.96) + (-0.689)\,(0.0963)\,(40.49)$$

$$= -1.334 - 2.687$$

$$= -4.021 \text{ per rad (based on the area and the square of the mean aerodynamic chord of the total panel and referred to a moment center at } \bar{c}/4 \text{ of the total panel)}$$

B. TRANSONIC

The comments of paragraph B of Section 7.3.1.1 are directly applicable here.

DATCOM METHODS

It is recommended that the methods presented in paragraph A for estimating the pitching derivative C_{m_q} of a wing-body configuration be applied to the transonic speed regime. Care should be taken to estimate the contributions of the lifting panel and body at the appropriate Mach number. The interference factors should be obtained from paragraph C, Section 4.3.1.2.

C. SUPERSONIC

The comments of paragraph C of Section 7.3.1.1 are directly applicable here.

DATCOM METHODS

The methods presented in paragraph A for estimating the pitching derivative C_{m_q} of a wing-body configuration are also applicable to the supersonic speed range. Care should be taken to estimate the contributions of the lifting panel and body at the appropriate Mach number.

Sample Problem

Method 1

Given: Same configuration as sample problem of paragraph C, Section 7.3.1.1 and paragraph A of this section.

$M = 1.4 \qquad \beta = 0.98$

Compute:

Step 1. Pitching derivative C_{m_q} for exposed panel (Section 7.1.1.2)

$\left(\frac{\bar{x}}{\bar{c}}\right)_e = 0.393$

$\beta \cot \Lambda_{LE} = 1.225$ (supersonic leading edge)

$A_e \beta = 4.90$

$\cot^{-1} (\beta \cot \Lambda_{LE}) = 39.23°$

$\left(C_{L_q}\right)_e = 3.21$ per rad

} (sample problem paragraph C, Section 7.3.1.1)

$-\beta \left(C_{m_q}'\right)_e = 1.018$ per rad (figure 7.1.1.2-10a)

$\left(C_{m_q}'\right)_e = -1.039$ per rad

$\left(C_{m_q}\right)_e = \left(C_{m_q}'\right)_e - \left(\frac{\bar{x}}{\bar{c}}\right)_e \left(C_{L_q}\right)_e$ (equation 7.1.1.2-d)

$= -1.039 - (0.393)(3.21)$

$= -2.301$ per rad (based on $S_e \bar{c}_e^{\,2}$)

Step 2. Wing-body interference factors (Section 4.3.1.2)

$K_{W(B)} = 1.125$

$K_{B(W)} = 0.181$

} (sample problem, paragraph C, Section 7.3.1.1)

Step 3. Pitching derivative C_{m_q} for body (Section 7.2.1.2)

$f_N = 3.51$

$f_A/f_N = 2.09$

$\frac{\beta}{f_N} = 0.279$

$\left(C_{N_\alpha}\right)_B = 2.74$ per rad

} (sample problem, paragraph C, Section 7.3.1.1)

$x_c = 44.48$ ft

$\frac{V_B}{S_b \ell_B} = 0.849$

$\left(1 - \frac{x_m}{\ell_B}\right) = 0.434$

} (sample problem, paragraph A)

$\frac{x_{c.p.}}{\ell_B} = 0.195$ (figure 4.2.2.1-18a, extrapolated)

$\frac{x_m}{\ell_B} = \frac{43.70}{77.20} = 0.566$

$\left(C_{m_\alpha}\right)_B = \left(\frac{x_m}{\ell_B} - \frac{x_{c.p.}}{\ell_B}\right)\left(C_{N_\alpha}\right)_B$ (equation 4.2.2.1-c)

$= (0.566 - 0.195)\, 2.74$

$= 1.017$ per rad (based on $S_b \ell_B$)

$$\left(C_{m_q}\right)_B = 2\left(C_{m_\alpha}\right)_B \left[\frac{\left(1 - \frac{x_m}{\ell_B}\right)^2 - \frac{V_B}{S_b \ell_B}\left(\frac{x_c}{\ell_B} - \frac{x_m}{\ell_B}\right)}{\left(1 - \frac{x_m}{\ell_B}\right) - \frac{V_B}{S_b \ell_B}}\right]$$ (equation 7.2.1.2-a)

$$= 2(1.017)\left[\frac{(0.434)^2 - (0.849)\left(\frac{44.48 - 43.70}{77.20}\right)}{0.434 - 0.849}\right]$$

$$= 2.034\left(\frac{0.1798}{-0.415}\right)$$

$$= -0.881 \text{ per rad (based on } S_b \ell_B{}^2)$$

Solution:

$$\left(C_{m_q}\right)_{WB} = [K_{W(B)} + K_{B(W)}]\left(\frac{S_e}{S}\right)\left(\frac{\bar{c}_e}{\bar{c}}\right)^2\left(C_{m_q}\right)_e + \left(C_{m_q}\right)_B\left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right)^2$$

(equation 7.3.1.2-a)

$$= (1.125 + 0.181)(0.7113)(0.7140)(-2.301) + (-0.881)(0.0963)(40.49)$$

$$= -1.526 - 3.435$$

$$= -4.961 \text{ per rad (based on the area and the square of the mean aerodynamic chord of the total panel and referred to a moment center at } \bar{c}/4 \text{ of the total panel)}$$

7.3.2.1 WING-BODY ROLLING DERIVATIVE C_{Y_p}

This section presents methods for estimating the wing-body contribution to the rolling derivative C_{Y_p} at subsonic and supersonic speeds. This derivative is the change in side-force coefficient with change in the wing-tip helix angle.

A. SUBSONIC

Experimental evidence indicates that the effect of the fuselage on the side force due to rolling is negligible throughout the angle-of-attack range up to the stall. Therefore, the method of Section 7.1.2.1 for estimating the wing-alone derivative at subsonic speeds is also applicable to wing-body configurations. Available test data are limited to wing-body configurations with body diameters less than about 30 percent of the wing span. Therefore, the application of the wing-alone method is limited to values of $d/b \leqslant 0.3$.

The method consists of determining the value of C_{Y_p} at zero lift and extrapolating this result to high lift coefficients by using experimental values of lift and drag at high lift coefficients. The method also includes the effect of geometric dihedral.

DATCOM METHOD

The variation of the wing-body rolling derivative C_{Y_p} with lift coefficient at subsonic speeds is obtained by using the method of paragraph A of Section 7.1.2.1. In using this method experimental values of wing-body lift and drag are used in evaluating the dimensionless correction factor K. This method is limited to configurations with body diameters less than about 30 percent of the wing span, i.e., $d/b \leqslant 0.3$.

If experimental wing-body lift and drag data are not available, wing-alone test data may be used. If experimental lift and drag data are not available, no attempt should be made to extrapolate the zero-lift value to higher lift coefficients. The negligible importance of the derivative does not warrant the complexities involved in estimating the lift and drag characteristics. Furthermore, no known general method for estimating the variation of the drag coefficient will give results reliable enough to use in determining the correction factor for extrapolating the potential-flow values to higher lift coefficients.

The sample problem presented at the conclusion of paragraph A of Section 7.1.2.1 illustrates the use of this method.

B. TRANSONIC

No generalized method is available in the literature for estimating transonic values of the rolling derivative C_{Y_p}. Furthermore, no known experimental results are available for this derivative at transonic speeds.

C. SUPERSONIC

No generalized method is available in the literature for estimating the effect of the fuselage on the rolling derivative C_{Y_p}.

For the purposes of the Datcom the fuselage effect is considered to be negligible for wing-body

configurations with body diameters less than about 30 percent of the wing span. Therefore, for configurations with d/b $\leqslant$ 0.3 the wing-body rolling derivative C_{Y_p} is estimated by the wing-alone method of paragraph C of Section 7.1.2.1.

No known experimental data are available for this derivative at supersonic speeds. Therefore, the validity of the Datcom application cannot be determined.

DATCOM METHOD

The wing-body rolling derivative C_{Y_p} at supersonic speeds and at low values of the lift coefficient is obtained by using the method of paragraph C of Section 7.1.2.1.

This method is limited to configurations with body diameters less than about 30 percent of the wing span, i.e., d/b $\leqslant$ 0.3.

The sample problem at the conclusion of paragraph C of Section 7.1.2.1 illustrates the use of this method.

7.3.2.2 WING-BODY ROLLING DERIVATIVE C_{l_p}

This section presents methods for estimating the wing-body contribution to the rolling derivative C_{l_p} at subsonic and supersonic speeds. This derivative is the change in rolling-moment coefficient with change in the wing-tip helix angle and is commonly referred to as the roll-damping derivative.

A. SUBSONIC

Experimental evidence indicates that in general for configurations with the ratio of maximum body diameter to wing span less than about 30 percent, i.e., $d/b \leq 0.3$, the effect of the fuselage on the roll damping is negligible over the angle-of-attack range up to the stall. Therefore, the method of Section 7.1.2.2 for estimating the wing-alone derivative at subsonic speeds is applied in this section to estimate the wing-body roll damping at subsonic speeds.

The method consists of first determining the value of C_{l_p} at zero lift based on simplified lifting-surface theory, then assuming that variations in the lift-curve slope will affect C_{l_p} in the same proportion as C_{L_α}, and finally accounting for the drag associated with the additional lift on the outer portion of the wing resulting from flow separation and the attendant formation of a stable leading-edge vortex. The method also accounts for geometric dihedral.

The Datcom method accounts for the variations in wing-body lift-curve slope, drag due to lift, profile drag, and the effect of dihedral. The method requires knowledge of the variation of lift and drag over the angle-of-attack range to the stall. Therefore, the method is quite readily applied if experimental lift and drag data are available.

This method is restricted to configurations with values of $d/b \leq 0.3$.

Although all the bodies of the wing-body configurations analyzed were bodies of circular cross section, the method should give reasonable values for configurations with noncircular cross-section bodies, provided reliable values of the wing-body lift-curve-slope variation are available.

DATCOM METHOD

The variation of the wing-body rolling derivative C_{l_p} with lift coefficient at subsonic speeds is obtained by using the method of Paragraph A of Section 7.1.2.2. In using this method experimental values of wing-body lift and drag are used in evaluating the variations of lift-curve slope and profile drag.

The limitations of the method as applied to wing-alone configurations are equally applicable to the method when applied to a wing-body configuration.

A comparison of the roll-damping derivative calculated by using this method with test results is presented as Table 7.3.2.2-A. Experimental values of wing-body lift and drag have been used in evaluating the roll-damping derivative of all the configurations listed in the table.

If test data for wing-body lift and drag are not available, the wing-alone result should be used for the wing-body roll damping of configurations with $d/b \leq 0.3$. In this case wing-alone test data are preferred, but if they are not available, the wing-alone lift and drag should be estimated as outlined in Section 7.1.2.2. The Datcom methods for estimating the wing-body lift and drag variations with angle of attack have not been substantiated and, therefore, should not be used in evaluating the wing-body roll damping.

The sample problem presented at the conclusion of Paragraph A of Section 7.1.2.2 illustrates the use of this method.

B. TRANSONIC

There are no reliable methods for estimating the derivative C_{l_p} in the transonic region. Although this derivative might be expected to vary with Mach number in the same manner as lift-curve slope, this trend is not exhibited by experimental data. A considerable quantity of wing-body test data is available, however, and reference should be made to Table 7-A.

C. SUPERSONIC

Reference 1 presents a linear-theory method for estimating the roll damping of thin supersonic-leading-edge triangular and rectangular wings mounted on cylindrical bodies. The roll damping of thin subsonic-leading-edge triangular wings mounted on cylindrical bodies is presented in Reference 2 based on slender-wing theory. These theoretical results show that for most of the range of variables the net effect of the body is to decrease the roll damping. The body effect is small for body diameters less than about 30 percent of the wing span ($d/b \leq 0.3$) for both triangular and rectangular wing configurations. However, the body effect increases rapidly as the ratio of body diameter to wing span increases beyond this value. Unfortunately, at the higher values of d/b the theory does not show the same trend with Mach number for the body effects of configurations with triangular and rectangular wings. At these higher values of d/b the body effect increases with increasing Mach number for configurations with rectangular wings; whereas, the body effect decreases with increasing Mach number for configurations with triangular wings. Therefore, at higher values of d/b the theoretical results for triangular and rectangular wings cannot be applied to indicate the general trend of the body effect for configurations with other planforms.

The Datcom uses a design chart, based on the theoretical results of References 1 and 2 and a limited amount of experimental data, to account for the effect of a circular body on the roll damping of a wing-body configuration at zero lift. This chart is applicable to all straight-tapered wing configurations at values of $d/b \leq 0.3$, but is restricted to triangular wing configurations at higher values of d/b.

DATCOM METHOD

The wing-body roll-damping derivative at supersonic speeds, based on the product of the wing area and the square of the wing span $S_W b_W^2$, is given by

$$\left(C_{l_p}\right)_{WB} = \left(C_{l_p}\right)_W \frac{C_{l_p}}{\left(C_{l_p}\right)_{d/b=0}} \quad \text{(per radian)} \qquad 7.3.2.2\text{-a}$$

where $(C_{l_p})_W$ is the wing contribution to the roll-damping derivative at supersonic speeds, obtained by using the method of Paragraph C of Section 7.1.2.2, including the effects of wing thickness, and

$\frac{C_{l_p}}{\left(C_{l_p}\right)_{d/b=0}}$ is the semiempirical body-correction factor obtained from Figure 7.3.2.2-13 as a function of the ratio of maximum body diameter to wing span and the Mach number normal to the leading edge.

Figure 7.3.2.2-13 is applicable to all straight-tapered wing configurations with circular bodies over the range $0 \leq d/b \leq 0.3$. For values of $d/b \geq 0.3$ this chart is applicable only to configurations consisting of triangular wings mounted on cylindrical bodies.

Experimental results reported in Reference 15 for triangular wing-body configurations with d/b = 0.4 and 0.6, and for subsonic, sonic, and supersonic leading edges, show good agreement with the values given by Figure 7.3.2.2-13.

No experimental data are presently available to substantiate the theoretical results of Reference 1 for rectangular wing-body configurations with values of $d/b > 0.3$.

As noted above, the triangular- and rectangular-wing results of References 1 and 2 at values of $d/b > 0.3$ cannot be used to indicate the general trend of the body effects for other planforms.

The supersonic roll-damping derivative in the linear-lift range calculated by this method is compared with test results in Table 7.3.2.2-B. Although all configurations listed in Table 7.3.2.2-B have cylindrical bodies, the method may be applied to configurations having bodies which are not true cylinders, but which are almost cylindrical.

Sample Problem

A triangular wing-body configuration of Reference 14.

$\Lambda_{LE} = 44.9^o$ $\quad \Lambda_{c/2} = 26.7^o$ $\quad A = 4.05$ $\quad \lambda = 0$

$d/b = 0.20$ $\quad M = 1.92 ; \beta = 1.639$

Airfoil: Hexagon, $\delta_\perp = 4.9^o$

Compute:

$\beta A = (1.639)(4.05) = 6.64$

$A \tan \Lambda_{c/2} = (4.05)(\tan 26.7^o) = 2.04$

$$\frac{\left(C_{l_p}\right)_{theory}}{A} = -0.0505 \text{ per rad} \qquad \text{(Figure 7.1.2.2-25a)}$$

$\beta \cot \Lambda_{LE} = (1.639)(\cot 44.9^o) = 1.642$ (supersonic leading edge)

$$\frac{\tan \Lambda_{LE}}{\beta} = \frac{\tan 44.9^o}{1.639} = 0.608$$

$$\frac{C_{l_p}}{\left(C_{l_p}\right)_{theory}} = 0.970 \qquad \text{(Figure 7.1.2.2-27)}$$

$$\frac{C_{l_p}}{(C_{l_p})_{d/b=0}} = 0.970 \qquad \text{(Figure 7.3.2.2-13)}$$

Solution:

$$(C_{l_p})_W = \left[\frac{(C_{l_p})_{theory}}{A}\right] A \frac{C_{l_p}}{(C_{l_p})_{theory}} \qquad \text{(Equation 7.1.2.2-d)}$$

$$= [-0.0505]\ (4.05)\ (0.970)$$

$$= -0.198 \text{ per rad}$$

$$(C_{l_p})_{WB} = (C_{l_p})_W \frac{C_{l_p}}{(C_{l_p})_{d/b=0}} \qquad \text{(Equation 7.3.2.2-a)}$$

$$= (-0.198)\ 0.970$$

$$= -0.192 \text{ per rad} \quad \text{(based on } S_W b_W^2\text{)}$$

This compares with a test value of −0.182 per radian from Reference 14.

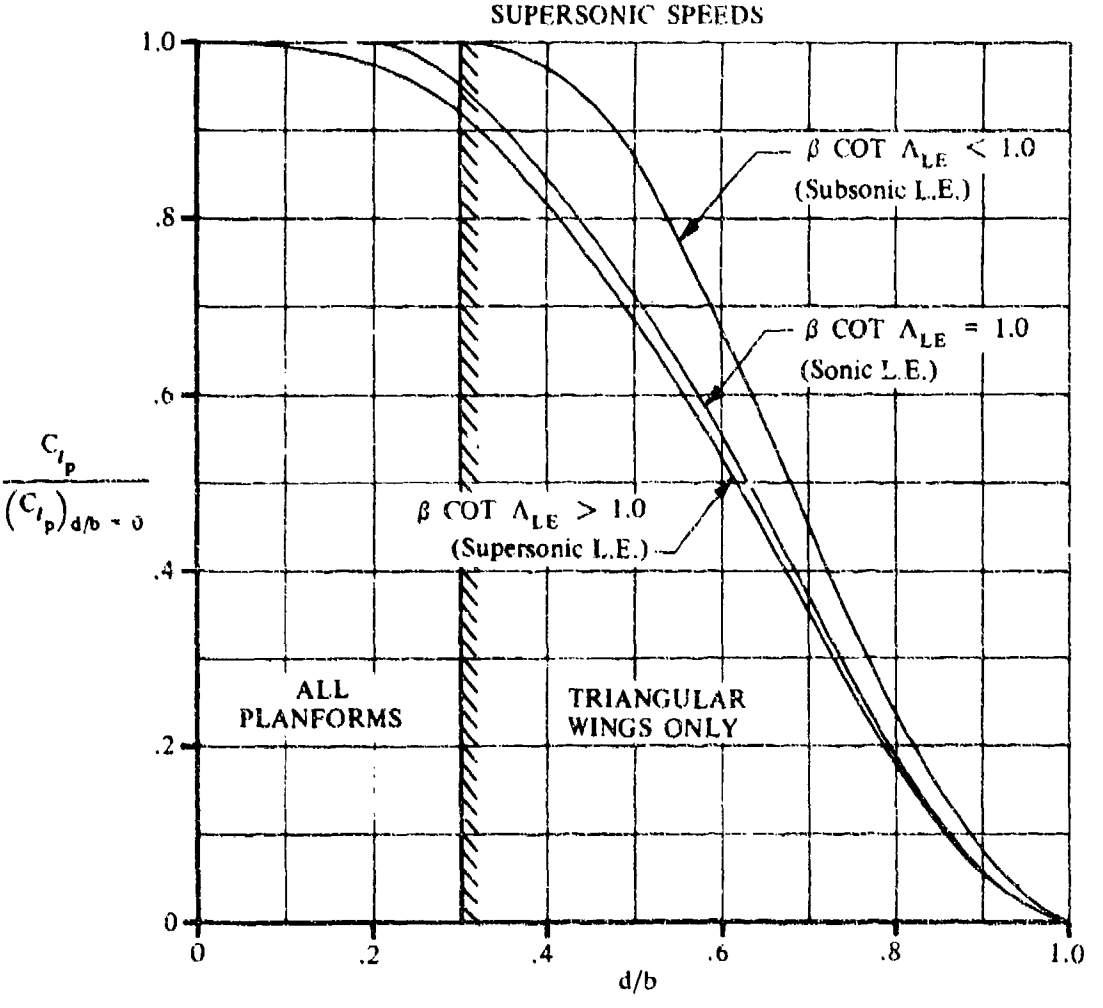

FIGURE 7.3.2.2-13 EFFECT OF THE FUSELAGE ON ROLL DAMPING

7.3.2.3 WING-BODY ROLLING DERIVATIVE C_{n_p}

This section presents methods for estimating the wing-body contribution to the rolling derivative C_{n_p} at subsonic and supersonic speeds. This derivative is the change in yawing-moment coefficient with change in wing-tip helix angle.

A. SUBSONIC

Experimental evidence indicates that the effect of the fuselage on the yawing moment due to rolling is negligible throughout the angle-of-attack range up to the stall. Therefore, the method of Section 7.1.2.3 for estimating the wing-alone derivative at subsonic speeds is also applicable to wing-body configurations. Available test data are limited to wing-body configurations with body diameters less than about 30 percent of the wing span. Therefore, the application of the wing-alone method is limited to values of $d/b \leqslant 0.3$.

The method consists of determining the value of C_{n_p} at zero lift and extrapolating the result to high lift coefficients by using experimental values of lift and drag at high lift coefficients. The method also includes the effects of wing twist and symmetric flap deflection.

DATCOM METHOD

The variation of the wing-body rolling derivative C_{n_p} with lift coefficient at subsonic speeds is obtained by using the method of Paragraph A of Section 7.1.2.3. In using this method experimental values of wing-body lift and drag are used in evaluating the dimensionless correction factor K. This method is limited to configurations with body diameters less than about 30 percent of the wing span, i.e., $d/b \leqslant 0.3$.

If experimental wing-body lift and drag data are not available, wing-alone test data may be used to determine the wing-body rolling derivative C_{n_p}. No attempt should be made to extrapolate the zero-lift value to higher lift coefficients using estimated lift and drag results. No known general method for estimating the variation of drag coefficient will give results reliable enough to use in determining the correction factor for extrapolating the potential-flow values to higher lift coefficients.

The sample problem at the conclusion of Paragraph A of Section 7.1.2.3 illustrates the use of this method.

B. TRANSONIC

No generalized method is available in the literature for estimating transonic values of the rolling derivative C_{n_p}. Furthermore, no known experimental results are available for this derivative at transonic speeds.

C. SUPERSONIC

No generalized method is available in the literature for estimating the effect of the fuselage on the rolling derivative C_{n_p} at supersonic speeds.

For the purpose of the Datcom the fuselage effect is considered to be negligible for wing-body configurations with body diameters less than about 30 percent of the wing span. Therefore, for

configurations with d/b $\leqslant$ 0.3 the wing-body rolling derivative C_{n_p} is estimated by the wing-alone method of Paragraph C of Section 7.1.2.3.

No known experimental data are available for this derivative at supersonic speeds. Therefore, the validity of the Datcom application cannot be determined.

DATCOM METHOD

The wing-body rolling derivative C_{n_p} at supersonic speeds in the range of lift coefficients for which C_{n_p} varies linearly with C_L is obtained by using the method of Paragraph C of Section 7.1.2.3.

This method is limited to configurations with body diameters less than about 30 percent of the wing span, i.e., d/b $\leqslant$ 0.3.

7.3.3 WING-BODY YAWING DERIVATIVES

7.3.3.1 WING-BODY YAWING DERIVATIVE C_{Y_r}

This section recommends methods for estimating the wing-body contribution to the yawing derivative C_{Y_r} at subsonic speeds. However, at subsonic, transonic, and supersonic speeds no generalized methods are available for estimating the wing-body contribution to the yawing derivative C_{Y_r}. This derivative is the change in side-force coefficient with variation in yawing velocity.

A. SUBSONIC

Experimental evidence indicates that the effect of the fuselage on the side force due to yawing is negligible throughout the angle-of-attack range up to the stall. Therefore, the recommendations of Section 7.1.3.1 for estimating the wing-alone derivative at subsonic speeds are also applicable to wing-body configurations.

The recommendations of Section 7.1.3.1 consist of using available experimental data, when applicable, or the method of reference 1 to estimate C_{Y_r}.

B. TRANSONIC

No generalized method is available in the literature for estimating transonic values of the wing-body contribution to the yawing derivative C_{Y_r}. Furthermore, there is a scarcity of experimental data for this derivative at transonic speeds.

C. SUPERSONIC

No generalized method is available in the literature for estimating supersonic values of the wing-body contribution to the yawing derivative C_{Y_r}. Furthermore, there is a scarcity of experimental data for this derivative at supersonic speeds.

REFERENCE

7.3.3.2 WING-BODY YAWING DERIVATIVE C_{l_r}

This section presents a method for estimating the wing-body contribution to the yawing derivative C_{l_r} at subsonic speeds. However, at transonic and supersonic speeds no generalized methods are available for estimating the wing-body contribution to the yawing derivative C_{l_r}. This derivative is the change in rolling-moment coefficient with change in the yawing velocity.

A. SUBSONIC

Experimental evidence indicates that the effect of the fuselage on the rolling moment due to yawing is negligible. Therefore, the method of Section 7.1.3.2 for estimating the wing-alone derivative at subsonic speeds is also applicable to wing-body configurations. Available test data are limited to wing-body configurations with body diameters less than about 30 percent of the wing span. Consequently, the application of the wing-alone method to estimate the wing-body contribution to C_{l_r} is limited to values of $d/b \leq 0.3$.

DATCOM METHOD

The variation of the wing-body yawing derivative C_{l_r} is obtained by using the method of Section 7.1.3.2. The method consists of determining the value of C_{l_r} at zero lift and extending this value to high lift coefficients by using a semiempirical correction factor and test data for C_{l_β}. The method also includes the effect of geometric dihedral, wing twist, and flap deflection. The method is limited to configurations with body diameters less than about 30 percent of the wing span; i.e., $d/b \leq 0.3$.

The sample problem presented at the conclusion of paragraph A of Section 7.1.3.2 illustrates the use of this method.

B. TRANSONIC

No generalized method is available in the literature for estimating transonic values of the wing-body contribution to the yawing derivative C_{l_r}. Furthermore, there is a scarcity of experimental data for this derivative at transonic speeds.

C. SUPERSONIC

No generalized method is available in the literature for estimating supersonic values of the wing-body contribution to the yawing derivative C_{l_r}. Furthermore, there is a scarcity of experimental data for this derivative at supersonic speeds.

7.3.3.3 WING-BODY YAWING DERIVATIVE C_{n_r}

This section presents a method for estimating the wing-body contribution to the yawing derivative C_{n_r} at subsonic speeds. However, at transonic and supersonic speeds no generalized methods are available for estimating the wing-body contribution to the yawing derivative C_{n_r}. This derivative is the change in yawing-moment coefficient with change in the yawing-velocity parameter and is commonly referred to as the yaw damping.

A. SUBSONIC

In general, the wing-fuselage contribution to damping in yaw is small in comparison to the vertical-tail contribution. The contribution from the fuselage depends upon the relative size of the fuselage in comparison to the wing. For configurations in which the fuselage is large relative to the wing, the fuselage contribution is important. Fuselages having flat sides or having a flattened cross section with the major axis vertical can also make a significant contribution (reference 1). Experimental data have also shown that a flattened cross-section fuselage with the major axis horizontal can have negative damping in yaw at moderate and high angles of attack.

No generalized method exists in the literature for predicting the fuselage contribution to yaw damping. Therefore, for the purposes of the Datcom, fuselage effects are considered to be negligible. Consequently, the Datcom method of Section 7.1.3.3 for estimating the wing-alone derivative at subsonic speeds is also applicable to wing-body configurations.

DATCOM METHOD

The estimated value of the wing-body yawing derivative C_{n_r} is obtained by using the method of Section 7.1.3.3. In using this method experimental values of wing profile drag coefficient, evaluated at the appropriate Mach number, are used in conjunction with the lift coefficient. These coefficients are used to evaluate the two major contributions to C_{n_r}; namely, that resulting from the drag due to lift and that resulting from the profile drag. The method does not account for the effects of wing flaps, wing twist, or wing dihedral.

The sample problem presented at the conclusion of paragraph A of Section 7.1.3.3 illustrates the use of this method.

B. TRANSONIC

No generalized method is available in the literature for estimating transonic values of the wing-body contribution to the yawing derivative C_{n_r}. Furthermore, there is a scarcity of experimental data for this derivative at transonic speeds.

C. SUPERSONIC

No generalized method is available in the literature for estimating supersonic values of the wing-body contribution to the yawing derivative C_{n_r}. Furthermore, there is a scarcity of experimental data for this derivative at supersonic speeds.

7.3.4 WING-BODY ACCELERATION DERIVATIVES

7.3.4.1 WING-BODY ACCELERATION DERIVATIVE $C_{L_{\dot{\alpha}}}$

The information contained in this section is for estimating the acceleration derivative $C_{L_{\dot{\alpha}}}$ of wing-body configurations at low angles of attack. In general, it consists of a synthesis of material presented in other sections; however, the method of application is new.

Datcom methods are based on the relatively simple results derived from slender-body theory in a manner similar to that used to predict the wing-body pitching derivatives. It is assumed that the mutual interferences that occur between components for angle-of-attack variations, determined in references 1 and 2 and presented in Section 4.3.1.2, may be applied with reasonable accuracy to the case of normal acceleration. This approach to the calculation of wing-body acceleration derivatives has been applied with reasonable success by Walker and Wolowicz in reference 3.

A. SUBSONIC

Two methods are presented for determining the acceleration derivative $C_{L_{\dot{\alpha}}}$ of a wing-body configuration, differing only in their treatment of the mutual interference effects.

DATCOM METHODS

Method 1

For wing-body configurations similar to sketch (d) of Section 4.3.1.2, the acceleration derivative $C_{L_{\dot{\alpha}}}$, based on the area and mean aerodynamic chord of the total panel, is given by

$$\left(C_{L_{\dot{\alpha}}}\right)_{WB} = [K_{W(B)} + K_{B(W)}] \left(\frac{S_e}{S}\right)\left(\frac{\bar{c}_e}{\bar{c}}\right)\left(C_{L_{\dot{\alpha}}}\right)_e + \left(C_{L_{\dot{\alpha}}}\right)_B \left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right) \qquad 7.3.4.1\text{-a}$$

where

$\left(C_{L_{\dot{\alpha}}}\right)_e$ is the contribution of the exposed panel to the acceleration derivative $C_{L_{\dot{\alpha}}}$, obtained from Section 7.1.4.1. (See Section 4.3.1.2 for the definition of exposed surfaces.)

$\left(C_{L_{\dot{\alpha}}}\right)_B$ is the contribution of the body to the acceleration derivative $C_{L_{\dot{\alpha}}}$, obtained from Section 7.2.2.1.

The remaining terms are defined in paragraph A of Section 7.3.1.1.

Method 2

For wing-body configurations similar to sketch (c) of Section 4.3.1.2, the acceleration derivative $C_{L_{\dot{\alpha}}}$, based on the area and mean aerodynamic chord of the total panel, is given by

$$\left(C_{L_{\dot{\alpha}}}\right)_{WB} = K_{(WB)}\left(C_{L_{\dot{\alpha}}}\right)_{W} + \left(C_{L_{\dot{\alpha}}}\right)_{B}\left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right) \qquad 7.3.4.1\text{-b}$$

where $\left(C_{L_{\dot{\alpha}}}\right)_W$ is the contribution of the total panel to the acceleration derivative $C_{L_{\dot{\alpha}}}$, obtained from Section 7.1.4.1, and the remaining terms are defined in paragraph A of Section 7.3.1.1 and method 1 above.

Sample Problem

Method 1

Given: Same configuration as sample problems of paragraph A, Sections 7.3.1.1 and 7.3.1.2. Some of the characteristics are repeated below.

The following ratios based on total panel dimensions:

$$\frac{S_e}{S} = 0.7113 \qquad \frac{\bar{c}_e}{\bar{c}} = 0.845 \qquad \frac{S_b}{S} = 0.0963 \qquad \frac{\ell_B}{\bar{c}} = 6.363$$

Additional Characteristics:

$$M = 0.60 \qquad \beta = 0.80 \qquad A_e = 5.0 \qquad \frac{d}{b} = 0.157 \qquad \ell_B = 77.2 \text{ ft}$$

Compute:

Step 1. Acceleration derivative $C_{L_{\dot{\alpha}}}$ for exposed panel (Section 7.1.4.1)

$$\left.\begin{aligned}\left(\frac{x_{a.c.}}{c_r}\right)_e &= 0.560\\ \left(C_{L_\alpha}\right)_e &= 4.50 \text{ per rad}\end{aligned}\right\} \text{ (sample problem, paragraph A, Section 7.3.1.1)}$$

$$\beta A_e = 4.0$$

$$\frac{-\beta^2 C_L(g)}{\pi A/2} = 0.140 \text{ per rad} \quad \text{(figure 7.1.4.1-6)}$$

$$C_L(g) = -1.718 \text{ per rad}$$

$$\left(C_{L_{\dot{\alpha}}}\right)_e = 1.5\left(\frac{x_{a.c.}}{c_r}\right)_e \left(C_{L_\alpha}\right)_e + 3\,C_L(g) \quad \text{(equation 7.1.4.1-a)}$$

$$= (1.5)\,(0.560)\,(4.50) + 3(-1.718)$$

$$= 3.780 - 5.154$$

$$= -1.374 \text{ per rad (based on } S_e \bar{c}_e)$$

Step 2. Wing-body interference factors (Section 4.3.1.2)

$K_{W(B)} = 1.125$

$K_{B(W)} = 0.215$

} (sample problem, paragraph A, Section 7.3.1.1)

Step 3. Acceleration derivative $C_{L_{\dot{\alpha}}}$ for body (Section 7.2.2.1)

$V_B = 2615.1$ cu ft

$S_b = 39.88$ sq ft

$\left(C_{L_\alpha}\right)_B = 1.894$ per rad (based on S_b)

} (sample problem, paragraph A, Section 7.3.1.1)

$$\left(\frac{V_B}{S_b \ell_B}\right) = \frac{2615.1}{(39.88)\,(77.20)} = 0.849$$

$$\left(C_{L_{\dot{\alpha}}}\right)_B = 2\left(C_{L_\alpha}\right)_B \left(\frac{V_B}{S_b \ell_B}\right) \quad \text{(equation 7.2.2.1-a)}$$

$$= 2(1.894)\,(0.849)$$

$$= 3.216 \text{ per rad (based on } S_b \ell_B)$$

Solution:

$$\left(C_{L_{\dot{\alpha}}}\right)_{WB} = [K_{W(B)} + K_{B(W)}]\left(\frac{S_e}{S}\right)\left(\frac{\bar{c}_e}{\bar{c}}\right)\left(C_{L_{\dot{\alpha}}}\right)_e + \left(C_{L_{\dot{\alpha}}}\right)_B \left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right)$$

(equation 7.3.4.1-a)

$$= (1.125 + 0.215)\,(0.7113)\,(0.845)\,(-1.374) + (3.216)\,(0.0963)\,(6.363)$$

$= -1.107 + 1.971$

$= 0.864$ per rad (based on the area and mean aerodynamic chord of the total panel)

B. TRANSONIC

The aerodynamic interference effects for slender wing-body configurations are relatively insensitive to Mach number; consequently, the slender-body interference factors of Section 4.3.1.2 should give reasonable results. For nonslender configurations transonic interference effects can become quite large and sensitive to minor changes in local contour.

DATCOM METHODS

It is recommended that the methods presented in paragraph A for estimating the acceleration derivative $C_{L_{\dot{\alpha}}}$ of a wing-body configuration be applied to the transonic speed range. Care should be taken to estimate the contributions of the lifting panel and body at the appropriate Mach number. The interference factors should be obtained from paragraph C, Section 4.3.1.2.

C. SUPERSONIC

The information included in the Datcom accounts for most of the mutual interferences that occur between components of a wing-body configuration at supersonic speeds. These interference effects are accounted for by the slender-body interference factors of Section 4.3.1.2.

DATCOM METHODS

The methods presented in paragraph A for estimating the acceleration derivative $C_{L_{\dot{\alpha}}}$ of a wing-body configuration are also applicable to the supersonic speed range. Care should be taken to estimate the contributions to the lifting panel and body at the appropriate Mach number.

Sample Problem

Method 1

Given: Same configuration as sample problems of paragraph C, Sections 7.3.1.1 and 7.3.1.2, and paragraph A of this section.

$M = 1.4$ $\beta = 0.98$ $\frac{d}{b} = 0.157$

Compute:

Step 1. Acceleration derivative $C_{N_{\dot{\alpha}}}$ for exposed panel (Section 7.1.4.1)

$\beta \cot \Lambda_{LE} = 1.225$ (supersonic leading edge)

$\beta A_e = 4.90$

$\cot^{-1} (\beta \cot \Lambda_{LE}) = 39.23°$

} (sample problem, paragraph C, Section 7.3.1.1)

$\beta \left[\left(C_{N_{\dot{\alpha}}}\right)_1\right]_e = 0$ (figure 7.1.4.1-11a)

$\left[\left(C_{N_{\dot{\alpha}}}\right)_1\right]_e = 0$

$\beta\left[\left(C_{N_{\dot{\alpha}}}\right)_2\right]_e = 4.00$ (figure 7.1.4.1-11c)

$\left[\left(C_{N_{\dot{\alpha}}}\right)_2\right]_e = 4.08$ per rad

$$\left(C_{N_{\dot{\alpha}}}\right)_e = \left(\frac{M^2}{\beta^2}\right)\left[\left(C_{N_{\dot{\alpha}}}\right)_1\right]_e - \left(\frac{1}{\beta^2}\right)\left[\left(C_{N_{\dot{\alpha}}}\right)_2\right]_e \text{ (equation 7.1.4.1-c)}$$

$$= \left(\frac{1.4}{0.98}\right)^2 (0) - \left[\frac{1}{(0.98)^2}\right](4.08)$$

$= -4.25$ per rad (based on $S_e \bar{c}_e$)

Step 2. Wing-body interference factors (Section 4.3.1.2)

$K_{W(B)} = 1.125$

$K_{B(W)} = 0.181$

} (sample problem, paragraph C, Section 7.3.1.1)

Step 3. Acceleration derivative $C_{N_{\dot{\alpha}}}$ for body (Section 7.2.2.1)

$$\frac{V_B}{S_b \ell_B} = 0.849 \text{ (sample problem, paragraph A)}$$

$\left(C_{N_\alpha}\right)_B = 2.74$ per rad (sample problem, paragraph C, Section 7.3.1.1)

$$\left(C_{N_{\dot{\alpha}}}\right)_B = 2\left(C_{N_\alpha}\right)_B \left(\frac{V_B}{S_b \ell_B}\right) \quad \text{(equation 7.2.2.1-a)}$$

$$= 2(2.74)\,(0.849)$$

$$= 4.653 \text{ per rad (based on } S_b \ell_B)$$

Solution:

$$\left(C_{N_{\dot{\alpha}}}\right)_{WB} = [K_{W(B)} + K_{B(W)}] \left(\frac{S_e}{S}\right)\left(\frac{\bar{c}_e}{\bar{c}}\right)\left(C_{N_{\dot{\alpha}}}\right)_e + \left(C_{N_{\dot{\alpha}}}\right)_B \left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right)$$

(equation 7.3.4.1-a)

$$= (1.125 + 0.181)\,(0.7113)\,(0.845)\,(-4.25) + (4.653)\,(0.0963)\,(6.363)$$

$$= -3.336 + 2.851$$

$$= -0.485 \text{ per rad (based on the area and mean aerodynamic chord of the total panel)}$$

7.3.4.2 WING-BODY ACCELERATION DERIVATIVE $C_{m_{\dot{\alpha}}}$

The information contained in this section is for estimating the acceleration derivative $C_{m_{\dot{\alpha}}}$ of wing-body configurations at low angles of attack.

The Datcom methods are based on the same assumption that was made in regard to the acceleration derivative $C_{L_{\dot{\alpha}}}$ of a wing-body configuration, and the general discussion of Section 7.3.4.1 is directly applicable here.

A. SUBSONIC

Two methods are presented for determining the acceleration derivative $C_{m_{\dot{\alpha}}}$ of a wing-body configuration, differing only in their treatment of the mutual interference effects.

DATCOM METHODS

Method 1

For wing-body configurations similar to sketch (d) of Section 4.3.1.2, the acceleration derivative $C_{m_{\dot{\alpha}}}$, based on the area and the square of the mean aerodynamic chord of the total panel and referred to a moment center at the assumed center of gravity, is given by

$$\left(C_{m_{\dot{\alpha}}}\right)_{WB} = [K_{W(B)} + K_{B(W)}] \left(\frac{S_e}{S}\right)\left(\frac{\bar{c}_e}{\bar{c}}\right)^2 \left(C_{\bar{m}_{\dot{\alpha}}}\right)_e + \left(C_{m_{\dot{\alpha}}}\right)_B \left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right)^2 \qquad 7.3.4.2\text{-a}$$

where

$\left(C_{m_{\dot{\alpha}}}\right)_e$ is the contribution of the exposed panel to the acceleration derivative $C_{m_{\dot{\alpha}}}$, obtained from Section 7.1.4.2. (See Section 4.3.1.2 for the definition of exposed surfaces.)

$\left(C_{m_{\dot{\alpha}}}\right)_B$ is the contribution of the body to the acceleration derivative $C_{m_{\dot{\alpha}}}$, obtained from Section 7.2.2.2.

The remaining terms are defined in paragraph A of Section 7.3.1.1. Moment transfer calculations are included as an integral part of the wing- and body-derivative estimation methods of Sections 7.1.4.2 and 7.2.2.2, respectively.

Method 2

For wing-body configurations similar to sketch (c) of Section 4.3.1.2, the acceleration derivative $C_{m_{\dot{\alpha}}}$, based on the area and the square of the mean aerodynamic chord of the total panel and referred to a moment center at the assumed center of gravity, is given by

$$\left(C_{m_{\dot{\alpha}}}\right)_{WB} = K_{(WB)} \left(C_{m_{\dot{\alpha}}}\right)_W + \left(C_{m_{\dot{\alpha}}}\right)_B \left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right)^2 \qquad 7.3.4.2\text{-b}$$

where $(C_{m_{\dot{\alpha}}})_W$ is the contribution of the total panel to the acceleration derivative $C_{m_{\dot{\alpha}}}$, and the remaining terms are defined in paragraph A of Section 7.3.1.1 and method 1 above. Moment transfer calculations are included as an integral part of the wing- and body-derivative estimation methods of Sections 7.1.4.2 and 7.2.2.2, respectively.

Sample Problem

Method 1

Given: Same configuration as sample problems of paragraph A, Sections 7.3.1.1, 7.3.1.2, and 7.3.4.1. Some of the characteristics are repeated below.

The following ratios based on total panel dimensions:

$$\frac{S_e}{S} = 0.7113 \qquad \left(\frac{\bar{c}_e}{\bar{c}}\right)^2 = 0.7140 \qquad \frac{c_{r_e}}{\bar{c}_e} = 1.50$$

$$\frac{S_b}{S} = 0.0963 \qquad \left(\frac{\ell_B}{\bar{c}}\right)^2 = 40.49$$

Additional Characteristics:

$$M = 0.60 \qquad A_e = 5.0 \qquad \frac{d}{b} = 0.157 \qquad \ell_B = 77.20 \text{ ft}$$

$$\beta = 0.80 \qquad x_m = 43.70 \text{ ft (moment center at } \bar{c}/4 \text{ of total panel)}$$

Compute:

Step 1. Acceleration derivative $C_{m_{\dot{\alpha}}}$ for exposed panel (Section 7.1.4.2)

$$\left.\begin{aligned} \left(\frac{x_{a.c.}}{c_r}\right)_e &= 0.560 \\ \left(\frac{x_{c.g.}}{c_r}\right)_e &= 0.408 \\ \left(C_{L_\alpha}\right)_e &= 4.50 \text{ per rad} \end{aligned}\right\} \text{(sample problem, paragraph A, Section 7.3.1.1)}$$

$$\left(\frac{x_{c.g.}}{\bar{c}}\right)_e = \left(\frac{x_{c.g.}}{c_r}\right)_e \left(\frac{c_{r_e}}{\bar{c}_e}\right) = (0.408)\,(1.50) = 0.612$$

$\left(C_{L_{\dot{\alpha}}}\right)_e = -1.374$ per rad (sample problem, paragraph A, Section 7.3.4.1)

$\beta A_e = 4.0$

$\dfrac{\beta^2 C_{m_0}(g)}{\pi A/2} = 0.0767$ per rad (figure 7.1.4.2-8)

$C_{m_0}(g) = 0.941$ per rad

$$\left(C_{m_{\dot{\alpha}}}''\right)_e = -\frac{27}{16}\left(\frac{x_{a.c.}}{c_r}\right)^2 \left(C_{L_\alpha}\right)_e + 3C_{m_0}(g) \quad \text{(equation 7.1.4.2-b)}$$

$$= -\frac{27}{16}\,(0.560)^2\,(4.50) + 3(0.941)$$

$$= -2.381 + 2.823$$

$$= 0.442 \text{ per rad}$$

$$\left(C_{m_{\dot{\alpha}}}\right)_e = \left(C_{m_{\dot{\alpha}}}''\right)_e + \left(\frac{x_{c.g.}}{\bar{c}}\right)_e \left(C_{L_{\dot{\alpha}}}\right)_e \quad \text{(equation 7.1.4.2-a)}$$

$$= 0.442 + (0.612)\,(-1.374)$$

$$= -0.399 \text{ per rad (based on } S_e \bar{c}_e{}^2)$$

Step 2. Wing-body interference factors (Section 4.3.1.2)

$K_{W(B)} = 1.125$

$K_{B(W)} = 0.215$

} (sample problem, paragraph A, Section 7.3.1.1)

Step 3. Acceleration derivative $C_{m_{\dot{\alpha}}}$ for body (Section 7.2.2.2)

$$\frac{V_B}{S_b \ell_B} = 0.849$$

$$\left(1 - \frac{x_m}{\ell_B}\right) = 0.434$$

$$x_c = 44.48 \text{ ft}$$

$$\left(C_{m_\alpha}\right)_B = 0.794 \text{ per rad}$$

} (sample problem, paragraph A, Section 7.3.1.2)

$$\left(C_{m_{\dot{\alpha}}}\right)_B = 2\left(C_{m_\alpha}\right)_B \left[\frac{\frac{V_B}{S_b \ell_B}\left(\frac{x_c}{\ell_B} - \frac{x_m}{\ell_B}\right)}{\left(1 - \frac{x_m}{\ell_B}\right) - \frac{V_B}{S_b \ell_B}}\right] \quad \text{(equation 7.2.2.2-a)}$$

$$= 2(0.794)\left[\frac{0.849\left(\frac{44.48 - 43.70}{77.20}\right)}{0.434 - 0.849}\right]$$

$$= 1.59\left[\frac{(0.849)(0.0101)}{-0.415}\right]$$

$$= -0.0328 \text{ per rad (based on } S_b \ell_B{}^2)$$

Solution:

$$\left(C_{m_{\dot{\alpha}}}\right)_{WB} = \left[K_{W(B)} + K_{B(W)}\right]\left(\frac{S_e}{S}\right)\left(\frac{\bar{c}_e}{\bar{c}}\right)^2\left(C_{m_{\dot{\alpha}}}\right)_e + \left(C_{m_{\dot{\alpha}}}\right)_B\left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right)^2$$

(equation 7.3.4.2-a)

$$= (1.125 + 0.215)(0.7113)(0.7140)(-0.399) + (-0.0328)(0.0963)(40.49)$$

$$= -0.272 - 0.128$$

= −0.400 per rad (based on the area and the square of the mean aerodynamic chord of the total panel and referred to a moment center at $\bar{c}/4$ of the total panel)

B. TRANSONIC

The comments of paragraph B of Section 7.3.4.1 are directly applicable here.

DATCOM METHODS

It is recommended that the methods presented in paragraph A for estimating the acceleration derivative $C_{m_{\dot{\alpha}}}$ of a wing-body configuration be applied to the transonic speed regime. Care should be taken to estimate the contributions of the lifting panel and body at the appropriate Mach number. The interference factors should be obtained from paragraph C, Section 4.3.1.2.

C. SUPERSONIC

The comments of paragraph C of Section 7.3.4.1 are directly applicable here.

DATCOM METHODS

The methods presented in paragraph A for estimating the acceleration derivative $C_{m_{\dot{\alpha}}}$ of a wing-body configuration are also applicable to the supersonic speed range. Care should be taken to estimate the contributions of the lifting panel and body at the appropriate Mach number.

Sample Problem

Method 1

Given: Same configuration as sample problems of paragraph C, Sections 7.3.1.1, 7.3.1.2, and 7.3.4.1, and paragraph A of this section

$M = 1.4$ $\beta = 0.98$ $\frac{d}{b} = 0.157$

Compute:

Step 1. Acceleration derivative $C_{m_{\dot{\alpha}}}$ for exposed panel (Section 7.1.4.2)

$\beta \cot \Lambda_{LE} = 1.225$ (supersonic leading edge)

$\cot^{-1} (\beta \cot \Lambda_{LE}) = 39.23°$

$\beta A_e = 4.90$

} (sample problem, paragraph C, Section 7.3.1.1)

$$\left(\frac{x_{c.g.}}{\bar{c}}\right)_e = 0.612 \quad \text{(sample problem, paragraph A)}$$

$$\left(C_{N_{\dot{\alpha}/e}}\right) = -4.25 \text{ per rad} \quad \text{(sample problem, paragraph C, Section 7.3.4.1)}$$

$$\beta\left[\left(C_{m_{\dot{\alpha}}}\right)_1\right]_e = 9.05 \quad \text{(figure 7.1.4.2-13a)}$$

$$\left[\left(C_{m_{\dot{\alpha}}}\right)_1\right]_e = 9.235 \text{ per rad}$$

$$\beta\left[\left(C_{m_{\dot{\alpha}}}\right)_2\right]_e = -4.52 \quad \text{(figure 7.1.4.2-13c)}$$

$$\left[\left(C_{m_{\dot{\alpha}}}\right)_2\right]_e = -4.612 \text{ per rad}$$

$$\left(C_{m_{\dot{\alpha}}''}\right)_e = \left(\frac{M^2}{\beta^2}\right)\left[\left(C_{m_{\dot{\alpha}}}\right)_1\right]_e + \left(\frac{M^2}{\beta^2} + 1\right)\left[\left(C_{m_{\dot{\alpha}}}\right)_2\right]_e \quad \text{(equation 7.1.4.2-e)}$$

$$= \left(\frac{1.4}{0.98}\right)^2 (9.235) + \left(\frac{1.4^2}{0.98^2} + 1\right)(-4.612)$$

$$= 18.85 - 14.03$$

$$= 4.82 \text{ per rad}$$

$$\left(C_{m_{\dot{\alpha}}}\right)_e = \left(C_{m_{\dot{\alpha}}''}\right)_e + \left(\frac{x_{c.g.}}{\bar{c}}\right)_e \left(C_{L_{\dot{\alpha}}}\right)_e \quad \text{(equation 7.1.4.2-a)}$$

$$= 4.82 + (0.612)(-4.25) \qquad \left(C_{N_{\dot{\alpha}}} \text{ is assumed to be equal to } C_{L_{\dot{\alpha}}}\right)$$

$$= 2.219 \text{ per rad} \quad \left(\text{based on } S_e \bar{c}_e^{\,2}\right)$$

Step 2. Wing-body interference factors (Section 4.3.1.2)

$$\left.\begin{aligned} K_{W(B)} &= 1.125 \\ K_{B(W)} &= 0.181 \end{aligned}\right\} \text{(sample problem, paragraph C, Section 7.3.1.1)}$$

Step 3. Acceleration derivative $C_{m_{\dot{\alpha}}}$ for body (Section 7.2.2.2)

$$\left.\begin{aligned} \frac{V_B}{S_b \ell_B} &= 0.849 \\ \left(1 - \frac{x_m}{\ell_B}\right) &= 0.434 \\ x_c &= 44.48 \text{ ft} \end{aligned}\right\} \text{(sample problem, paragraph A, Section 7.3.1.2)}$$

$\left(C_{m_\alpha}\right)_B = 1.017$ per rad (sample problem, paragraph C, Section 7.3.1.2)

$$\left(C_{m_{\dot{\alpha}}}\right)_B = 2\left(C_{m_\alpha}\right)_B \left[\frac{\frac{V_B}{S_b \ell_B}\left(\frac{x_c}{\ell_B} - \frac{x_m}{\ell_B}\right)}{\left(1 - \frac{x_m}{\ell_B}\right) - \frac{V_B}{S_b \ell_B}}\right] \quad \text{(equation 7.2.2.2-a)}$$

$$= 2(1.017)\left[\frac{(0.849)\left(\frac{44.48 - 43.70}{77.20}\right)}{0.434 - 0.849}\right]$$

$$= 2.034\left[\frac{(0.849)\,(0.0101)}{-0.415}\right]$$

$$= -0.0420 \text{ per rad (based on } S_b \ell_B{}^2)$$

Solution:

$$\left(C_{m_{\dot{\alpha}}}\right)_{WB} = \left[K_{W(B)} + K_{B(W)}\right]\left(\frac{S_e}{S}\right)\left(\frac{\bar{c}_e}{\bar{c}}\right)^2 \left(C_{m_{\dot{\alpha}}}\right)_e + \left(C_{m_{\dot{\alpha}}}\right)_B \left(\frac{S_b}{S}\right)\left(\frac{\ell_B}{\bar{c}}\right)^2$$

(equation 7.3.4.2-a)

$$= (1.125 + 0.181)\,(0.7113)\,(0.7140)\,(2.219) + (-0.0420)\,(0.0963)\,(40.49)$$

$$= 1.472 - 0.164$$

$$= 1.308 \text{ per rad}$$ (based on the area and the square of the mean aerodynamic chord of the total panel and referred to a moment center at $\bar{c}/4$ of the total panel)

7.4 WING-BODY-TAIL DYNAMIC DERIVATIVES

7.4.1 WING-BODY-TAIL PITCHING DERIVATIVES

7.4.1.1 WING-BODY-TAIL PITCHING DERIVATIVE C_{L_q}

The information contained in this section is for estimating the nondimensional pitching derivative C_{L_q} of wing-body-tail combinations at low angles of attack. This derivative represents the lift due to pitching velocity at a constant angle of attack and is defined as

$$C_{L_q} = \frac{\partial C_L}{\partial\left(\frac{q\bar{c}}{2V_\infty}\right)}$$

In general, the methods presented consist of a synthesis of material presented in other sections, although some new information is presented.

The derivative is presented in a manner similar to that used in reference 1 to calculate the lift of a wing-body-tail combination. The complete derivative is the sum of contributions of individual components, treated as isolated surfaces or bodies, and mutual interference effects. The mutual interference effects are assumed to correspond to those due to angle-of-attack variations, established in references 1 and 2 and presented in Section 4.3.1.2.

The horizontal-tail contribution to the derivative C_{L_q} is based on the assumption that instantaneous forces on the tail correspond to the instantaneous angle of attack. This assumption is also the basis used in estimating the horizontal-tail contribution to the derivative C_{m_q} in Section 7.4.1.2. The effect of this assumption is presented in numerous aerodynamic texts, for example, reference 3. The effects of C_{L_q} are generally small and frequently neglected in dynamic analyses.

A. SUBSONIC

Two methods are presented for determining the pitching derivative C_{L_q} of wing-body-tail combinations, differing only in their treatment of the effect of the flow field of the forward surface on the aft surface.

DATCOM METHODS

Method 1: $(b'/b'' \geq 1.5)$

For configurations in which the span of the forward surface is large compared to that of the aft surface, the following approach can be used. This method is to be used when the ratio of the forward-panel span to the aft-panel span is 1.5 or greater. The equation of the nondimensional pitching derivative C_{L_q} of a wing-body-tail configuration, based on the area and mean

aerodynamic chord of the total forward panel and referred to a moment center at the assumed center of gravity or center of rotation, is given by

$$C_{L_q} = \left(C_{L_q}\right)_{WB} + 2\left[K_{W(B)} + K_{B(W)}\right]'' \left(\frac{S_e''}{S'}\right)\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)\left(\frac{q''}{q_\infty}\right)\left(C_{L_\alpha}\right)_e'' \qquad 7.4.1.1\text{-a}$$

where the primed quantities refer to the forward panel, the double-primed quantities refer to the aft panel, and the subscript e refers to the exposed panel. (See Section 4.3.1.2 for the definition of exposed surfaces.)

$\left(C_{L_q}\right)_{WB}$ is the contribution of the wing-body configuration to the pitching derivative C_{L_q}, obtained from Section 7.3.1.1.

$\left[K_{W(B)} + K_{B(W)}\right]''$ is the appropriate wing-body interference factor obtained from Section 4.3.1.2 for the aft panel.

$\left(C_{L_\alpha}\right)_e''$ is the lift-curve slope of the exposed aft panel, obtained from Section 4.1.3.2.

$\frac{S_e''}{S'}$ is the ratio of the exposed aft panel planform area to the total planform area of the forward panel.

$x_{c.g.} - x''$ is the distance parallel to the longitudinal axis between the moment reference center (usually the vehicle center of gravity) and the quarter-chord point of the mean aerodynamic chord of the total aft horizontal panel.

This parameter is approximated in Section 4.5.2.1 as $x_{c.g.} - x'' = \ell'' + x_{c.g.}$ (equation 4.5.2.1-e) where $x_{c.g.}$ and ℓ'' are defined in figures 4.5.2.1-7a and -7b.

$\frac{q''}{q_\infty}$ is the average dynamic-pressure ratio acting on the aft surface, obtained from Section 4.4.1.

Method 2. ($b'/b'' < 1.5$)

For configurations in which the span of the forward surface is approximately equal to or less than that of the aft surface, the vortex shed from the forward surface interacts directly with the aft surface and the resulting interference effects must be accounted for in the tail terms. This method is to be used when the ratio of the forward-panel span to the aft-panel span is less than 1.5. The equation for the nondimensional pitching derivative C_{L_q} of a wing-body-tail configuration, based on the area and mean aerodynamic chord of the total forward panel and referred to a moment center at the assumed center of gravity or center of rotation, is given by

$$C_{L_q} = \left(C_{L_q}\right)_{WB} + 2.\frac{x_{c.g.} - x''}{\bar{c}'}\left\{\left[K_{W(B)} + K_{B(W)}\right]''\left(\frac{S_e''}{S'}\right)\left(\frac{q''}{q_\infty}\right)\left(C_{L_\alpha}\right)_e'' + \left(C_{L_\alpha}\right)_{W''(v)}\right\}$$

7.4.1.1-b

The parameters in the first two terms on the right-hand side are the same as those in equation 7.4.1.1-a. The last term represents the effect of the forward-panel vortices on the aft panel and is given by

$$\left(C_{L_\alpha}\right)_{W''(v)} = \frac{\left(C_{L_\alpha}\right)_e'\left(\frac{S_e'}{S'}\right)\left(C_{L_\alpha}\right)_e''\left(\frac{q''}{q_\infty}\right)K_{W(B)}'\, I_{v_{W'(W'')}}\left(\frac{b''}{2} - \frac{d''}{2}\right)}{2\pi A_e''\left(\frac{b_v'}{2} - \frac{d'}{2}\right)} \qquad 7.4.1.1\text{-c}$$

where

d' and d'' are the body diameters at the midchord points of the MAC of the forward and aft surfaces, respectively.

b'' is the span of the total aft panel.

$\left(\frac{b_v'}{2} - \frac{d'}{2}\right)$ is obtained from figure 4.4.1-71 as a function of forward-panel geometry.

$I_{v_{W'(W'')}}$ is the vortex interference factor, obtained from Section 4.4.1.

A_e'' is the aspect ratio of the exposed aft panel.

$\left(C_{L_\alpha}\right)_e'$ is the lift-curve slope of the exposed forward panel, obtained from Section 4.1.3.2 (per radian).

$\left(C_{L_\alpha}\right)_e''$ is the lift-curve slope of the exposed aft panel, obtained from Section 4.1.3.2 (per radian).

The remaining terms are defined in method 1 above.

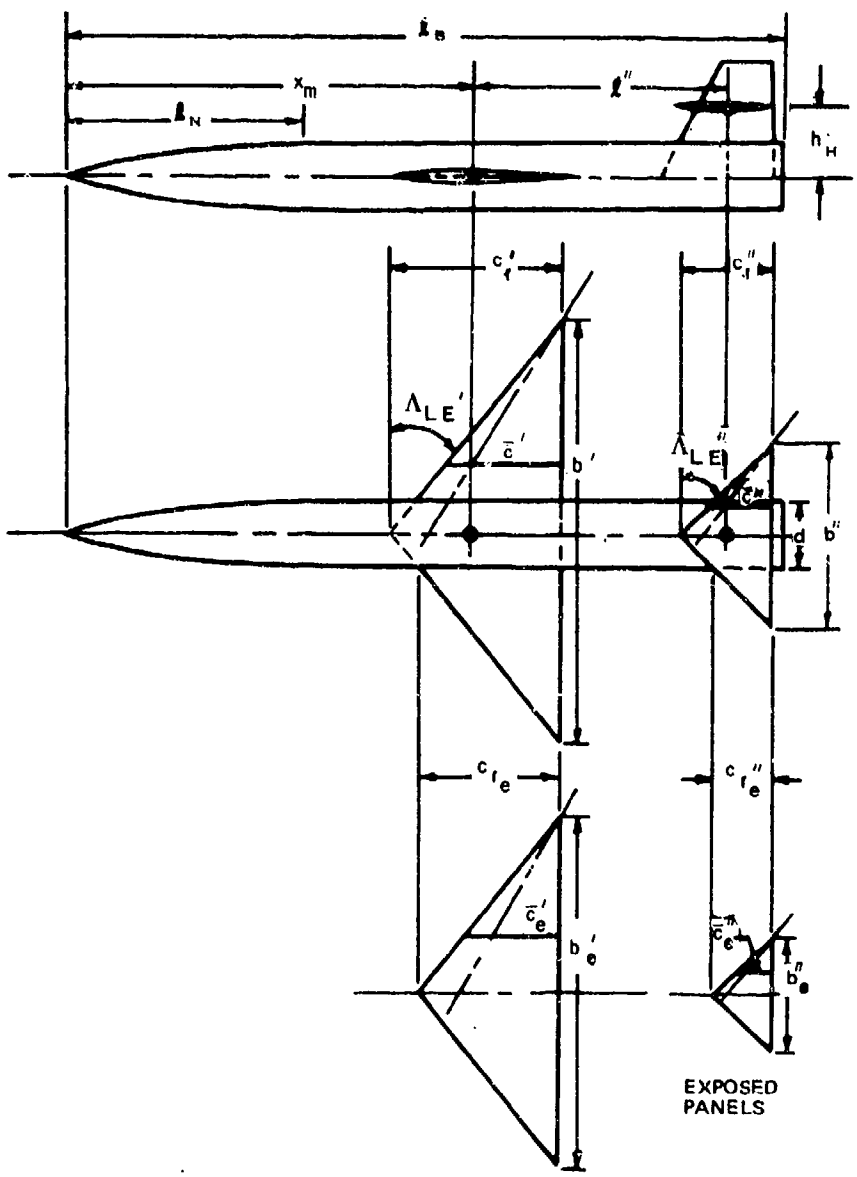
The quantities $\left(C_{L_\alpha}\right)_e'$ and $\left(C_{L_\alpha}\right)_e''$ in the last term of equation 7.4.1.1-b must be expressed in radians. If the result of this term is desired per degree, the conversion must be applied after the term is evaluated.

Because of the similarity of the two methods a sample problem of method 2 is not included. However, evaluation of the term $\left(C_{L_\alpha}\right)_{W''(v)}$ for a wing-body-tail configuration is presented in Section 4.5.1.1.

Sample Problem

Method 1

Given: An ogive-cylinder-body—triangular-wing and triangular-tail configuration. The wing-body configuration is the same as that of the sample problem of Sections 7.3.1 and 7.3.4. Many of the characteristics are repeated below.



Although a tail has been added to the wing-body configuration of Sections 7.3.1 and 7.3.4, for the sake of simplicity the vehicle center of gravity is taken at $\bar{c}'/4$. Therefore, $x_{c.g.} - x'' = \ell''$, the longitudinal distance from the quarter-chord point of the MAC of the forward surface to the quarter-chord point of the MAC of the aft surface.

Wing Characteristics:

Total Panel		Exposed Panel	
$A' = 5.0$	$\lambda' = 0$	$A_e' = 5.0$	$\lambda_e' = 0$
$\Lambda'_{LE} = 38.67°$	$\Gamma' = 0$	$b_e' = 38.37$ ft	$S_e' = 294.50$ sq ft
$i' = 0$	$c_r' = 18.20$ ft		$c_{r_e}' = 15.375$ ft
$b' = 45.50$ ft	$\bar{c}' = 12.133$ ft		$\bar{c}_e' = 10.25$ ft
$S' = 414.0$ sq ft			

NACA 66-206 airfoil section

Horizontal-Tail Characteristics:

Total Panel		Exposed Panel	
$A'' = 4.0$	$\lambda'' = 0$	$A_e'' = 4.0$	$\lambda_e'' = 0$
$\Lambda''_{LE} = 45°$	$\Gamma'' = 0$	$b_e'' = 12.788$ ft	$S_e'' = 40.90$ sq ft
$i'' = 0$	$c_r'' = 9.958$ ft	$\Lambda''_{c/2} = 26.56°$	$c_{r_e}'' = 6.394$ ft
$b'' = 19.915$ ft	$\bar{c}'' = 6.638$ ft		$\bar{c}_e'' = 4.263$ ft
$S'' = 99.16$ sq ft			

NACA 66-206 airfoil section

Body Characteristics:

$\ell_N = 25.0$ ft $\quad \ell_B = 77.20$ ft $\quad d = 7.127$ ft

The following ratios based on total forward-panel dimensions:

$\frac{\ell''}{\bar{c}'} = 2.26 \quad \frac{S_e''}{S'} = 0.0988$

Additional Characteristics:

$h_H = 7.18$ ft	$\frac{b''}{d''} = 2.794$	$R_\ell = 5.16 \times 10^7$ (based on $\bar{c}'$)
$\ell'' = 27.425$ ft	$M = 0.60$	Sea level
$x = 18.32$ ft*	$\beta = 0.80$	Smooth surfaces
	$\alpha' = 4°$	$\frac{S_{wet}}{S_{ref}} = 2$

Compute:

Step 1. Wing-body C_{L_q} (Section 7.3.1.1)

$$\left(C_{L_q}\right)_{WB} = [K_{W(B)} + K_{B(W)}]' \left(\frac{S_e'}{S'}\right)\left(\frac{\bar{c}_e'}{\bar{c}'}\right)\left(C_{L_q}\right)_e' + \left(C_{L_q}\right)_B \left(\frac{S_b}{S'}\right)\left(\frac{\ell_B}{\bar{c}'}\right)$$

(equation 7.3.1.1-a)

$\left(C_{L_q}\right)_{WB} = 4.467$ per rad (sample problem, paragraph A, Section 7.3.1.1)

Step 2. Lift-curve slope for the exposed horizontal tail panel (Section 4.1.3.2)

$c_{\ell_\alpha} = 6.19$ per rad (table 4.1.1-B)

$$\kappa = \frac{c_{\ell_\alpha}}{2\pi} = 0.985$$

$$\frac{A_e''}{\kappa}\left[\beta^2 + \tan^2 \Lambda_{c/2}''\right]^{1/2} = \frac{4.0}{0.985}[0.64 + 0.25]^{1/2} = 3.83$$

$$\frac{\left(C_{L_{\alpha/e}}\right)''}{A_e''} = 1.00 \quad \text{(figure 4.1.3.2-49)}$$

$$\left(C_{L_\alpha}\right)_e'' = 4.00 \text{ per rad}$$

*x is the longitudinal distance measured from the wing root trailing edge aft. For this problem it is taken equal to ℓ_2 defined in Section 4.4.1.

Step 3. Tail-body interference factors (Section 4.3.1.2)

$$\frac{d''}{b''} = \frac{7.127}{19.915} = 0.358$$

$$\left.\begin{aligned} K_{W(B)}'' &= 1.315 \\ K_{B(W)}'' &= 0.550 \end{aligned}\right\} \text{(figure 4.3.1.2-10)}$$

Step 4. Dynamic pressure ratio (Section 4.4.1)

Obtain value at $\alpha' = 4°$

$C_L' = 0.391$ (sample problem, paragraph A, Section 7.4.4.1)

$$\epsilon = \frac{1.62\, C_L}{\pi A'} \qquad \text{(equation 4.4.1-k)}$$

$$= \frac{1.62\,(0.391)}{5\pi}\, 57.3$$

$$= 2.3°$$

$$\gamma = \tan^{-1}\frac{h_H}{x} = \tan^{-1}\left(\frac{7.18}{18.32}\right) = 21.4° \text{ (see sketch (d), Section 4.4.1)}$$

$$\gamma + \epsilon - \alpha' = 21.4 + 2.3 - 4 = 19.7°$$

$$z = x \tan(\gamma + \epsilon - \alpha') \quad \text{(equation 4.4.1-ℓ)}$$

$$= 18.32\,(0.3581) = 6.56$$

$C_f = 0.00236$ (figure 4.1.5.1-26)

$$C_{D_0} = C_f\left[1 + L\left(\frac{t}{c}\right) + 100\left(\frac{t}{c}\right)^4\right] R_{L.S.}\,\frac{S_{wet}}{S_{ref}} \qquad \text{(equation 4.1.5.1-a)}$$

$$\left[1 + L\left(\frac{t}{c}\right) + 100\left(\frac{t}{c}\right)^4\right] = 1.072 \qquad \text{(figure 4.1.5.1-28a)}$$

$$\cos \Lambda_{(t/c)_{max}} = \cos \Lambda_{.45c} = \cos 23.76° = 0.915$$

$R_{L.S.} = 1.14$ (figure 4.1.5.1-28b)

$$C_{D_0} = (0.00236)\,(1.072)\,(1.14)\,(2) = 0.00577$$

$$\left(\frac{\Delta q}{q}\right)_o = \frac{2.42\left(C_{D_0}\right)^{1/2}}{\frac{x}{\bar{c}} + 0.30} \quad \text{(equation 4.4.1-m)}$$

$$= \frac{2.42\,(0.00577)^{1/2}}{1.51 + 0.30} = 0.102$$

$$\frac{z_w}{\bar{c}} = 0.68\sqrt{C_{D_0}\left(\frac{x}{\bar{c}} + 0.15\right)} \quad \text{(equation 4.4.1-j)}$$

$$= 0.68\sqrt{0.00577\,(1.51 + 0.15)} = 0.0666$$

$$\frac{z}{z_w} = \frac{z/\bar{c}}{z_w/\bar{c}} = \frac{6.56/12.133}{0.0666} = 8.12$$

$$\frac{\Delta q}{q} = \left(\frac{\Delta q}{q}\right)_o \cos^2\left(\frac{\pi}{2}\,\frac{z}{z_w}\right) \quad \text{(equation 4.4.1-n)}$$

$$= (0.102)\cos^2\left[\left(\frac{3.14}{2}\right)(8.12)\,(57.3)\right]$$

$$= (0.102)\,(0.9834)^2$$

$$= 0.099$$

$$\frac{q''}{q_\infty} = 1 - \frac{\Delta q}{q} \quad \text{(equation 4.4.1-o)}$$

$$= 1 - 0.099 = 0.901$$

Solution:

$$C_{L_q} = \left(C_{L_q}\right)_{WB} + 2[K_{W(B)} + K_{B(W)}]''\left(\frac{S_e''}{S'}\right)\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)\left(\frac{q''}{q_\infty}\right)\left(C_{L_\alpha}\right)_e'' \quad \text{(equation 7.4.1.1-a)}$$

$= 4.467 + 2(1.315 + 0.550)\,(0.0988)\,(2.26)\,(0.901)\,(4.00)$

$= 4.467 + 3.002$

$= 7.47$ per rad (based on the area and mean aerodynamic chord of the total panel and referred to a moment center at $\bar{c}'/4$)

B. TRANSONIC

No accurate methods are available for estimating the characteristics of isolated panels or the dynamic-pressure ratio in the transonic speed regime. The aerodynamic interference "K" factors for slender configurations are relatively insensitive to Mach number; however, for nonslender configurations transonic interference effects can become quite large and sensitive to minor changes in local contour.

DATCOM METHODS

It is recommended that the methods presented in paragraph A above be applied directly to the transonic speed regime. Care should be taken to estimate the various parameters of equations 7.4.1.1-a and -b at the appropriate Mach number. The interference "K" factors should be obtained from paragraph C, Section 4.3.1.2.

C. SUPERSONIC

The information included in the Datcom accounts for most of the mutual interferences that occur between components of wing-body-tail configurations at supersonic speeds.

DATCOM METHODS

The methods presented in paragraph A above are also applicable to the supersonic speed range. Care should be taken to estimate the various parameters of equations 7.4.1.1-a and -b at the appropriate Mach number. Method 3 of paragraph C of Section 4.4.1 should be used to evaluate the last term of equation 7.4.1.1-b.

Sample Problem

Method 1

Given: Same configuration as sample problem of paragraph A. Some of the characteristics are repeated below.

The following ratios based on total forward-panel dimensions:

$$\frac{\ell''}{\bar{c}'} = 2.26 \qquad \frac{S_e''}{S'} = 0.0988$$

Additional Characteristics:

$M = 1.40$	$\alpha' = 4°$	Sea level
$\beta = 0.98$	$\Lambda''_{LE} = 45°$	$R_\ell = 1.2 \times 10^8$ (based on $\bar{c}'$)
$A' = 5.0$	$K = \frac{16}{3}$ (page 4.1.5.1-16)	Smooth surfaces
cg at $\bar{c}'/4$		

Compute:

Step 1. Wing-body C_{L_q} (Section 7.3.1.1)

$$\left(C_{L_q}\right)_{WB} = [K_{W(B)} + K_{B(W)}]' \left(\frac{S_e'}{S'}\right)\left(\frac{\bar{c}_e'}{\bar{c}'}\right)\left(C_{L_q}\right)_e' + \left(C_{L_q}\right)_B \left(\frac{S_b}{S'}\right)\left(\frac{\ell_B}{\bar{c}'}\right)$$

(equation 7.3.1.1-a)

$\left(C_{L_q}\right)_{WB} = 3.977$ per rad (sample problem, paragraph C, Section 7.3.1.1)

Step 2. Lift-curve slope for the exposed horizontal-tail panel (Section 4.1.3.2)

$$\frac{\beta}{\tan \Lambda''_{LE}} = 0.98$$

$A_e'' \tan \Lambda''_{LE} = 4.0$

$\tan \Lambda''_{LE} \left(C_{N_\alpha}\right)_e'' = 4.025$ (figure 4.1.3.2-56a)

$\left(C_{N_\alpha}\right)_e'' = 4.025$ per rad

Step 3. Tail-body interference factors (Section 4.3.1.2)

$\frac{d''}{b''} = 0.358$ (sample problem, paragraph A)

$K_{W(B)}'' = 1.315$ (figure 4.3.1.2-10)

$$\frac{\beta d''}{c_{r_e}''} = \frac{0.98\ (7.127)}{6.394} = 1.092$$

$\beta \cot \Lambda''_{LE} = 0.98$

$K_{B(W)}'' \left[\beta\left(C_{N_\alpha}\right)_e'' (\lambda_e'' + 1)\left(\frac{b''}{d''} - 1\right)\right] = 2.85$ (figure 4.3.1.2-11a)

$\beta\left(C_{N_\alpha}\right)_e'' (\lambda_e'' + 1)\left(\frac{b''}{d''} - 1\right) = 0.98(4.025)\,(1)\,(1.794) = 7.076$

$K_{B(W)}'' = \frac{2.85}{7.076} = 0.4028$

Step 4. Dynamic pressure ratio (Section 4.4.1)

Obtain at $\alpha' = 4°$ Viscous flow field

$\alpha_0' = -1.6°$ (table 4.1.1-B)

$C_{N_\alpha}' = 0.0712$ per deg (sample problem, paragraph C, Section 7.3.1.1)

$C_N' = C_{N_\alpha}'(\alpha' - \alpha_0') = 0.0712[4 - (-1.6)] = 0.399$

$C_f = 0.0018$ (figure 4.1.5.1-26)

$C_{D_f} = C_f \frac{S_{wet}}{S_{ref}}$ (equation 4.1.5.1-i)

$= (0.0018)\,(2) = 0.0036$

$\beta \cot \Lambda_{LE_{bw}} = (0.98)\,(1.25) = 1.225$ (supersonic leading edge)

$C_{D_w} = \frac{K}{\beta}\left(\frac{t}{c}\right)^2_{eff}\left(\frac{S_{bw}}{S_{ref}}\right)$ (equation 4.1.5.1-k)

$= \frac{16}{3(0.98)}\,(0.06)^2\,(1)$

$= 0.0196$

$C_{D_0} = C_{D_f} + C_{D_w}$ (equation 4.1.5.1-h)

$= 0.0036 + 0.0196 = 0.0232$

$$\left(\frac{\Delta q}{q}\right)_o = \frac{2.42\left(C_{D_0}\right)^{1/2}}{\frac{x}{\bar{c}} + 0.30} \qquad \text{(equation 4.4.1-m)}$$

$$= \frac{2.42(0.0232)^{1/2}}{1.51 + 0.30} = 0.204$$

$$\frac{z_w}{\bar{c}} = 0.68\sqrt{C_{D_0}\left(\frac{x}{\bar{c}} + 0.15\right)} \qquad \text{(equation 4.4.1-j)}$$

$$= 0.68\ \sqrt{(0.0232)\ (1.51 + 0.15)}$$

$$= 0.1334$$

$$\epsilon = \frac{1.62\ C_N}{\pi A'} \qquad \text{(equation 4.4.1-k)}$$

$$= \frac{(1.62)\ (0.399)}{5\pi}\ (57.3)$$

$$= 2.36°$$

$\gamma = 21.4°$ (sample problem, paragraph A)

$\gamma + \epsilon - \alpha' = 21.4 + 2.36 - 4 = 19.76°$

$z = x \tan (\gamma + \epsilon - \alpha')$ (equation 4.4.1-ℓ)

$= 18.32(0.3592) = 6.581$

$$\frac{z}{z_w} = \frac{z/\bar{c}}{z_w/\bar{c}} = \frac{6.581/12.133}{0.1334} = 4.07$$

$$\frac{\Delta q}{q} = \left(\frac{\Delta q}{q}\right)_o \cos^2\left(\frac{\pi}{2}\ \frac{z}{z_w}\right) \qquad \text{(equation 4.4.1-n)}$$

$$= (0.204)\cos^2\left[\left(\frac{3.14}{2}\right)(4.07)\ (57.3)\right]$$

$$= (0.204)\ (0.9943)^2 = 0.20$$

$$\frac{q}{q_\infty} = 1 - \frac{\Delta q}{q} \qquad \text{(equation 4.4.1-o)}$$

$$= 1.0 - 0.20 = 0.80$$

Solution:

$$C_{L_q} = \left(C_{L_q}\right)_{WB} + 2[K_{W(B)} + K_{B(W)}]'' \left(\frac{S_e''}{S'}\right) \left(\frac{x_{c.g.} - x''}{\bar{c}'}\right) \left(\frac{q''}{q_\infty}\right) \left(C_{N_\alpha}\right)_e''$$

(equation 7.4.1.1-a)

$$= 3.977 + 2(1.315 + 0.4028)\,(0.0988)\,(2.26)\,(0.80)\,(4.025)$$

$$= 3.977 + 2.47$$

= 6.447 per rad (based on the area and mean aerodynamic chord of the total panel and referred to a moment center at $\bar{c}'/4$)

7.4.1.2 WING-BODY-TAIL PITCHING DERIVATIVE C_{m_q}

The information contained in this section is for estimating the nondimensional pitching derivative C_{m_q} of wing-body-tail combinations at low angles of attack. The derivative C_{m_q} is the change in pitching-moment coefficient with varying pitch velocity and is commonly referred to as the pitch-damping derivative. It is expressed as

$$C_{m_q} = \frac{\partial C_m}{\partial\left(\frac{q\bar{c}}{2V_\infty}\right)}$$

This derivative is very important in longitudinal dynamics, since it represents a major portion of the damping of the short-period mode for conventional aircraft.

The Datcom methods are based on the same assumptions that were made for the total pitching derivative C_{L_q} of wing-body-tail combinations, and the general discussion of Section 7.4.1.1 is directly applicable here.

A. SUBSONIC

Two methods are presented for determining the pitching derivative C_{m_q} of wing-body-tail combinations, differing only in their treatment of the effect of the flow field of the forward surface on the aft surface.

DATCOM METHODS

Method 1. ($b'/b'' \geq 1.5$)

For configurations in which the span of the forward surface is large compared to that of the aft surface, the following approach can be used. This method is to be used when the ratio of the forward-panel span to the aft-panel span is 1.5 or greater. The equation for the nondimensional pitching derivative C_{m_q} of a wing-body-tail configuration, based on the area and the square of the mean aerodynamic chord of the total forward panel and referred to a moment center at the assumed center of gravity or center of rotation, is given by

$$C_{m_q} = \left(C_{m_q}\right)_{WB} - 2[K_{W(B)} + K_{(B)W}]'' \left(\frac{S_e''}{S'}\right)\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)^2 \left(\frac{q''}{q_\infty}\right)\left(C_{L_\alpha}\right)_e'' \qquad 7.4.1.2\text{-a}$$

where the primed quantities refer to the forward panel, the double-primed quantities refer to the aft panel, and the subscript e refers to the exposed panel. (See Section 4.3.1.2 for the definition of exposed surfaces.)

$(C_{m_q})_{WB}$ is the contribution of the wing-body configuration to the pitching derivative C_{m_q}, obtained from Section 7.3.1.2.

The remaining terms are defined in paragraph A of Section 7.4.1.1.

Method 2. $(b'/b'' < 1.5)$

For configurations in which the span of the forward surface is approximately equal to or less than that of the aft surface, the vortex shed from the forward surface interacts directly with the aft surface, and the resulting interference effects must be accounted for in the tail terms. This method is to be used when the ratio of the forward-panel span to the aft-panel span is less than 1.5. The equation for the nondimensional pitching derivative C_{m_q} of a wing-body-tail configuration, based on the area and the square of the mean aerodynamic chord of the total forward panel and referred to a moment center at the assumed center of gravity or center of rotation, is given by

$$C_{m_q} = \left(C_{m_q}\right)_{WB} - 2\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)^2 \left\{[K_{W(B)} + K_{B(W)}]'' \left(\frac{S_e''}{S'}\right)\left(\frac{q''}{q_\infty}\right)\left(C_{L_\alpha}\right)_e'' + \left(C_{L_\alpha}\right)_{W''(v)}\right\}$$

7.4.1.2-b

All the above terms are defined in paragraph A of Section 7.4.1.1 and method 1 above.

Because of the similarity of the two methods, a sample problem for method 2 is not included. However, evaluation of the term $\left(C_{L_\alpha}\right)_{W''(v)}$ for a wing-body-tail configuration is presented in Section 4.5.1.1.

Sample Problem

Method 1

Given: Same configuration as sample problem of paragraph A, Section 7.4.1.1. Some of the characteristics are repeated below.

The following ratios based on total forward panel dimensions:

$$\frac{\ell''}{\bar{c}'} = 2.26 \qquad \frac{S_e''}{S'} = 0.0988$$

Additional Characteristics:

$M = 0.60$ $\beta = 0.80$ $\alpha' = 4^\circ$ cg at $\bar{c}'/4$

Compute:

Step 1. Wing-body C_{m_q} (Section 7.3.1.2)

$\left(C_{m_q}\right)_{WB}$ = −4.021 per rad (sample problem, paragraph A, Section 7.3.1.2)

Step 2. Lift-curve slope for the exposed horizontal tail (Section 4.1.3.2)

$\left(C_{L_\alpha}\right)_e''$ = 4.0 per rad (sample problem, paragraph A, Section 7.4.1.1)

Step 3. Tail-body interference factors (Section 4.3.1.2)

$K_{W(B)}''$ = 1.315

$K_{B(W)}''$ = 0.550

} (sample problem, paragraph A, Section 7.4.1.1)

Step 4. Dynamic pressure ratio (Section 4.4.1)

$\frac{q''}{q_\infty}$ = 0.901 (sample problem, paragraph A, Section 7.4.1.1)

Solution:

$$C_{m_q} = \left(C_{m_q}\right)_{WB} - 2[K_{W(B)} + K_{B(W)}]'' \left(\frac{S_e''}{S''}\right)\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)^2 \left(\frac{q''}{q_\infty}\right)\left(C_{L_\alpha}\right)_e''$$

(equation 7.4.1.2-a)

$$= -4.021 - 2(1.315 + 0.550)\,(0.0988)\,(2.26)^2\,(0.901)\,(4.0)$$

$$= -4.021 - 6.78$$

$$= -10.80 \text{ per rad}$$ (based on the area and the square of the mean aerodynamic chord of the total forward panel and referred to a moment center at $\bar{c}'/4$)

B. TRANSONIC

The comments of paragraph B of Section 7.4.1.1 are directly applicable here.

DATCOM METHODS

It is recommended that the methods presented in paragraph A above be applied to the transonic speed regime. Care should be taken to estimate the parameters of equations 7.4.1.2-a and -b at the appropriate Mach number. The interference "K" factors should be obtained from paragraph C, Section 4.3.1.2.

C. SUPERSONIC

The comments of paragraph C of Section 7.4.1.1 are directly applicable here.

DATCOM METHODS

The methods presented in paragraph A above are also applicable to the supersonic speed range. Care should be taken to estimate the parameters of equations 7.4.1.2-a and -b at the appropriate Mach number. Method 3 of paragraph C of Section 4.4.1 should be used to evaluate the last term of equation 7.4.1.2-b.

Sample Problem

Method 1

Given: Same configuration as sample problem of paragraph C Section 7.4.1.1 and paragraph A of this section. Some of the characteristics are repeated below.

The following ratios based on total forward panel dimensions:

$$\frac{S_e''}{S'} = 0.0988 \qquad \frac{\ell''}{\bar{c}'} = 2.26$$

Additional Characteristics:

$M = 1.40$ $\beta = 0.98$ $\alpha' = 4^\circ$ cg at $\bar{c}'/4$

Compute:

Step 1. Wing-body C_{m_q} (Section 7.3.1.2)

$\left(C_{m_q}\right)_{WB} = -4.961$ per rad (sample problem, paragraph C, Section 7.3.1.2)

Step 2. Lift-curve slope for the exposed horizontal tail (Section 4.1.3.2)

$\left(C_{N_\alpha}\right)_e'' = 4.025$ per rad (sample problem, paragraph C, Section 7.4.1.1)

Step 3. Tail-body interference factors (Section 4.3.1.2)

$$\left.\begin{aligned} K_{W(B)}'' &= 1.315 \\ K_{B(W)}'' &= 0.4028 \end{aligned}\right\} \text{ (sample problem, paragraph C, Section 7.4.1.1)}$$

Step 4. Dynamic pressure ratio (Section 4.4.1)

$$\frac{q''}{q_\infty} = 0.80 \text{ (sample problem, paragraph C, Section 7.4.1.1)}$$

Solution:

$$C_{m_q} = \left(C_{m_q}\right)_{WB} - 2[K_{W(B)} + K_{W(B)}]''\left(\frac{S_e''}{S'}\right)\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)^2 \left(\frac{q''}{q_\infty}\right)\left(C_{N_\alpha}\right)_e''$$

(equation 7.4.1.2-a)

$$= -4.961 - 2(1.315 + 0.4028)\,(0.0988)\,(2.26)^2\,(0.80)\,(4.025)$$

$$= -4.961 - 5.583$$

$$= -10.54 \text{ per rad}$$ (based on the area and the square of the mean aerodynamic chord of the total forward panel and referred to a moment center at $\bar{c}'/4$)

7.4.1.3 WING-BODY-TAIL PITCHING DERIVATIVE C_{D_q}

This section presents a method for estimating the wing-body-tail derivative C_{D_q} at subsonic speeds. This derivative is the change in the drag coefficient due to a change in pitching velocity at a constant angle of attack and is defined as

$$C_{D_q} = \frac{\partial C_D}{\partial\left(\frac{q\bar{c}}{2V}\right)}, \text{ where } C_D \qquad \text{sed on } S_W.$$

In general, this derivative is small and has a negligible effect on longitudinal stability; hence, it is usually neglected.

A. SUBSONIC

The wing-body-tail derivative is obtained by adding the horizontal-tail contribution to the wing-alone contribution developed in Section 7.1.1.3. The body contribution is negligible and has been neglected. The horizontal-tail contribution to C_{D_q} was computed from the tail-damping angle of attack and also from wing-induced downwash at the tail due to pitch rate. The horizontal-tail lift was taken to act normal to the local flow direction at the tail to produce a force component in the direction of the free-stream flow.

DATCOM METHOD

The wing-body-tail derivative C_{D_q} is given by

$$C_{D_q} = C_{D_{q_W}} + \left(C_{D_{q_0}}\right)_H + \left(\frac{\partial C_{D_{q_H}}}{\partial \alpha_F}\right)\alpha_F \qquad 7.4.1.3\text{-a}$$

where

$C_{D_{q_W}}$ is the wing contribution from Section 7.1.1.3-a

$\left(C_{D_{q_0}}\right)_H$ is the horizontal-tail contribution due to zero-angle-of-attack loading given by

$$\left(C_{D_{q_0}}\right)_H = C_{L_{\alpha_H}} \frac{i_H}{57.3}\left(\frac{S_H}{S_W}\right)\left[\epsilon_q - \frac{2(\ell_H \cos\alpha_F + z_H \sin\alpha_F)}{\bar{c}} - \frac{2\,\epsilon_q\,\epsilon}{i_H}\right.$$

$$\left. + \left(\frac{4\epsilon}{i_H}\right)\left(\frac{\ell_H \cos\alpha_F + z_H \sin\alpha_F}{\bar{c}}\right)\right] \text{ (per degree)} \qquad 7.4.1.3\text{-b}$$

where

$C_{L_{\alpha_H}}$ is the horizontal-tail lift-curve slope (based on S_H) obtained from test data or Section 4.1.3.2 (per degree).

i_H is the incidence of the horizontal tail with respect to the fuselage reference line in degrees.

S_H is the horizontal-tail reference area.

S_W is the wing reference area.

ϵ_q is the variation in downwash with respect to pitch rate, $\epsilon_q = \dfrac{\partial \epsilon}{\partial\left(\dfrac{q\bar{c}}{2V}\right)}$

(at $\bar{c}/4$ of the horizontal tail). Design charts are presented in Figures 7.4.1.3-4a through -4x for Mach numbers of 0.2 and 0.8. These charts are presented as a function of wing geometry and the spanwise location of the horizontal-tail MAC relative to the wing span.

ℓ_H is the distance from the moment reference center to the center-of-pressure location of the horizontal stabilizer, measured parallel to the body center line. For Datcom purposes, the horizontal-tail center-of-pressure location is assumed to be at $\bar{c}_H/4$.

z_H is the distance from the moment reference center to the center-of-pressure location of the vertical stabilizer, measured normal to the body center line, positive for the stabilizer above the body.

α_F is the fuselage angle of attack.

$\bar{c}$ is the wing MAC.

ϵ is the downwash of the wing at $\bar{c}/4$ of the horizontal tail, excluding the contribution due to pitch rate. This may be obtained from test data or from Section 4.4.1.

$\dfrac{\partial C_{D_{q_H}}}{\partial \alpha_F}$ is the change in horizontal-tail contribution with angle of attack, obtained by

$$\frac{\partial C_{D_q}}{\partial \alpha_F} = C_{L_{\alpha_H}} \frac{S_H}{S_W} \frac{1}{57.3} \left[\epsilon_q - \frac{2(\ell_H \cos \alpha_F + z_H \sin \alpha_F)}{\bar{c}} \right] \qquad 7.4.1.3\text{-c}$$

where all the terms are defined above.

Sample Problem

Given: Same configuration as sample problem of Paragraph A of Section 7.1.1.3.

Tail Characteristics:

$C_{L_{\alpha_H}} = 0.08$ per deg $\qquad i_H = 1$ deg $\qquad \frac{S_H}{S_W} = 0.37$

$\ell_H = 60.0$ ft $\qquad z_H = 8.0$ ft $\qquad \epsilon = 1.6$ deg

$\frac{y_{\bar{c}_H}}{b/2} = 0.19$

Compute:

$\epsilon_q = -0.02$ (interpolated using Figures 7.4.1.3-4p, −4q, and −4r)

$$\left(C_{D_{q_0}}\right)_H = C_{L_{\alpha_H}} \frac{i_H}{57.3} \frac{S_H}{S_W} \left[\epsilon_q - \frac{2(\ell_H \cos\alpha_F + z_H \sin\alpha_F)}{\bar{c}} - \frac{2\,\epsilon_q\,\epsilon}{i_H} + \frac{4\epsilon}{i_H} \frac{(\ell_H \cos\alpha_F + z_H \sin\alpha_F)}{\bar{c}}\right] \qquad \text{(Equation 7.4.1.3-b)}$$

$$= (0.08)\frac{1}{57.3}\ (0.37)\left\{-0.02 - \frac{2[(60.0)(0.99985) + (8.0)(0.01745)\ ]}{25.0} - \frac{2(-0.02)(1.6)}{1.0} + \frac{4(1.6)}{1.0}\left[\frac{(60.0)(0.99985) + (8.0)(0.01745)}{25.0}\right]\right\}$$

$$= 0.00549 \text{ per deg}$$

$$\frac{\partial C_{D_{q_H}}}{\partial \alpha_F} = C_{L_{\alpha_H}} \frac{S_H}{S_W} \frac{1}{57.3}\left[\epsilon_q - \frac{2(\ell_H \cos\alpha_F + z_H \sin\alpha_F)}{\bar{c}}\right] \qquad \text{(Equation 7.4.1.3-c)}$$

$$= (0.08)(0.37)\frac{1}{57.3}\left[-0.02 - \frac{2[(60.0)(0.99985) + (8.0)(0.01745)]}{25.0}\right]$$

$$= -0.00249 \text{ per deg}^2$$

Solution:

$C_{D_{q_W}} = 0.00272$ per deg (Sample Problem, Paragraph A Section 7.1.1.3)

$$C_{D_q} = C_{D_{q_W}} + \left(C_{D_{q_0}}\right)_H + \left(\frac{\partial C_{D_{q_H}}}{\partial \alpha_F}\right) \alpha_F \qquad \text{(Equation 7.4.1.3-a)}$$

$$= 0.00272 + 0.00549 - (0.00249)\,(1.0)$$

$$= 0.00572 \text{ per deg}$$

B. TRANSONIC

No method is presented.

C. SUPERSONIC

No method is presented.

7.4.2 WING-BODY-TAIL ROLLING DERIVATIVES

7.4.2.1 WING-BODY-TAIL ROLLING DERIVATIVE C_{Y_p}

This section presents methods for estimating the nondimensional rolling derivative C_{Y_p} of wing-body-tail combinations at subsonic speeds. However, at transonic and supersonic speeds no generalized methods are available for estimating the wing-body-tail rolling derivative C_{Y_p}. The derivative C_{Y_p} is the change in side-force coefficient with change in wing-tip helix angle and is expressed as

$$C_{Y_p} = \frac{\partial C_Y}{\partial\left(\frac{pb}{2V_\infty}\right)}$$

In general, the Datcom methods consist of a synthesis of material presented in Sections 7.1.2.1 and 7.3.2.1, and the vertical-tail contribution based on the methods of reference 1.

The derivative C_{Y_p} arises mainly from the wing and vertical tail. At high angles of attack the vertical-tail contribution predominates. The resultant side force on the vertical tail is generated when the aircraft has a rolling velocity p about its longitudinal body axis and the vertical tail is located either above or below the longitudinal axis. Generally C_{Y_p} is of little importance in lateral dynamics, hence is frequently neglected.

The side force at the vertical tail is created by the effective angle of attack due to the rolling velocity p and the sidewash generated from the wing and fuselage. The sidewash at the vertical tail can significantly alter the tail contribution. This effect is discussed more fully in reference 2. Studies have indicated that the effect of the sidewash varies considerably with tail size, location, and to some extent with wing planform.

A. SUBSONIC

Two methods are presented for determining the rolling derivative C_{Y_p} of the wing-body-tail combination, differing only in their treatment of wing sidewash on the vertical tail. The first method is applicable to conventionally located vertical tails, and the second method applies to tails located directly above, or above and slightly behind the wing. Both methods are based on the assumption that the vertical-tail contribution to C_{Y_p} is zero at $\alpha = 0$ and varies with angle of attack.

For an isolated-tail configuration the vertical-tail value of C_{Y_p} is approximated by

$$\left(C_{Y_p}\right)_V = 2\left(\frac{z}{b_W}\right)\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$$

For a conventionally located vertical tail the effect of wing sidewash on the vertical tail has been approximately accounted for by

$$\left(C_{Y_p}\right)_V = 2\left(\frac{z - z_p}{b_W}\right)\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$$

For configurations with tails located directly above or slightly behind the wing, the effect of wing sidewash has been approximated by using the average of the isolated-tail and conventional-tail values.

DATCOM METHODS

Method 1

For conventionally located vertical tails, the equation for the nondimensional rolling derivative C_{Y_p} of a wing-body configuration, based on the product of wing area and span $S_W b_W$, is given by

$$C_{Y_p} = \left(C_{Y_p}\right)_{WB} + 2\left[\frac{z - z_p}{b_W}\right]\left(\Delta C_{Y_\beta}\right)_{V(WBH)} \text{ (per radian)} \qquad 7.4.2.1\text{-a}$$

where

$\left(C_{Y_p}\right)_{WB}$ is the wing-body contribution to C_{Y_p} obtained from test data or Section 7.3.2.1 and based on the product of wing area and span (per radian).

b_W is the wing span.

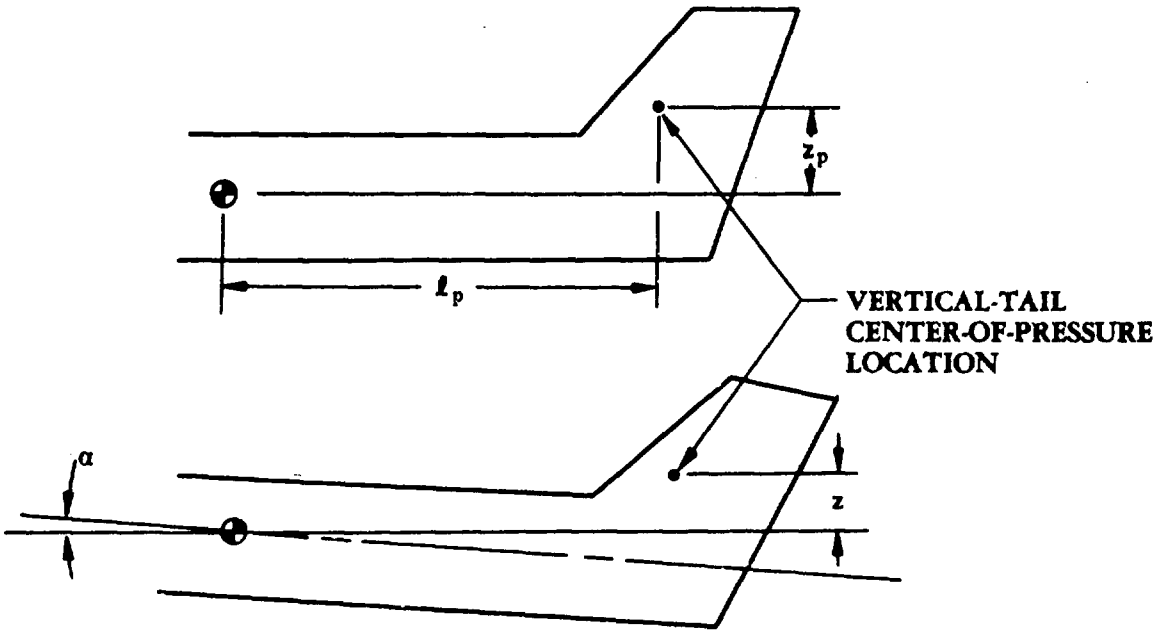
z_p is the distance from the moment reference center to the center-of-pressure location of the vertical stabilizer, measured normal to the body center line, positive for the stabilizer above the body. For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be the quarter-chord point of the MAC of the total added panel.

ℓ_p is the distance from the moment reference center to the center-of-pressure location of the vertical stabilizer, measured parallel to the body center line. For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be the quarter-chord point of the MAC of the total added panel.

z is the vertical distance of the vertical-tail center-of-pressure location above or below the moment-reference-center location. This value must be calculated for each angle of attack (see sketch (a)). From sketch (a), z may be expressed as

$$z = z_p \cos\alpha - \ell_p \sin\alpha \qquad 7.4.2.1\text{-b}$$

$\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$ is the tail-body sideslip derivative from test data or Section 5.3.1.1, based on the wing area (per radian). This derivative should include the end-plate effects of the horizontal tail.



SKETCH (a)

Method 2

For vertical tails located either directly above, or above and slightly behind the wing, the equation for the nondimensional rolling derivative C_{Y_p} of a wing-body-tail configuration, based on the product of wing area and span $S_W b_W$, is given by

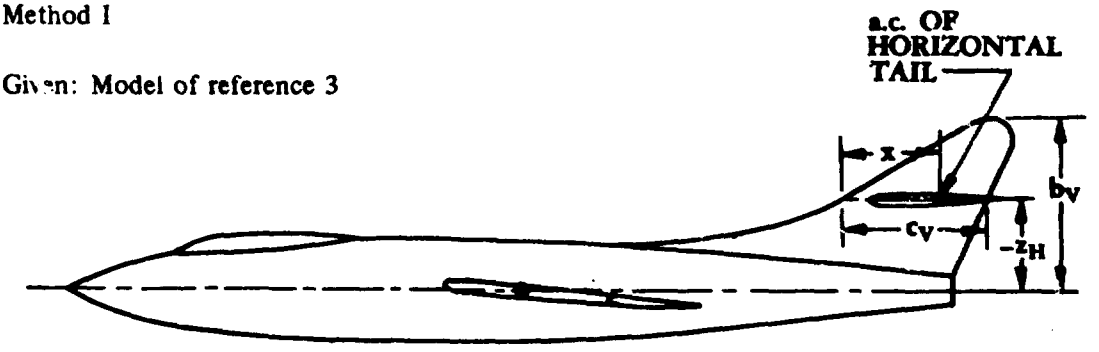
$$C_{Y_p} = \left(C_{Y_p}\right)_{WB} + \left[\frac{2z - z_p}{b_W}\right] \left(\Delta C_{Y_\beta}\right)_{V(WBH)} \quad \text{(per radian)} \qquad 7.4.2.1\text{-c}$$

where the components are described in method 1 above.

Sample Problem

Method 1

Given: Model of reference 3



Wing Parameters:

S_W = 428.0 sq in. b_W = 38.84 in. A_W = 3.57

λ = 0.565 $\Lambda_{c/4}$ = 36.2° z_W = 0

Horizontal-Tail Parameters:

S_H = 97.10 sq in. b_H = 18.66 in. A_H = 3.59

λ = 0.50 $-z_H$ = 6.60 in.

Vertical-Tail Parameters:

S_V = 140.5 sq in. b_V = 12.68 in. A_V = 1.15

λ = 0.176 c_V = 11.0 in. $\Lambda_{c/2}$ = 45°

z_p = 5.0 in. ℓ_p = 24.3 in. x = 7.25 in.

Additional Parameters:

α = 8.0° M = 0.17 $\left(C_{Y_p}\right)_{WB}$ = 0.52 per rad (test data)

$2r_1$ = 4.0 in. d = 7.5 in.

Compute:

Calculate the tail-body sideslip derivative $\left(\Delta C_{Y_\beta}\right)_{V\,(WBH)}$ from Section 5.3.1.1

$$\frac{b_V}{2r_1} = \frac{12.68}{4} = 3.17$$

$$\frac{A_{V\,(B)}}{A_V} = 1.29 \quad \text{(figure 5.3.1.1-22a)}$$

$$\frac{z_H}{b_V} = \frac{-6.60}{12.68} = -0.52$$

$$\frac{x}{c_V} = \frac{7.25}{11.0} = 0.659$$

$$\frac{A_{V(HB)}}{A_{V(B)}} = 0.90 \qquad \text{(figure 5.3.1.1-22b)}$$

$$\frac{S_H}{S_V} = \frac{97.1}{140.5} = 0.691$$

$$K_H = 0.76 \qquad \text{(figure 5.3.1.1-22 c)}$$

$$A_{eff} = \frac{A_{V(B)}}{A_V} A_V \left\{1 + K_H \left[\frac{A_{V(HB)}}{A_{V(B)}} - 1\right]\right\} \qquad \text{(equation 5.3.1.1-a)}$$

$$= (1.29)(1.15)\{1 + 0.76\ [0.90 - 1.0]\}$$

$$= (1.29)(1.15)(0.924)$$

$$= 1.37$$

$\kappa = 1$ (assumed)

$$\frac{A_{eff}}{\kappa}\left[\beta^2 + \tan^2 \Lambda_{c/2}\right]^{1/2} = (1.37)\ [0.971 + 1]^{1/2}$$

$$= (1.37)(1.404)$$

$$= 1.923$$

$$\frac{C_{L_\alpha}}{A_{eff}} = 1.315 \qquad \text{(figure 4.1.3.2-49)}$$

$$C_{L_\alpha} = (1.315)(1.37)$$

$$= 1.80 \text{ per rad (based on } S_V)$$

$$\left(1 + \frac{\partial\sigma}{\partial\beta}\right)\frac{q_V}{q_\infty} = 0.724 + 3.06\frac{S_V/S_W}{1 + \cos\Lambda_{c/4}} + \frac{0.4\ z_W}{d} + 0.009A \qquad \text{(equation 5.4.1-a)}$$

$$= 0.724 + 3.06\ \frac{(140.5)/(428.0)}{1.807} + \frac{(0.4)\ 0}{7.5} + (0.009)(3.57)$$

$$= 0.724 + 0.556 + 0.0321$$

$$= 1.312$$

$k = 0.94$ (figure 5.3.1.1-22d)

$$\left(\Delta C_{Y_\beta}\right)_{V\,(WBH)} = -k \left(C_{L_\alpha}\right)_V \left(1 + \frac{\partial \sigma}{\partial \beta}\right) \frac{q_V}{q_\infty} \frac{S_V}{S_W}$$ (equation 5.3.1.1-b)

$$= -(0.94)\,(1.80)\,(1.312)\,\frac{140.5}{428.0}$$

$$= -0.729 \text{ per rad (based on } S_W)$$

Calculate the vertical distance z of the vertical-tail center-of-pressure location above or below the moment-reference-center location

$$z = z_p \cos \alpha - \ell_p \sin \alpha$$ (equation 7.4.2.1-b)

$$= (5.0)\,(0.9903) - (24.3)\,(0.1392)$$

$$= 4.95 - 3.38$$

$$= 1.57 \text{ in.}$$

Calculate the rolling derivative C_{Y_p} for the wing-body-tail configuration

$$C_{Y_p} = \left(C_{Y_p}\right)_{WB} + 2\left[\frac{z - z_p}{b_W}\right]\left(\Delta C_{Y_\beta}\right)_{V\,(WBH)}$$ (equation 7.4.2.1-a)

$$= 0.52 + 2\left[\frac{1.57 - 5.00}{38.84}\right](-0.729)$$

$$= 0.52 + (2)\,(-0.0883)\,(-0.729)$$

$$= 0.52 + 0.129$$

$$= 0.649 \text{ per rad (based on } S_W b_W)$$

This compares with a test value of 0.62 per radian from reference 3.

B. TRANSONIC

No generalized method is available in the literature for estimating transonic values of the rolling derivative C_{Y_p}. Furthermore, only limited experimental data are available for this derivative at transonic speeds (see table 7-A).

C. SUPERSONIC

No generalized method is available in the literature for estimating supersonic values of the rolling derivative C_{Y_p}. Furthermore, there is a scarcity of experimental data for this d ivative at supersonic speeds.

For the purposes of the Datcom the fuselage effect is considered to be negligible for wing-body configurations with body diameters less than about 30 percent of the wing span. Therefore, for configurations with $d/b \leq 0.3$, the wing-body rolling derivative C_{Y_p} is estimated by the wing-alone method of paragraph C of Section 7.1.2.1.

Methods are presented in reference 4 for evaluating the vertical-tail contribution to C_{Y_p}. The stability derivatives presented therein are derived by using supersonic linearized theory for families of thin, isolated vertical tails performing steady rolling motions. Vertical-tail families (half-delta and rectangular planforms) are considered over a broad Mach number range. Also considered are vertical tails with arbitrary sweepback and taper ratio at Mach numbers for which both the leading edge and trailing edge of the tail are supersonic, and triangular vertical tails with a subsonic leading edge and a supersonic trailing edge.

7.4.2.2 WING-BODY-TAIL ROLLING DERIVATIVE C_{l_p}

This section presents methods for estimating the nondimensional rolling derivative C_{l_p} of wing-body-tail combinations at subsonic speeds. However, at transonic and supersonic speeds no generalized methods are available for estimating the wing-body-tail rolling derivative C_{l_p}. The derivative C_{l_p} is the change in rolling-moment coefficient with change in wing-tip helix angle and is commonly referred to as the roll-damping derivative. It is expressed as

$$C_{l_p} = \frac{\partial C_l}{\partial\left(\frac{pb}{2V_\infty}\right)}$$

In general, the Datcom methods consist of a synthesis of material presented in Sections 7.1.2.2 and 7.3.2.2, and the vertical-tail contribution based on the methods of reference 1.

The derivative C_{l_p} is important in lateral dynamics, since it determines the damping-in-roll characteristics of the vehicle. The derivative is composed of contributions, negative in sign, from the wing, the horizontal tail, and the vertical tail, with the main contribution coming from the wing. The contribution from the vertical tail is usually negligible at low and moderate angles of attack. However, the vertical-tail contribution can become significant at high angles of attack, when the effective moment arm of the tail (z/b_W) becomes a large negative value.

The rolling wing produces a sidewash at the vertical tail, which can significantly alter the vertical-tail contribution. This effect is discussed more fully in reference 2. Studies have indicated that the effect of the sidewash varies considerably with tail size, tail location, and to some extent with wing planform.

Conventional horizontal-tail effects on C_{l_p} are usually small and often neglected, although unusually large horizontal tails can contribute significantly (see references 1 and 3). The horizontal-tail contribution is obtained by using the horizontal-tail geometry and the method of Section 7.1.2.2. The value from Section 7.1.2.2 is then multiplied by a constant, which accounts for the flow rotation produced by the wing, and by the appropriate geometrical parameters to refer the result to the proper reference base.

A. SUBSONIC

Two methods are presented for determining the rolling derivative C_{l_p} of the wing-body-tail combination, differing only in their treatment of wing sidewash on the vertical tail. The first method is applicable to conventionally located vertical tails, and the second method applies to tails located directly above, or above and slightly behind the wing. Both methods are based on the assumption that the vertical-tail contribution to C_{l_p} is zero at $\alpha = 0$ and varies with angle of attack.

For an isolated-tail configuration the vertical-tail value of C_{l_p} is approximated by

$$\left(C_{l_p}\right)_V = 2\left(\frac{z}{b_W}\right)^2 \left(\Delta C_{Y_\beta}\right)_{V(WBH)}$$

For a conventionally located vertical tail the effect of wing sidewash on the vertical tail has been approximately accounted for by

$$\left(C_{l_p}\right)_V = 2\frac{z(z - z_p)}{{b_W}^2} \left(\Delta C_{Y_\beta}\right)_{V(WBH)}$$

For configurations with tails located directly above or slightly behind the wing, the effect of wing sidewash has been approximated by using the average of the isolated-tail and conventional-tail values.

DATCOM METHODS

Method 1

For conventionally located vertical tails, the equation for the nondimensional rolling derivative C_{l_p} of a wing-body-tail configuration, based on the product of wing area and the square of wing span $S_W b_W{}^2$, is given by

$$C_{l_p} = \left(C_{l_p}\right)_{WB} + 0.5\left(C_{l_p}\right)_H \left(\frac{S_H}{S_W}\right)\left(\frac{b_H}{b_W}\right)^2 + \left|2\left(\frac{z}{b_W}\right)\left[\frac{z - z_p}{b_W}\right]\right| \left(\Delta C_{Y_\beta}\right)_{V(WBH)}$$

(per radian) 7.4.2.2-a

where

$\left(C_{l_p}\right)_{WB}$ is the wing-body contribution to C_{l_p}, obtained from test data or Section 7.1.2.2 and based on the product of wing area and the square of wing span (per radian).

$\left(C_{l_p}\right)_H$ is the horizontal-tail contribution obtained from test data or Section 7.1.2.2, based on the horizontal-tail geometry (per radian).

$\frac{S_H}{S_W}\left(\frac{b_H}{b_W}\right)^2$ is the ratio of the horizontal-tail area to the wing area times the square of the ratio of the horizontal-tail span to the wing span.

z is the vertical distance of the vertical-tail center-of-pressure location above or below the moment-reference-center location. This value must be calculated for each angle of attack. (See sketch (a) in Section 7.4.2.1.) From equation 7.4.2.1-b, z is expressed as

$$z = z_p \cos\alpha - \ell_p \sin\alpha$$

ℓ_p is the distance from the moment reference center to the center-of-pressure location of the vertical stabilizer, measured parallel to the body center line (see sketch (a) in Section 7.4.2.1). For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be the quarter-chord point of the MAC of the total added panel.

z_p is the distance from the moment reference center to the center of pressure of the vertical stabilizer, measured normal to the body center line, positive for the stabilizer above the body. For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be the quarter-chord point of the MAC of the total added panel.

$\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$ is the tail-body sideslip derivative obtained from test data or Section 5.3.1.1. It includes the end-plate effects of the horizontal tail and is based on the wing area (per radian).

Method 2

For vertical tails located either directly above, or above and slightly behind the wing, the equation of the nondimensional rolling derivative C_{l_p} of a wing-body-tail configuration, based on the product of wing area and the square of wing span $S_W b_W{}^2$, is given by

$$C_{l_p} = \left(C_{l_p}\right)_{WB} + 0.5\left(C_{l_p}\right)_H \left(\frac{S_H}{S_W}\right)\left(\frac{b_H}{b_W}\right)^2 + \left|\frac{z}{b_W}\left[\frac{2z - z_p}{b_W}\right]\right| \left(\Delta C_{Y_\beta}\right)_{V(WBH)}$$

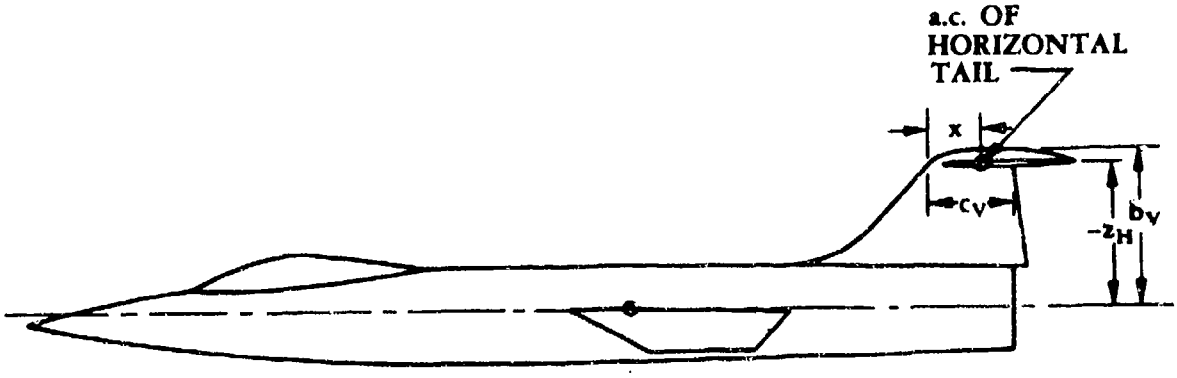
(per radian) 7.4.2.2-b

where the components are described in method 1 above.

Example Problem

Method 1

Given: Model of reference 4



Wing Parameters:

S_W = 1.90 sq ft b_W = 2.16 ft A_W = 2.44 λ = 0.38

Γ = −10° $\bar{c}$ = 0.94 ft $\Lambda_{c/4}$ = 18.0° z_W = 0

Horizontal-Tail Parameters:

S_H = 0.48 sq ft b_H = 1.20 ft A_H = 2.97 λ = 0.31

$\Lambda_{c/4}$ = 10.5° Γ = 0 $\frac{t}{c}$ = 0.05 $\bar{c}$ = 0.44 ft $-z_H$ = 8.30 in.

Vertical-Tail Parameters:

S_V = 0.56 sq ft b_V = 9.0 in. A_V = 0.86 λ_V = 0.37

c_V = 0.42 ft $\bar{c}$ = 0.87 ft $\Lambda_{c/2}$ = 23.25° z_p = 0.308 ft

ℓ_p = 1.25 ft x = 0.25 ft

Additional Parameters:

α = 4.0° M = 0.25 $(C_{l_p})_{WB}$ = −0.30 per rad (test data)

C_L = 0.3 R_ℓ = 1.5 x 10^6 $2r_1$ = 4.88 in.

Compute:

Calculate $\left(C_{l_p}\right)_H$ for the horizontal tail from Section 7.1.2.2

$$\left(C_{l_p}\right)_H = \left(\frac{\beta C_{l_p}}{\kappa}\right)_{C_L=0} \left(\frac{\kappa}{\beta}\right) \frac{\left(C_{L_\alpha}\right)_{C_L}}{\left(C_{L_\alpha}\right)_{C_L=0}} \frac{\left(C_{l_p}\right)_\Gamma}{\left(C_{l_p}\right)_{\Gamma=0}} + \left(\Delta C_{l_p}\right)_{drag}$$

(equation 7.1.2.2-a)

$$\Lambda_\beta = \tan^{-1}\left(\frac{\tan \Lambda_{c/4}}{\beta}\right)$$

$$\beta = \sqrt{1 - M^2} = \sqrt{1 - (.25)^2} = 0.968$$

$$\Lambda_\beta = \tan^{-1}\left(\frac{0.1853}{0.968}\right)$$

$$= \tan^{-1}(0.1914) = 10.8°$$

$\kappa = 1$ (assumed)

$$\frac{\beta A_H}{\kappa} = \frac{(0.968)(2.97)}{1.0} = 2.87$$

$$\left(\frac{\beta C_{l_p}}{\kappa}\right)_{C_L=0} = -0.245 \qquad \text{(figure 7.1.2.2-20b)}$$

$$\frac{\left(C_{L_\alpha}\right)_{C_L}}{\left(C_{L_\alpha}\right)_{C_L=0}} = 1.0 \text{ (assumed)}$$

$$\frac{\left(C_{l_p}\right)_\Gamma}{\left(C_{l_p}\right)_{\Gamma=0}} = 1 \text{ (no dihedral)}$$

$$\left(\Delta C_{l_p}\right)_{drag} = \frac{\left(C_{l_p}\right)_{C_{D_L}}}{C_L{}^2} C_L{}^2 - \frac{1}{8} C_{D_0} \qquad \text{(equation 7.1.2.2-c)}$$

$$\frac{\left(C_{l_p}\right)_{C_{D_L}}}{C_L{}^2} = 0.015 \text{ per rad} \qquad \text{(figure 7.1.2.2-24)}$$

$$C_{D_0} = C_f\left[1 + L\left(\frac{t}{c}\right) + 100\left(\frac{t}{c}\right)^4\right] R_{L.S.} \frac{S_{wet}}{S_{ref}} \qquad \text{(equation 4.1.5.1-a)}$$

$\ell = \bar{c}_H = 0.44$ ft

$k = 0.05 \times 10^{-3}$ in (table 4.1.5.1-A, assume polished wood surface)

$$\frac{\ell}{k} = \frac{(0.44)(12)}{5 \times 10^{-5}} = 1.056 \times 10^5$$

Cutoff Reynolds number, $R_\ell = 7 \times 10^6$ (figure 4.1.5.1-27)

Test Reynolds number, $R_\ell = 1.5 \times 10^6$

$C_f = 0.00410$ (figure 4.1.5.1-26)

$L = 1.2$ (assume $(t/c)_{max}$ is located at $x = .50c$)

$$\left[1 + L\left(\frac{t}{c}\right) + 100\left(\frac{t}{c}\right)^4\right] = 1.06 \quad \text{(figure 4.1.5.1-28a)}$$

$$\cos \Lambda_{(t/c)_{max}} = \cos 0^\circ = 1.0$$

$R_{L.S.} = 1.067$ (figure 4.1.5.1-28b)

$\frac{S_{wet}}{S_{ref}} = 2.0$ (assumed) $\quad S_{ref} = S_{\text{horizontal tail}}$

$$C_{D_0} = C_f \left[1 + L\left(\frac{t}{c}\right) + 100\left(\frac{t}{c}\right)^4\right] R_{L.S.} \frac{S_{wet}}{S_{ref}} \quad \text{(equation 4.1.5.1-a)}$$

$$= (0.00410)\,(1.06)\,(1.067)\,(2.0)$$

$$= 0.00927$$

$$\left(\Delta C_{l_p}\right)_{drag} = \frac{\left(C_{l_p}\right)_{C_{D_L}}}{C_L^{\,2}} C_L^{\,2} - \frac{1}{8} C_{D_0} \text{ (per radian)} \quad \text{(equation 7.1.2.2-c)}$$

$$= (0.015)\,(0.3)^2 - \frac{0.00927}{8}$$

$$= 0.001350 - 0.001159$$

$$= 0.000191 \text{ per rad}$$

$$\left(C_{l_p}\right)_H = \left(\frac{\beta C_{l_p}}{\kappa}\right)_{C_L=0} \left(\frac{\kappa}{\beta}\right) \frac{\left(C_{L_\alpha}\right)_{C_L}}{\left(C_{L_\alpha}\right)_{C_L=0}} \frac{\left(C_{l_p}\right)_\Gamma}{\left(C_{l_p}\right)_{\Gamma=0}} + \left(\Delta C_{l_p}\right)_{drag} \text{ (per radian)}$$

(equation 7.1.2.2-a)

$$\left(C_{l_p}\right)_H = (-0.245)\left(\frac{1.0}{0.068}\right)(1)(1) + 0.000191$$

$$= -0.253 + 0.000191$$

$$\simeq -0.253 \text{ per rad} \quad \text{(based on product of horizontal tail area and the square of tail span } S_H b_H{}^2\text{)}$$

Calculate the vertical distance z of the vertical-tail center-of-pressure location above or below the moment-reference-center location

$$z = z_p \cos\alpha - \ell_p \sin\alpha \qquad \text{(equation 7.4.2.1-b)}$$

$$= (0.308)(0.9976) - (1.25)(0.06976)$$

$$= 0.220 \text{ ft}$$

Calculate the tail-body sideslip derivative $\left(\Delta C_{Y_\beta}\right)_{V\,(WBH)}$ from Section 5.3.1.1

$$\frac{b_V}{2r_1} = \frac{9.0}{4.88} = 1.84$$

$$\frac{A_{V\,(B)}}{A_V} = 1.63 \qquad \text{(figure 5.3.1.1-22a)}$$

$$\frac{z_H}{b_V} = \frac{-8.30}{9.0} = -0.922$$

$$\frac{x}{c_V} = \frac{0.25}{0.42} = 0.595$$

$$\frac{A_{V\,(HB)}}{A_{V\,(B)}} = 1.39 \qquad \text{(figure 5.3.1.1-22b)}$$

$$\frac{S_H}{S_V} = \frac{0.48}{0.56} = 0.857$$

$$K_H = 0.85 \qquad \text{(figure 5.3.1.1-22c)}$$

$$A_{eff} = \frac{A_{V(B)}}{A_V} A_V \left\{1 + K_H \left[\frac{A_{V(HB)}}{A_{V(B)}} - 1\right]\right\} \quad \text{(equation 5.3.1.1-a)}$$

$$= (1.63)(0.86)\ \{1 + 0.85\ [1.39-1]\}$$

$$= (1.63)(0.86)(1.33)$$

$$= 1.86$$

$\kappa = 1$ (assumed)

$$\frac{A_{eff}}{\kappa}\left[\beta^2 + \tan^2 \Lambda_{c/2}\right]^{1/2} = 1.86\ [0.9375 + (0.4296)^2]^{1/2} = 1.86\ (1.06) = 1.97$$

$$\frac{C_{L_\alpha}}{A_{eff}} = 1.30 \quad \text{(figure 4 1.3.2-49)}$$

$$C_{L_\alpha} = (1.30)(1.86)$$

$$= 2.42 \text{ per rad (based on } S_V)$$

$$\left(1 + \frac{\partial\sigma}{\partial\beta}\right)\frac{q_V}{q_\infty} = 0.724 + 3.06\frac{S_V/S_W}{1 + \cos\Lambda_{c/4}} + 0.4\frac{z_W}{d} + 0.009A \quad \text{(equation 5.4.1-a)}$$

$$= 0.724 + 3.06\ \frac{0.56/1.90}{1.9511} + 0 + (0.009)(2.44)$$

$$= 0.724 + 0.462 + 0.022$$

$$= 1.208$$

$k = 0.75$ (figure 5.3.1.1-22d)

$$\left(\Delta C_{Y_\beta}\right)_{V(WBH)} = -k\left(C_{L_\alpha}\right)_V \left(1 + \frac{\partial\sigma}{\partial\beta}\right)\frac{q_V}{q_\infty}\frac{S_V}{S_W} \quad \text{(equation 5.3.1.1-b)}$$

$$= (0.75)(2.42)(1.208)\frac{0.56}{1.90}$$

$$= -0.646 \text{ per rad (based on } S_W)$$

$$C_{l_p} = \left(C_{l_p}\right)_{WB} + 0.5\left(C_{l_p}\right)_H \left(\frac{S_H}{S_W}\right)\left(\frac{b_H}{b_W}\right)^2 + \left|2\left(\frac{z}{b_W}\right)\left[\frac{z - z_p}{b_W}\right]\right|\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$$

(equation 7.4.2.2-a)

$$= -0.30 + (0.5)(-0.253)\left(\frac{0.48}{1.90}\right)\left(\frac{1.20}{2.16}\right)^2 + \left|2\left(\frac{0.22}{2.16}\right)\left[\frac{0.22 - 0.308}{2.16}\right]\right|(-0.646)$$

$$= -0.30 - 0.00986 - 0.00536$$

$$= -0.315 \text{ per rad} \quad \text{(based on the product of wing area and the square of wing span } S_W b_W{}^2\text{)}$$

This compares with a test value of −0.33 per radian from reference 4.

B. TRANSONIC

No generalized reliable method is available in the literature for estimating transonic values of the roll-damping derivative C_{l_p}. However, a considerable quantity of test data is available and reference should be made to table 7-A.

C. SUPERSONIC

No generalized method is available in the literature for estimating supersonic values of the roll-damping derivative C_{l_p}.

The wing-body roll-damping derivative at supersonic speeds is estimated by the wing-body method of paragraph C of Section 7.3.2.2.

Methods are presented in reference 5 for evaluating the vertical-tail contribution to C_{l_p}. The stability derivatives presented therein are derived by using supersonic linearized theory for families of thin isolated vertical tails performing steady rolling motions. Vertical-tail families (half-delta and rectangular planforms) are considered over a broad Mach number range. Also considered are vertical tails with arbitrary sweepback and taper ratio at Mach numbers for which both the leading edge and trailing edge of the tail are supersonic, and triangular vertical tails with a subsonic leading edge and a supersonic trailing edge.

7.4.2.3 WING-BODY-TAIL ROLLING DERIVATIVE C_{n_p}

This section presents methods for estimating the nondimensional rolling derivative C_{n_p} of wing-body-tail combinations at subsonic speeds. However, at transonic and supersonic speeds no generalized methods are available for estimating the wing-body-tail rolling derivative C_{n_p}. This derivative is the change in yawing-moment coefficient with change in wing-tip helix angle and is expressed as

$$C_{n_p} = \frac{\partial C_n}{\partial \left(\frac{pb}{2V_\infty}\right)}$$

In general, the Datcom methods consist of a synthesis of material presented in Sections 7.1.2.3 and 7.3.2.3, and the vertical-tail contribution based on the methods of reference 1.

Contributions to this derivative arise from two sources, the wing and the vertical tail. The wing contribution is usually negative; whereas the tail contribution may be positive or negative depending on vertical-tail geometry, sidewash, and equlibrium angle of attack.

The rolling wing produces a sidewash at the vertical tail, which can significantly alter the vertical-tail contribution. This effect is discussed more fully in reference 2. Studies have indicated that the effect of the sidewash varies considerably with tail size, tail location, and to some extent with wing planform.

The derivative C_{n_p} is important in lateral dynamics because of its influence on Dutch-roll damping. Although for most configurations C_{n_p} is negative, positive values of C_{n_p} are desired to increase the Dutch-roll damping characteristics.

A. SUBSONIC

Two methods are presented for determining the rolling derivative C_{n_p} of the wing-body-tail combination, differing only in their treatment of wing sidewash on the vertical tail. The first method is applicable to conventionally located vertical tails, and the second method applies to tails located directly above, or above and slightly behind the wing.

Both methods are based on the assumption that the vertical-tail contribution to C_{n_p} is zero at $\alpha = 0$ and varies with angle of attack.

For an isolated-tail configuration the vertical-tail value of C_{n_p} is approximated by

$$\left(C_{n_p}\right)_V = 2\left(\frac{z}{b_w}\right)\left(\Delta C_{n_\beta}\right)_p$$

For a conventionally located vertical tail the effect of wing sidewash on the vertical tail has been approximately accounted for by $\left(C_{n_p}\right)_V = 2\left[\frac{z-z_p}{b_W}\right]\left(\Delta C_{n_\beta}\right)_p$. For configurations with tails located directly above or slightly behind the wing, the effect of wing sidewash has been approximated by using the average of the isolated-tail and conventional-tail values.

DATCOM METHODS

Method 1

For conventionally located vertical tails, the equation for the nondimensional rolling derivative C_{n_p} of a wing-body-tail configuration, based on the product of wing area and the square of wing span $S_W b_W{}^2$, is given by

$$C_{n_p} = \left(C_{n_p}\right)_{WB} - \frac{2}{b_W}\left(\ell_p \cos\alpha + z_p \sin\alpha\right)\left[\frac{z - z_p}{b_W}\right]\left(\Delta C_{Y_\beta}\right)_{V\,(WBH)} \text{ (per radian)}$$

7.4.2.3-a

However, if test data for $\left(\Delta C_{n_\beta}\right)_p$ of the empennage are available, the above equation can be rewritten to include the effective tail length, i.e.,

$$C_{n_p} = \left(C_{n_p}\right)_{WB} + 2\left[\frac{z - z_p}{b_W}\right]\left(\Delta C_{n_\beta}\right)_p \text{ (per radian)} \qquad 7.4.2.3\text{-b}$$

where

$\left(C_{n_p}\right)_{WB}$ is the wing-body contribution to C_{n_p}, obtained from test data or Section 7.3.2.3 and based on the product of wing area and the square of wing span (per radian).

ℓ_p is the distance from the moment reference center to the center-of-pressure location of the vertical stabilizer, measured parallel to the body center line (see sketch (a) in Section 7.4.2.1). For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be the quarter-chord point of the MAC of the total added panel.

b_W is the wing span.

z is the vertical distance of the vertical-tail center-of-pressure location above or below the moment-reference-center location. This value must be calculated for each angle of attack. (See sketch (a) in Section 7.4.2.1.) From equation 7.4.2.1-b, z can be expressed as

$$z = z_p \cos\alpha - \ell_p \sin\alpha$$

z_p is the distance from the moment reference center to the center of pressure of the vertical stabilizer, measured normal to the body center line, positive for the stabilizer above the body. For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be the quarter-chord point of the MAC of the total added panel.

$\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$ is the tail-body sideslip derivative from test data or Section 5.3.1.1. It includes the end-plate effects of the horizontal tail and is based on the wing area (per radian).

$\left(\Delta C_{n_\beta}\right)_p$ is the tail-body sideslip derivative from force-test data, where p refers to panels present in the empennage. It is based on the product of wing area and span (per radian).

Method 2

For vertical tails located either directly above, or above and slightly behind the wing, the equation for the nondimensional rolling derivative C_{n_p} of a wing-body-tail configuration, based on the product of wing area and the square of wing span $S_W b_W{}^2$, is given by

$$C_{n_p} = \left(C_{n_p}\right)_{WB} - \left[\frac{\ell_p \cos\alpha + z_p \sin\alpha}{b_W}\right] \left[\frac{2z - z_p}{b_W}\right] \left(\Delta C_{Y_\beta}\right)_{V(WBH)} \text{ (per radian)} \qquad 7.4.2.3\text{-c}$$

However, if test data for $\left(\Delta C_{n_\beta}\right)_p$ of the empennage are available, the equation can be rewritten to include the effective tail length, i.e.,

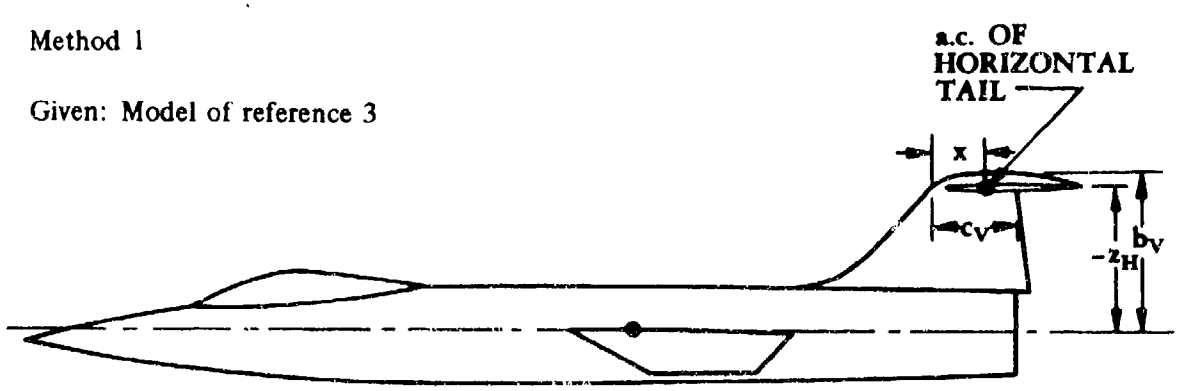
$$C_{n_p} = \left(C_{n_p}\right)_{WB} + \left[\frac{2z - z_p}{b_W}\right] \left(\Delta C_{n_\beta}\right)_p \text{ (per radian)} \qquad 7.4.2.3\text{-d}$$

where the components are described in method 1 above.

Sample Problem

Method 1

Given: Model of reference 3



Wing Parameters:

S_W = 1.90 sq ft $\quad b_W$ = 2.16 ft $\quad A_W$ = 2.44

γ = 0.38 $\quad \Lambda_{c/4}$ = 18.0°

Horizontal-Tail Parameters:

S_H = 0.48 sq ft $\quad b_H$ = 1.20 ft $\quad A_H$ = 2.97

γ = 0.31 $\quad -z_H$ = 8.30 in.

Vertical-Tail Parameters:

S_V = 0.56 sq ft $\quad b_V$ = 9.0 in. $\quad A_V$ = 0.86

λ_V = 0.37 $\quad c_V$ = 0.42 ft $\quad \Lambda_{c/2}$ = 23.25°

z_p = 0.308 ft $\quad \ell_p$ = 1.25 ft $\quad x$ = 0.25 ft

Additional Parameters:

α = 6.0° $\quad$ M = 0.25 $\quad \left(C_{n_p}\right)_{WB}$ = 0.02 per rad (test data)

$2r_1$ = 4.88 in.

Compute:

Calculate the tail-body sideslip derivative $\left(\Delta C_{Y_\beta}\right)_{V\,(WBH)}$ from Section 5.3.1.1

$$\frac{b_V}{2r_1} = \frac{9.0}{4.88} = 1.84$$

$$\frac{A_{V\,(B)}}{A_V} = 1.63 \quad \text{(figure 5.3.1.1-22a)}$$

$$\frac{z_H}{b_V} = \frac{8.30}{9.0} = -0.922$$

$$\frac{x}{c_V} = \frac{0.25}{0.42} = 0.595$$

$$\frac{A_{V(HB)}}{A_{V(B)}} = 1.39 \quad \text{(figure 5.3.1.1-22b)}$$

$$\frac{S_H}{S_V} = \frac{0.48}{0.56} = 0.857$$

$$K_H = 0.85 \quad \text{(figure 5.3.1.1-22c)}$$

$$A_{eff} = \frac{A_{V(B)}}{A_V} A_V \left\{1 + K_H \left[\frac{A_{V(HB)}}{A_{V(B)}} - 1\right]\right\} \quad \text{(equation 5.3.1.1-a)}$$

$$= (1.63)(0.85)\{1 + 0.85 \quad [1.39 - 1]\}$$

$$= (1.63)(0.86)(1.33)$$

$$= 1.86$$

$$\kappa = 1 \text{ (assumed)}$$

$$\frac{A_{eff}}{\kappa}\left[\beta^2 + \tan^2 \Lambda_{c/2}\right]^{1/2} = 1.86\,[0.9375 + (0.4296)^2]^{1/2} = 1.86\,(1.06) = 1.97$$

$$\frac{C_{L_\alpha}}{A_{eff}} = 1.30 \quad \text{(figure 4.1.3.2-49)}$$

$$C_{L_\alpha} = (1.30)(1.86)$$

$$= 2.42 \text{ per rad (based on } S_V)$$

$$\left(1 + \frac{\partial\sigma}{\partial\beta}\right)\frac{q_V}{q_\infty} = 0.724 + 3.06\frac{S_V/S_W}{1 + \cos\Lambda_{c/4}} 0.4\frac{z_W}{d} + 0.009A \quad \text{(equation 5.4.1-a)}$$

$$= 0.724 + 3.06\left(\frac{0.56/1.90}{1.9511}\right) + 0 + (0.009)(2.44)$$

$$= 0.724 + 0.462 + 0.022$$

$$= 1.208$$

$$k = 0.75 \quad \text{(figure 5.3.1.1-22d)}$$

$$\left(\Delta C_{Y_\beta}\right)_{V\,(WBH)} = -k\left(C_{L_\alpha}\right)_V \left(1 + \frac{\partial\sigma}{\partial\beta}\right) \frac{q_V}{q_\infty} \frac{S_V}{S_W} \quad \text{(equation 5.3.1.1-b)}$$

$$= -(0.75)\,(2.42)\,(1.208)\left(\frac{0.56}{1.90}\right)$$

$$= -0.646 \text{ per rad (based on } S_W)$$

Calculate the vertical distance z of the vertical-tail center-of-pressure location above or below the moment-reference-center location

$$z = z_p \cos\alpha - \ell_p \sin\alpha \quad \text{(equation 7.4.2.1-b)}$$

$$= (0.308)\,(0.9945) - (1.25)\,(0.1045)$$

$$= 0.176 \text{ ft}$$

$$C_{n_p} = \left(C_{n_p}\right)_{WB} - \frac{2}{b_W}\left(\ell_p \cos\alpha + z_p \sin\alpha\right)\left[\frac{z - z_p}{b_W}\right]\left(\Delta C_{Y_\beta}\right)_{V\,(WBH)}$$

(equation 7.4.2.3-a)

$$= (0.02) - \frac{2}{2.16}\left[(1.25)\,(0.9945) + (0.308)\,(0.1045)\right]\left[\frac{0.176 - 0.308}{2.16}\right](-0.646)$$

$$= 0.02 - \frac{2}{2.16}\,(1.275)\left(\frac{-0.132}{2.16}\right)(-0.646)$$

$$= 0.02 - 0.0466$$

$$= -0.0266 \text{ per rad (based on } S_W b_W{}^2)$$

This compares with a test value of −0.048 per radian from reference 3.

B. TRANSONIC

No generalized method is available in the literature for estimating transonic values of the rolling derivative C_{n_p}.

C. SUPERSONIC

No generalized method is available in the literature for estimating supersonic values of the rolling derivative C_{n_p}.

For the purpose of the Datcom the fuselage effect is considered to be negligible for wing-body configurations with body diameters less than about 30 percent of the wing span. Therefore, for configurations with $d/b \leq 0.3$, the wing-body rolling derivative C_{n_p} is estimated by the wing-alone method of paragraph C of Section 7.1.2.3.

Methods are presented in reference 4 for evaluating the vertical-tail contribution to C_{n_p}. The stability derivatives presented therein are derived by using supersonic linearized theory for families of thin isolated vertical tails performing steady rolling motions. Vertical-tail families (half-delta and rectangular planforms) are considered over a broad Mach number range. Also considered are vertical tails with arbitrary sweepback and taper ratio at Mach numbers for which both the leading edge and trailing edge of the tail are supersonic, and triangular vertical tails with a subsonic leading edge and a supersonic trailing edge.

7.4.3 WING-BODY-TAIL YAWING DERIVATIVES

7.4.3.1 WING-BODY-TAIL YAWING DERIVATIVE C_{Y_r}

This section presents a method for estimating the nondimensional yawing derivative C_{Y_r} of wing-body-tail combinations at subsonic speeds. However, at transonic and supersonic speeds no generalized methods are available for estimating the wing-body-tail yawing derivative C_{Y_r}. This derivative is the change in side-force coefficient with variation in yawing velocity and is expressed as

$$C_{Y_r} = \frac{\partial C_Y}{\partial\left(\frac{rb}{2V_\infty}\right)}$$

In general, the Datcom method consists of a synthesis of material presented in Sections 7.1.3.1 and 7.3.3.1, and the vertical-tail contribution based on the methods of reference 1.

Contributions to the derivative C_{Y_r} arise from two sources, the wing and the vertical tail. The vertical-tail contribution, which constitutes the major portion, is small and positive in sign. Generally C_{Y_r} is of little importance in lateral dynamics, hence it is frequently neglected.

A. SUBSONIC

For the oscillatory mode, the effects due to lag of sidewash in free oscillation are important and hence should be considered. However, no generalized method is available in the literature to account for oscillating sidewash effects on C_{Y_r}; therefore, only the aperiodic mode of C_{Y_r} is presented here.

In the equation for estimating the yawing derivative C_{Y_r}, the sideslip-derivative contribution of the vertical tail should include the end-plate effects of the horizontal tail.

DATCOM METHOD

The equation for the nondimensional yawing derivative C_{Y_r} of a wing-body-tail configuration, based on the product of wing area and wing span $S_W b_W$, is given by

$$C_{Y_r} = \left(C_{Y_r}\right)_{WB} - \frac{2}{b_W}\left(\ell_p \cos\alpha + z_\Gamma \sin\alpha\right)\left(\Delta C_{Y_\beta}\right)_{V(WBH)} \quad \text{(per radian)} \qquad 7.4.3.1\text{-a}$$

However, if test data for $\left(\Delta C_{n_\beta}\right)_p$ of the empennage are available, the above equation can be rewritten to include the effective tail length, i.e.,

$$C_{Y_r} = \left(C_{Y_r}\right)_{WB} + 2\left(\Delta C_{n_\beta}\right)_p \quad \text{(per radian)} \qquad 7.4.3.1\text{-b}$$

where

$(C_{Y_r})_{WB}$ is the wing-body contribution to C_{Y_r} obtained from test data or by using the recommendations of Section 7.1.3.1, based on the product of wing area and wing span (per radian).

b_W is the wing span.

ℓ_p is the distance from the moment reference center to the center-of-pressure location of the vertical stabilizer, measured parallel to the body center line. (See sketch (a) in Section 7.4.2.1.) For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be the quarter-chord point of the MAC of the total added panel.

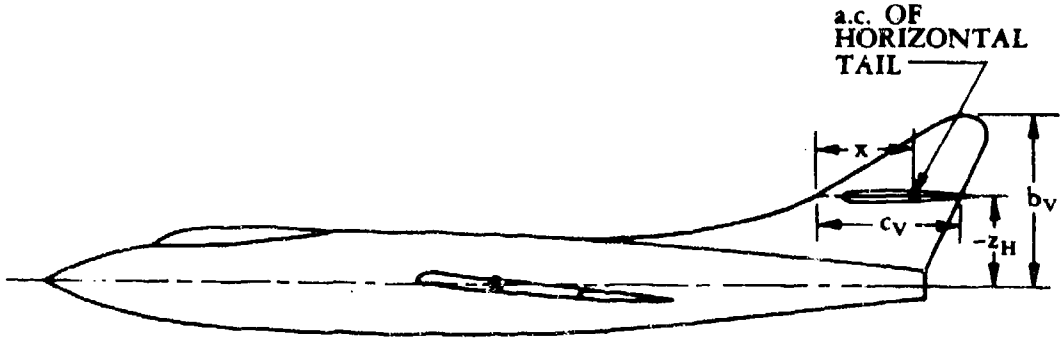
z_p is the distance from the moment reference center to the center of pressure of the vertical stabilizer, measured normal to the body center line, positive for the stabilizer above the body. For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be the quarter-chord point of the MAC of the total added panel.

$(\Delta C_{Y_\beta})_{V\,(WBH)}$ is the tail-body sideslip derivative obtained from test data or Section 5.3.1.1. It includes the end-plate effects of the horizontal tail and is based on the wing area (per radian).

$(\Delta C_{n_\beta})_p$ is the tail-body sideslip derivative from test data where p refers to panels in the empennage. It is based on the product of wing area and span (per radian).

Sample Problem

Given: Model of reference 2



$\alpha = 8.0°$ $\quad (C_{Y_r})_{WB} = -0.10$ per rad (test data) $\quad (\Delta C_{n_\beta})_p = 0.42$ per rad (test data)

Compute:

Calculate the yawing derivative C_{Y_r} for the wing-body-tail configuration

$$C_{Y_r} = \left(C_{Y_r}\right)_{WB} + 2\left(\Delta C_{n_\beta}\right)_p \qquad \text{(equation 7.4.3.1-b)}$$

$$= -0.10 + 2\,(0.42)$$

$$= 0.74 \text{ per rad (based on } S_W b_W)$$

This compares with a test value of 0.50 per radian from reference 2.

B. TRANSONIC

No generalized method is available in the literature for estimating transonic values of the yawing derivative C_{Y_r}. Furthermore, there is a scarcity of experimental data for this derivative at transonic speeds.

C. SUPERSONIC

No generalized method is available in the literature for estimating supersonic values of the yawing derivative C_{Y_r}. Furthermore, there is a scarcity of experimental data for this derivative at supersonic speeds.

7.4.3.2 WING-BODY-TAIL YAWING DERIVATIVE C_{l_r}

This section presents a method for estimating the nondimensional yawing derivative C_{l_r} of wing-body-tail combinations at subsonic speeds. However, at transonic and supersonic speeds no generalized methods are available for estimating the yawing derivative C_{l_r}. This derivative is the change in rolling-moment coefficient with change in the yawing velocity and is expressed as

$$C_{l_r} = \frac{\partial C_l}{\partial\left(\frac{rb}{2V_\infty}\right)}$$

In general, the Datcom method consists of a synthesis of material presented in Sections 7.1.3.2 and 7.3.3.2, and the vertical-tail contribution based on the methods of reference 1.

Contributions to this derivative arise from two sources, the wing and the vertical tail. The wing contribution constitutes the major portion and is positive in sign. The lesser contribution of the vertical tail can be positive or negative, depending upon tail equilibrium angle of attack. This derivative is not of primary importance; however, it is not neglected in lateral dynamic calculations.

A. SUBSONIC

The method presented here is based on the assumption that the wing and fuselage interference effects on tail effectiveness can be determined from geometric dimensions and the sideslip derivatives. This is particularly true if experimental test data are available for $\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$ or $\left(\Delta C_{l_\beta}\right)_p$ in the equations given below.

DATCOM METHOD

The equation for the nondimensional yawing derivative C_{l_r} of a wing-body-tail configuration, based on the product of the wing area and the square of wing span $S_W b_W{}^2$, is given by

$$C_{l_r} = \left(C_{l_r}\right)_{WB} - \frac{2}{b_W{}^2}\left(\ell_p \cos\alpha + z_p \sin\alpha\right)\left(z_p \cos\alpha - \ell_p \sin\alpha\right)\left(\Delta C_{Y_\beta}\right)_{V(WBH)} \quad 7.4.3.2\text{-a}$$

However, if test data for $\left(\Delta C_{l_\beta}\right)_p$ are available, the above equation can be rewritten to approximate the effective vertical-tail center-of-pressure location (the height of the body center line).

$$C_{l_r} = \left(C_{l_r}\right)_{WB} - \frac{2}{b_W}\left(\ell_p \cos\alpha + z_p \sin\alpha\right)\left(\Delta C_{l_\beta}\right)_p \quad 7.4.3.2\text{-b}$$

If test data for $\left(\Delta C_{n_\beta}\right)_p$ and $\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$ are available, the above equation can be rewritten to include the total effective vertical-tail center-of-pressure location.

$$C_{l_r} = \left(C_{l_r}\right)_{WB} + 2\,\frac{\left(\Delta C_{n_\beta}\right)_p}{\left(\Delta C_{Y_\beta}\right)_{V(WBH)}}\left(\Delta C_{l_\beta}\right)_p \text{ (per radian)} \qquad 7.4.3.2\text{-c}$$

where

$\left(C_{l_r}\right)_{WB}$ is the wing-body contribution to C_{l_r} obtained from test data or Section 7.3.3.2, based on the product of wing area and the square of wing span (per radian).

b_W is the wing span.

ℓ_p is the distance from the moment reference center to the center-of-pressure location of the vertical stabilizer, measured parallel to the body center line. (See sketch (a) in Section 7.4.2.1.) For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be the quarter-chord point of the MAC of the total added panel.

z_p is the distance from the moment reference center to the center of pressure of the vertical stabilizer, measured normal to the body center line, positive for the stabilizer above the body. For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be the quarter-chord point of the MAC of the total added panel.

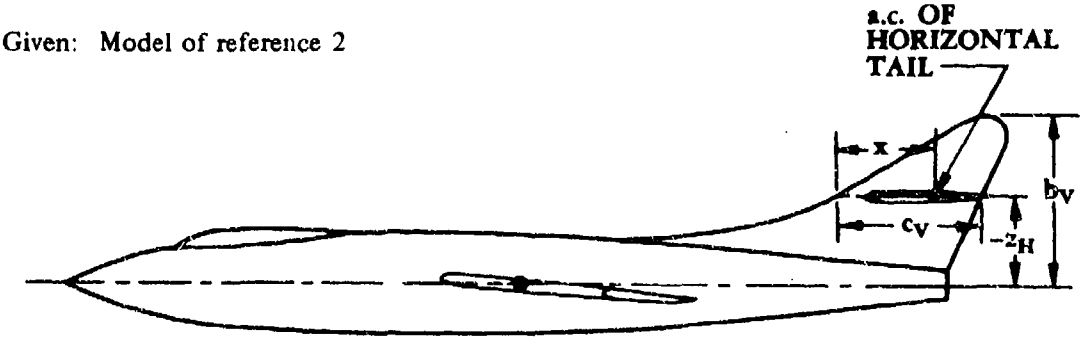
$\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$ is the tail-body sideslip derivative obtained from test data or Section 5.3.1.1. It includes the end-plate effects of the horizontal tail and is based on the wing area (per radian).

$\left(\Delta C_{l_\beta}\right)_p$ is the tail-body sideslip derivative from test data, where p refers to the panels in the empennage. It is based on the product of wing area and span (per radian).

$\left(\Delta C_{n_\beta}\right)_p$ is the tail-body sideslip derivative from test data, where p refers to the panels in the empennage. It is based on the product of wing area and span (per radian).

Sample Problem

Given: Model of reference 2



$\alpha = 6.0°$ $\quad b_W = 38.84$ in. $\quad \ell_p = 24.3$ in. $\quad z_p = 5.0$ in.

$\left(C_{l_r}\right)_{WB} = 0.10$ per rad (test data) $\quad \left(C_{Y_\beta}\right)_{V(WBH)} = -0.64$ per rad (test data)

Compute:

Calculate the yawing derivative C_{l_r} for the wing-body-tail configuration

$$C_{l_r} = \left(C_{l_r}\right)_{WB} - \frac{2}{b_W{}^2}\left(\ell_p \cos\alpha + z_p \sin\alpha\right)\left(z_p \cos\alpha - \ell_p \sin\alpha\right)\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$$

(equation 7.4.3.2-a)

$$= 0.10 - \frac{2}{(38.84)^2}\left[(24.3)(0.0045) + (5.0)(0.1045)\right]$$

$$\left[(5.0)(0.0045) - (24.3)(0.1045)\right](-0.64)$$

$$= 0.10 + 0.051$$

$$= 0.151 \text{ per rad (based on } S_W b_W{}^2)$$

This compares with a test value of 0.15 per radian from reference 2.

B. TRANSONIC

No generalized method is available in the literature for estimating transonic values of the yawing derivative C_{l_r}. Furthermore, there is a scarcity of experimental data for this derivative at transonic speeds.

C. SUPERSONIC

No generalized method is available in the literature for estimating supersonic values of the yawing derivative C_{l_r}. Furthermore, there is a scarcity of experimental data for this derivative at supersonic speeds.

7.4.3.3 WING-BODY-TAIL YAWING DERIVATIVE C_{n_r}

This section presents a method for estimating the nondimensional yawing derivative C_{n_r} of wing-body-tail combinations at subsonic speeds. However, at transonic and supersonic speeds no generalized methods are available for estimating the wing-body-tail yawing derivative C_{n_r}. This derivative is the change in yawing-moment coefficient with change in the yawing-velocity parameter. It is commonly referred to as the yaw damping and is expressed as

$$C_{n_r} = \frac{\partial C_n}{\partial\left(\frac{rb}{2V_\infty}\right)}$$

In general, the Datcom method consists of a synthesis of material presented in Sections 7.1.3.3 and 7.3.3.3, and the vertical-tail contribution based on the methods of reference 1.

Contributions to this derivative arise from the wing, the fuselage, and the vertical tail. The vertical-tail contribution usually constitutes the major portion and is negative in sign (positive damping).

The derivative C_{n_r} is very important in lateral dynamics because of the important contribution it makes to the damping of the Dutch-roll oscillatory mode. Its contribution to the spiral-mode damping is also important. It is desirable to have a large negative value of C_{n_r} for each mode.

A. SUBSONIC

For the oscillatory mode, the effects due to lag of sidewash in free oscillation are important and hence should be considered. However, no generalized method is available in the literature to account for oscillating sidewash effects on C_{n_r}; therefore, only the aperiodic mode of C_{n_r} is presented here.

In the equation for determining the yawing derivative C_{n_r}, the sideslip-derivative contribution of the vertical tail should include the end-plate effects of the horizontal tail.

DATCOM METHOD

The equation for the nondimensional yawing derivative C_{n_r} of a wing-body-tail configuration, based on the product of wing area and the square of wing span $S_W b_W{}^2$, is given by

$$C_{n_r} = \left(C_{n_r}\right)_{WB} + \frac{2}{b_W{}^2}\left(\ell_p \cos\alpha + z_p \sin\alpha\right)^2 \left(\Delta C_{Y_\beta}\right)_{V(WBH)} \quad \text{(per radian)} \qquad 7.4.3.3\text{-a}$$

However, if test data for ΔC_{n_β} are available, the above equation can be expressed as

$$C_{n_r} = \left(C_{n_r}\right)_{WB} + 2\frac{\left(\Delta C_{n_\beta}\right)_p{}^2}{\left(\Delta C_{Y_\beta}\right)_{V(WBH)}} \quad \text{(per radian)} \qquad 7.4.3.3\text{-b}$$

where

$\left(C_{n_r}\right)_{WB}$ is the wing-body contribution to C_{n_r} obtained from test data or Section 7.3.3.3, based on the product of wing area and the square of wing span (per radian).

b_W is the wing span.

ℓ_p is the distance from the moment reference center to the center-of-pressure location of the vertical stabilizer, measured parallel to the body center line. (See sketch (a) in Section 7.4.2.1.) For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be the quarter-chord point of the MAC of the total added panel.

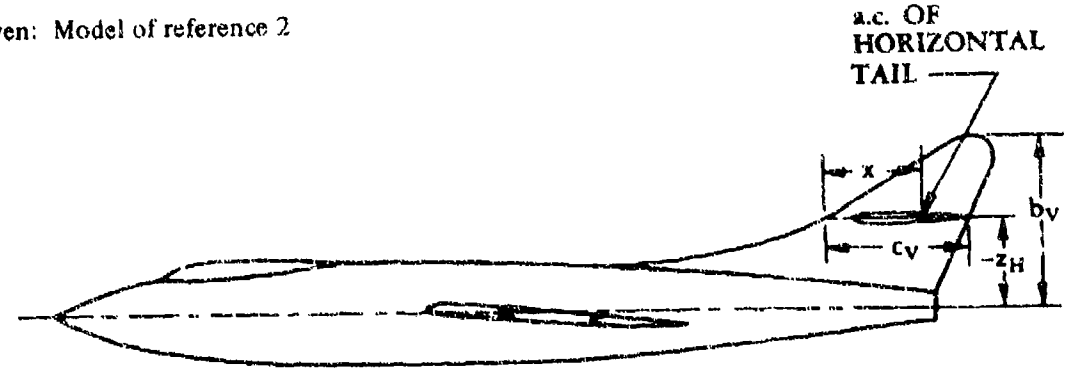
z_p is the distance from the moment reference center to the center of pressure of the vertical stabilizer, measured normal to the body center line, positive for the stabilizer above the body. For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be the quarter-chord point of the MAC of the total added panel.

$\left(\Delta C_{Y_\beta}\right)_{V(WBH)}$ is the tail-body sideslip derivative from test data or Section 5.3.1.1 and is based on the wing area (per radian).

$\left(\Delta C_{n_\beta}\right)_p$ is the tail-body sideslip derivative from test data, where p refers to the panels in the empennage. It is based on the product of wing area and span (per radian).

Sample Problem

Given: Model of reference 2



$\alpha = 6^\circ$ $\left(C_{n_r}\right)_{WB} = -0.15$ per r[illegible] (test dat

$\left(\Delta C_{n_\beta}\right)_p = 0.43$ per rad (test data) $\left(\Delta C_{Y_\beta}\right)_{V(WBH)} = -0.64$ per (test data)

Compute:

Calculate the yawing derivative C_{n_r} for the wing-body-tail configuration

$$C_{n_r} = \left(C_{n_r}\right)_{WB} + 2 \frac{\left(\Delta C_{n_\beta}\right)_p^2}{\left(\Delta Y_\beta\right)_{V(WBH)}} \quad \text{(equation 7.4.3.3-b)}$$

$$= -0.15 + (2) \frac{(0.43)^2}{(-0.64)}$$

$$= -0.15 - 0.578$$

$$= -0.728 \text{ per rad (based on } S_W b_W^2)$$

This compares with a test value of −0.60 per radian from reference 2.

B. TRANSONIC

No generalized method is available in the literature for estimating transonic values of the yawing derivative C_{n_r}. Furthermore, there is a scarcity of experimental data for this derivative at transonic speeds.

C. SUPERSONIC

No generalized method is available in the literature for estimating supersonic values of the yawing derivative C_{n_r}. Furthermore, there is a scarcity of experimental data for this derivative at supersonic speeds.

7.4.4 WING-BODY-TAIL ACCELERATION DERIVATIVES

7.4.4.1 WING-BODY-TAIL ACCELERATION DERIVATIVE $C_{L_{\dot{\alpha}}}$

The information contained in this section is for estimating the nondimensional acceleration derivative $C_{L_{\dot{\alpha}}}$ of wing-body-tail combinations at low angles of attack. This derivative is the change in lift coefficient with rate of change of angle of attack and is expressed as

$$C_{L_{\dot{\alpha}}} = \frac{\partial C_L}{\partial\left(\frac{\dot{\alpha}\bar{c}}{2V_\infty}\right)}$$

In general, the methods presented consist of a synthesis of material presented in other sections, although some new information is presented.

This derivative is presented in a manner similar to that used in reference 1 to calculate the lift of a wing-body-tail combination. The complete derivative is the sum of contributions of individual components, treated as isolated surfaces or bodies, and mutual interference effects. The mutual interference effects are assumed to correspond to those due to angle-of-attack variations, established in references 1 and 2 and presented in Section 4.3.1.2.

The horizontal-tail contribution to the derivative $C_{L_{\dot{\alpha}}}$ is based on the concept of the lag of the downwash. The nonstationary character of the lift response of the tail to changes in tail angle of attack is neglected, and the result is attributed entirely to the fact that the downwash at the tail does not respond instantaneously to changes in wing angle of attack. This concept is also the basis used in estimating the horizontal-tail contribution to the derivative $C_{m_{\dot{\alpha}}}$ in Section 7.4.4.2. The result of this concept is presented in numerous aerodynamic texts, for example, reference 3. The effect of $C_{L_{\dot{\alpha}}}$ on longitudinal stability is usually unimportant and is therefore frequently neglected in dynamic analyses.

A. SUBSONIC

Two methods are presented for determining the acceleration derivative $C_{L_{\dot{\alpha}}}$ of wing-body-tail combinations, differing only in their treatment of the effect of the flow field of the forward surface on the aft surface

DATCOM METHODS

Method 1. ($b'/b'' \geq 1.5$)

For configurations in which the span of the forward surface is large compared to that of the aft surface, the following approach can be used. This method is to be used when the ratio of the forward-panel span to the aft-panel span is 1.5 or greater. The equation of the nondimensional acceleration derivative $C_{L_{\dot{\alpha}}}$ of a wing-body-tail configuration, based on the area and mean

aerodynamic chord of the total forward panel and referred to a moment center at the assumed center of gravity or center of rotation, is given by

$$C_{L_{\dot{\alpha}}} = \left(C_{L_{\dot{\alpha}}}\right)_{WB} + 2\left[K_{W(B)} + K_{B(W)}\right]'' \left(\frac{S_e''}{S'}\right)\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)\left(\frac{q''}{q_\infty}\right)\left(\frac{\partial \bar{\epsilon}}{\partial \alpha}\right)\left(C_{L_\alpha}\right)_e''$$

7.4.4.1-a

where the primed quantities refer to the forward panel, the double-primed quantities refer to the aft panel, and the subscript e refers to the exposed panel. (See Section 4.3.1.2 for the definition of exposed surfaces.)

$\left(C_{L_{\dot{\alpha}}}\right)_{WB}$ is the contribution of the wing-body configuration to the acceleration derivative $C_{L_{\dot{\alpha}}}$, obtained from Section 7.3.4.1.

$\frac{\partial \bar{\epsilon}}{\partial \alpha}$ is the downwash gradient averaged over the aft surface, obtained from Section 4.4.1.

The remaining terms are defined in paragraph A of Section 7.4.1.1.

Method 2. $(b'/b'' < 1.5)$

For configurations in which the span of the forward surface is approximately equal to or less than that of the aft surface, the vortex shed from the forward surface interacts directly with the aft surface and the resulting interference effects must be accounted for in the tail terms. This method is to be used when the ratio of the forward-panel span to the aft-panel span is less than 1.5. The equation for the nondimensional acceleration derivative $C_{L_{\dot{\alpha}}}$ of a wing-body-tail configuration, based on the area and mean aerodynamic chord of the total forward panel and referred to a moment center at the assumed center of gravity or center of rotation, is given by

$$C_{L_{\dot{\alpha}}} = \left(C_{L_{\dot{\alpha}}}\right)_{WB} - 2\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)\left(C_{L_\alpha}\right)_{W''(v)}$$

7.4.4.1-b

All the terms are defined in paragraph A of Section 7.4.1.1 and method 1 above.

Because of the similarity of the two methods a sample problem for method 2 is not included. However, evaluation of the term $\left(C_{L_\alpha}\right)_{W''(v)}$ for a wing-body-tail configuration is presented in Section 4.5.1.1.

Sample Problem

Method 1

Given: Same configuration as sample problems of paragraph A, Sections 7.4.1.1 and 7.4.1.2. Some of the characteristics are repeated below. Note that for the sake of simplicity the vehicle center of gravity has been taken at $\bar{c}'/4$ and $x_{c.g.} - x'' = \ell''$.

The following ratios based on total forward panel dimensions:

$$\frac{b''}{b'} = 0.4377 \qquad \frac{2\ell_2}{b'} = 0.8053 \qquad \frac{\ell_{eff}}{b'} = 0.4026 \qquad \frac{h_H}{b'} = 0.1578$$

$$\frac{\ell''}{\bar{c}'} = 2.26 \qquad \frac{\ell_3}{b'} = 0.2667 \qquad \frac{S_e''}{S'} = 0.0988$$

Additional Characteristics:

$h_H = 7.18$ feet	$M = 0.60$	$R_\ell = 5.16 \times 10^7$ (based on $\bar{c}'$)
$\ell_{eff} = \ell_2 = 18.32$ feet	$\beta = 0.80$	Sea level
$\ell_3 = \bar{c}' = 12.133$ feet	$\alpha' = 4°$	Smooth surfaces
$\ell'' = 27.425$ feet	$\Gamma = 0$	NACA 66-206 airfoil sections
$\Lambda'_{c/4} = 30.97°$		

Compute:

Step 1. Wing-body $C_{L_{\dot{\alpha}}}$ (Section 7.3.4.1)

$\left(C_{L_{\dot{\alpha}}}\right)_{WB} = 0.864$ per rad (sample problem, paragraph A, Section 7.3.4.1)

Step 2. Lift-curve slope for the exposed horizontal-tail panel (Section 4.1.3.2)

$\left(C_{L_\alpha}\right)_e'' = 4.0$ per rad (sample problem, paragraph A, Section 7.4.1.1)

Step 3. Tail-body interference factors (Section 4.3.1.2)

$K_{W(B)}'' = 1.315$

$K_{B(W)}'' = 0.550$

(sample problem, paragraph A, Section 7.4.1.1)

Step 4. Dynamic pressure ratio (Section 4.4.1)

$\frac{q''}{q_\infty} = 0.901$ (sample problem, paragraph A, Section 7.4.1.1)

Step 5. Downwash parameter (Section 4.4.1)

Obtain value for $\alpha' = 4°$ at M = 0.2 and correct for Mach number effects by equation 4.4.1-g

$\alpha_0' = -1.6°$ (table 4.1.1-B)

$\tan \Lambda_{c/2} = 0.4003$

$$\frac{A'}{\kappa}\left(\beta^2 + \tan^2 \Lambda_{c/2}\right)^{1/2} = \frac{5}{0.985}\left[0.98 + (0.4003)^2\right]^{1/2} = 5.43$$

$\frac{C_{L_\alpha}}{A} = 0.80$ (figure 4.1.3.2-49)

$C_{L_\alpha}' = 4.00$ per rad $= 0.0698$ per deg

$$\left(C_{L_\alpha}'\right)_{\alpha'=4°} = C_{L_{\alpha'}}(\alpha' - \alpha_0') = 0.0698\,[4 - (-1.6)] = 0.391$$

$\alpha'_{C_{L_{max}}} = 21.0°$ (Section 4.1.3.4)

$$\frac{\alpha' - \alpha_0}{\alpha'_{C_{L_{max}}} - \alpha_0'} = \frac{4 - (-1.6)}{21.0 - (-1.6)} = 0.248$$

$\frac{A'_{eff}}{A'} = 1.0$

$\frac{b'_{eff}}{b'} = 1.0$

(figure 4.4.1-66)

$A'_{eff} = 5.0$

$b'_{eff} = 45.50$ ft

$$\left(\frac{\partial \epsilon}{\partial \alpha}\right)_{\infty} = 0.40$$

$$\left(\frac{\partial \epsilon}{\partial \alpha}\right)_{v} = 0.49$$

(figure 4.4.1-67)

$\Delta y = 1.10$ (figure 2.2.1-8)

Type of flow separation: Leading-edge separation is predominant (figure 4.4.1-68a)

$$a = h_H - (\ell_2 + \ell_3)\left(\alpha - \frac{0.41 C_L}{\pi A_{eff}}\right) - \frac{b_{eff}}{2} \tan \Gamma \quad \text{(equation 4.4.1-d)}$$

$$= 7.18 - (18.32 + 12.133)\left(\frac{4}{57.3} - \frac{(0.41)(0.391)}{(3.14)(5.0)}\right) - \frac{45.50}{2}(0)$$

$$= 7.18 - (30.453)(0.0596) = 5.37$$

$$\xi_{ru} = \frac{0.56 A'}{C_L'} = \frac{0.56(5.0)}{0.391} = 7.16 \text{ (See page 4.4.1-6)}$$

$$b_{v_{ru}} = [0.78 + 0.10(\lambda' - 0.4) + 0.003 \Lambda'_{c/4}]\, b'_{eff} \quad (\Lambda_{c/4} \text{ in deg}) \quad \text{(equation 4.4.1-f)}$$

$$= (0.833)(45.50)$$

$$= 37.90 \text{ ft}$$

$$b_v = b'_{eff} - \left(b'_{eff} - b_{v_{ru}}\right)\left[\frac{2\ell_{eff}}{b' \xi_{ru}}\right]^{1/2} \quad \text{(equation 4.4.1-e)}$$

$$= 45.5 - (45.5 - 37.9)\left[\frac{36.64}{(45.5)(7.16)}\right]^{1/2}$$

$$= 45.5 - 2.5 = 43.0$$

$$\frac{b_H}{b_v} = \frac{b''}{b_v} = \frac{19.915}{43.0} = 0.463$$

$$\frac{2a}{b_v} = \frac{2(5.37)}{43.0} = 0.25$$

$$\frac{\left(\frac{\partial \bar{\epsilon}}{\partial \alpha}\right)}{\left(\frac{\partial \epsilon}{\partial \alpha}\right)_v} = 0.93 \quad \text{(figure 4.4.1-68b)}$$

$$\left(\frac{\partial \bar{\epsilon}}{\partial \alpha}\right)_{\substack{\text{low} \\ \text{speed}}} = \frac{\left(\frac{\partial \bar{\epsilon}}{\partial \alpha}\right)}{\left(\frac{\partial \epsilon}{\partial \alpha}\right)_v} \left(\frac{\partial \epsilon}{\partial \alpha}\right)_v = (0.93)(0.49) = 0.4557$$

$$\left(C_{L_\alpha}{}'\right)_{M=0.6} = 4.50 \quad \text{(sample problem, paragraph A, Section 7.3.1.1)}$$

$$\left(\frac{\partial \bar{\epsilon}}{\partial \alpha}\right)_{M=0.6} = \left(\frac{\partial \bar{\epsilon}}{\partial \alpha}\right)_{\substack{\text{low} \\ \text{speed}}} \frac{\left(C_{L_\alpha}{}'\right)_{M=0.6}}{\left(C_{L_\alpha}{}'\right)_{\substack{\text{low} \\ \text{speed}}}} \quad \text{(equation 4.4.1-g)}$$

$$= (0.4557)\left(\frac{4.50}{4.00}\right)$$

$$= (0.513)$$

Solution:

$$C_{L_{\dot{\alpha}}} = \left(C_{L_{\dot{\alpha}}}\right)_{WB} + 2[K_{W(B)} + K_{B(W)}]'' \left(\frac{S_e''}{S'}\right)\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)\left(\frac{\partial \bar{\epsilon}}{\partial \alpha}\right)\left(\frac{q''}{q_\infty}\right)\left(C_{L_\alpha}\right)_e''$$

(equation 7.4.4.1-a)

$$= 0.864 + 2(1.315 + 0.550)(0.0988)(2.26)(0.513)(0.901)(4.0)$$

$$= 0.864 + 1.540$$

$$= 2.404 \text{ per rad} \quad \text{(based on the area and mean aerodynamic chord of the total forward panel and referred to a moment center at } \bar{c}'/4)$$

B. TRANSONIC

No accurate methods are available for estimating the characteristics of isolated panels, the dynamic-pressure ratio, or the downwash gradient in the transonic speed regime. The aerodynamic interference "K" factors for slender configurations are relatively insensitive to Mach number; however, for nonslender configurations transonic interference effects can become quite large and sensitive to minor changes in local contour.

DATCOM METHODS

It is recommended that the methods presented in paragraph A above be applied directly to the transonic speed regime. Care should be taken to estimate the various parameters of equations 7.4.4.1-a and -b at the appropriate Mach number. The interference "K" factors should be obtained from paragraph C, Section 4.3.1.2.

C. SUPERSONIC

The information included in the Datcom accounts for most of the mutual interferences that occur between components of wing-body-tail configurations at supersonic speeds.

DATCOM METHODS

The methods presented in paragraph A above are also applicable to the supersonic speed range. Care should be taken to estimate the various parameters of equations 7.4.4.1-a and -b at the appropriate Mach number. Method 3 of paragraph C of Section 4.4.1 should be used to evaluate the last term of equation 7.4.4.1-b.

Sample Problem

Method 1

Given: Same configuration as sample problems of paragraph C, Sections 7.4.1.1 and 7.4.1.2, and paragraph A of this section. Some of the characteristics are repeated below.

The following ratios based on total forward panel dimensions:

$$\frac{\ell''}{\bar{c}'} = 2.26 \qquad \frac{S_e''}{S'} = 0.0988$$

Additional Characteristics:

$h_H = 7.18$ ft $M = 1.40$ $\alpha' = 4°$

$A' = 5.0$ $\beta = 0.98$ cg at $\bar{c}'/4$

Compute:

Step 1. Wing-body $C_{N_{\dot{\alpha}}}$ (Section 7.3.4.1)

$$\left(C_{N_{\dot{\alpha}}}\right)_{WB} = \left[K_{W(B)} + K_{B(W)}\right]' \left(\frac{S_e'}{S'}\right)\left(\frac{\bar{c}_e'}{\bar{c}'}\right)\left(C_{L_{\dot{\alpha}}}\right)_e + \left(C_{L_{\dot{\alpha}}}\right)_B \left(\frac{S_b}{S'}\right)\left(\frac{\ell_B}{\bar{c}'}\right)$$

(equation 7.3.4.1-a)

$\left(C_{N_{\dot{\alpha}}}\right)_{WB}$ = -0.485 per rad (sample problem, paragraph C, Section 7.3.4.1)

Step 2. Lift-curve slope for the exposed horizontal-tail panel (Section 4.1.3.2)

$\left(C_{N_\alpha}\right)_e''$ = 4.025 per rad (sample problem, paragraph C, Section 7.4.1.1)

Step 3. Tail-body interference factors (Section 4.3.1.2)

$K_{W(B)}''$ = 1.315

$K_{B(W)}''$ = 0.4028

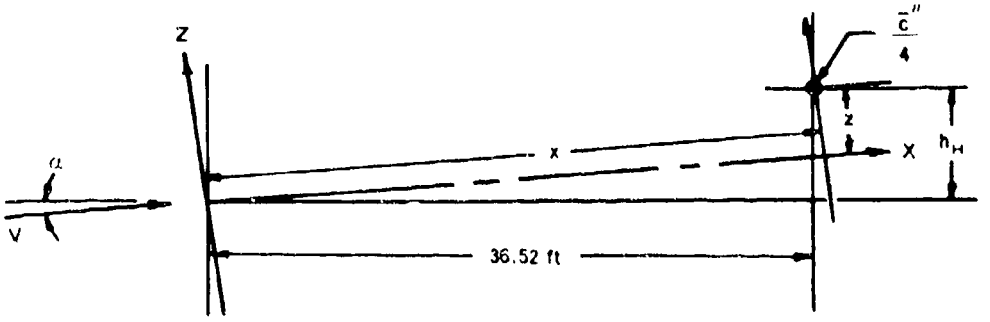
(sample problem, paragraph C, Section 7.4.1.1)

Step 4. Dynamic pressure ratio (Section 4.4.1)

$\frac{q''}{q_\infty}$ = 0.80 (sample problem, paragraph C, Section 7.4.1.1)

Step 5. Downwash parameter (Section 4.4.1)

Obtain value in the plane of symmetry at $\frac{\bar{c}''}{4}$



x, y, and z referred to wind axes:

$x = h_H \sin\alpha + (36.52)\cos\alpha = 36.93$

$y = 0$ (plane of symmetry)

$z = h_H \cos\alpha - (36.52)\sin\alpha = 4.615$

$$\frac{2x}{\beta b'} = 1.656 \qquad \frac{2z}{b'} = 0.2029 \qquad \frac{2y}{b'} = 0$$

$\beta A' = 4.90$

$$\frac{2h}{\alpha'\beta b'} = 1.0^* \quad \text{(figure 4.4.1-74a)}$$

$$\left(\frac{2z}{b'}\right)_{eff} = \frac{2z}{b'} + \frac{2h}{\alpha'\beta b'}\,\alpha'\beta \quad (\alpha' \text{ in rad})$$

$$= 0.2029 + (1.0)(0.0684)$$

$$= 0.2713$$

$$\frac{\partial\bar{\epsilon}}{\partial\alpha} = 0.29^* \quad \text{(figure 4.4.1-76a)}$$

Solution:

$$C_{L_{\dot{\alpha}}} = \left(C_{L_{\dot{\alpha}}}\right)_{WB} + 2[K_{W(B)} + K_{B(W)}]'' \left(\frac{S_e''}{S'}\right)\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)\left(\frac{q''}{q_\infty}\right)\left(\frac{\partial\bar{\epsilon}}{\partial\alpha}\right)\left(C_{N_\alpha}\right)_e''$$

(equation 7.4.4.1-a)

$$= -0.485 + 2(1.315 + 0.4028)(0.0988)(2.26)(0.80)(0.29)(4.025)$$

$$= -0.485 + 0.716$$

$$= 0.231 \text{ per rad} \quad \text{(based on the area and mean aerodynamic chord of the total forward panel and referred to a moment center at } \bar{c}'/4)$$

7.4.4.2 WING-BODY-TAIL ACCELERATION DERIVATIVE $C_{m_{\dot{\alpha}}}$

The information contained in this section is for estimating the nondimensional acceleration derivative $C_{m_{\dot{\alpha}}}$ of wing-body-tail combinations at low angles of attack. This derivative is the change in pitching-moment coefficient with rate of change of angle of attack and is expressed by

$$C_{m_{\dot{\alpha}}} = \frac{\partial C_m}{\partial\left(\frac{\dot{\alpha}\bar{c}}{2V_\infty}\right)}$$

This derivative is important in longitudinal dynamics, since it is involved in the damping of the short-period mode.

The Datcom methods are based on the same assumptions that were made for the total pitching derivative $C_{L_{\dot{\alpha}}}$ of the wing-body-tail combinations, and the general discussion of Section 7.4.4.1 is directly applicable here.

A. SUBSONIC

Two methods are presented for determining the acceleration derivative $C_{m_{\dot{\alpha}}}$ of wing-body-tail combinations, differing only in their treatment of the effect of the flow field of the forward surface on the aft surface.

DATCOM METHODS

Method 1. ($b'/b'' \geq 1.5$)

For configurations in which the span of the forward surface is large compared to that of the aft surface, the following approach can be used. This method is to be used when the ratio of the forward-panel span to the aft-panel span is 1.5 or greater. The equation for the nondimensional acceleration derivative $C_{m_{\dot{\alpha}}}$ of a wing-body-tail configuration, based on the area and the square of the mean aerodynamic chord of the total forward panel and referred to a moment center at the assumed center of gravity or center of rotation, is given by

$$C_{m_{\dot{\alpha}}} = \left(C_{m_{\dot{\alpha}}}\right)_{WB} - 2[K_{W(B)} + K_{B(W)}]'' \left(\frac{S_e''}{S'}\right)\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)^2 \left(\frac{q''}{q_\infty}\right)\left(\frac{\partial\bar{\epsilon}}{\partial\alpha}\right)\left(C_{L_\alpha}\right)_e''$$

7.4.4.2-a

where the primed quantities refer to the forward panel, the double-primed quantities refer to the aft panel, and the subscript e refers to the exposed panel. (See Section 4.3.1.2 for the definition of exposed surfaces.)

$(C_{m_{\dot{\alpha}}})_{WB}$ is the contribution of the wing-body configuration to the acceleration derivative $C_{m_{\dot{\alpha}}}$, obtained from Section 7.3.4.2.

$\frac{\partial \bar{\epsilon}}{\partial \alpha}$ is the downwash gradient averaged over the aft panel, obtained from Section 4.4.1.

The remaining terms are defined in paragraph A of Section 7.4.1.1.

Method 2. $(b'/b'' < 1.5)$

For configurations in which the span of the forward surface is approximately equal to or less than that of the aft surface, the vortex shed from the forward surface interacts directly with the aft surface, and the resulting interference effects must be accounted for in the tail- or aft-surface-contribution terms. This method is to be used when the ratio of the forward-panel span to the aft-panel span is less than 1.5. The equation for the nondimensional acceleration derivative $C_{m_{\dot{\alpha}}}$ of a wing-body-tail configuration, based on the area and the square of the mean aerodynamic chord of the total forward panel and referred to a moment center at the assumed center of gravity or center of rotation, is given by

$$C_{m_{\dot{\alpha}}} = \left(C_{m_{\dot{\alpha}}}\right)_{WB} + 2\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)^2 \left(C_{L_\alpha}\right)_{W''(v)} \qquad 7.4.4.2\text{-b}$$

All the above terms are defined in paragraph A of Section 7.4.1.1 and method 1 above.

Because of the similarity of the two methods a sample problem for method 2 is not included. However, evaluation of the term $(C_{L_\alpha})_{W''(v)}$ for a wing-body-tail configuration is presented in Section 4.5.1.1.

Sample Problem

Method 1

Given: Same configuration as sample problems of paragraph A, Sections 7.4.1.1, 7.4.1.2, and 7.4.4.1. Some of the characteristics are repeated below.

The following ratios based on total forward-panel dimensions:

$$\frac{\ell''}{\bar{c}'} = 2.26 \qquad \frac{S_e''}{S'} = 0.0988$$

Additional Characteristics:

$M = 0.60$ $\beta = 0.80$ $\alpha' = 4^\circ$ cg at $\bar{c}'/4$

Compute:

Step 1 Wing-body $C_{m_{\dot{\alpha}}}$ (Section 7.3.4.2)

$$\left(C_{m_{\dot{\alpha}}}\right)_{WB} = [K_{W(B)} + K_{B(W)}]' \left(\frac{S_e'}{S'}\right)\left(\frac{\bar{c}_e'}{\bar{c}'}\right)^2 \left(C_{m_{\dot{\alpha}}}\right)_e' + \left(C_{m_{\dot{\alpha}}}\right)_B \left(\frac{S_b}{S'}\right)\left(\frac{\ell_B}{\bar{c}'}\right)^2$$

(equation 7.3.4.2-a)

$\left(C_{m_{\dot{\alpha}}}\right)_{WB}$ = −0.400 per rad (sample problem, paragraph A, Section 7.3.4.2)

Step 2. Lift-curve slope for the exposed horizontal-tail panel (Section 4.1.3.2)

$\left(C_{L_\alpha}\right)_e''$ = 4.0 per rad (sample problem, paragraph A, Section 7.4.1.1)

Step 3. Tail-body interference factors (Section 4.3.1.2)

$K_{W(B)}'' = 1.315$

$K_{B(W)}'' = 0.550$

} (sample problem, paragraph A, Section 7.4.1.1)

Step 4. Dynamic pressure ratio (Section 4.4.1)

$\frac{q''}{q_\infty}$ = 0.901 (sample problem, paragraph A, Section 7.4.1.1)

Step 5. Downwash parameter (Section 4.4.1)

$\frac{\partial \bar{\epsilon}}{\partial \alpha}$ = 0.513 (sample problem, paragraph A, Section 7.4.4.1)

Solution:

$$C_{m_{\dot{\alpha}}} = \left(C_{m_{\dot{\alpha}}}\right)_{WB} - 2[K_{W(B)} + K_{B(W)}]'' \left(\frac{S_e''}{S'}\right)\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)^2 \left(\frac{q''}{q_\infty}\right)\left(\frac{\partial \bar{\epsilon}}{\partial \alpha}\right)\left(C_{L_\alpha}\right)_e''$$

(equation 7.4.4.2-a)

$= -0.400 - 2(1.315 + 0.550)\,(0.0988)\,(2.26)^2\,(0.901)\,(0.513)\,(4.0)$

$= -0.400 - 3.48$

$= -3.88$ per rad (based on the area and the square of the mean aerodynamic chord of the total forward panel and referred to a moment center at $\bar{c}'/4$)

B. TRANSONIC

The comments of paragraph B of Section 7.4.4.1 are directly applicable here.

DATCOM METHODS

It is recommended that the methods presented in paragraph A above be applied to the transonic speed regime. Care should be taken to estimate the parameters of equations 7.4.4.2-a and -b at the appropriate Mach number. The interference "K" factors should be obtained from paragraph C, Section 4.3.1.2.

C. SUPERSONIC

The comments of paragraph C of Section 7.4.4.1 are directly applicable here.

DATCOM METHODS

The methods presented in paragraph A above are also applicable to the supersonic speed range. Care should be taken to estimate the parameters of equations 7.4.4.2-a and -b at the appropriate Mach number. Method 3 of paragraph C of Section 4.4.1 should be used to evaluate the last term of equation 7.4.4.2-b.

Sample Problem

Method 1

Given: Same configuration as sample problems of paragraph C, Sections 7.4.1.1, 7.4.1.2, and 7.4.4.1, and paragraph A of this section. Some of the characteristics are repeated below.

The following ratios based on total forward-panel dimensions:

$$\frac{\ell''}{\bar{c}'} = 2.26 \qquad \frac{S_e''}{S'} = 0.0988$$

Additional Characteristics:

$M = 1.4 \qquad \beta = 0.98 \qquad \alpha' = 4^\circ \qquad$ cg at $\bar{c}/4$

Compute:

Step 1. Wing-body $C_{m_{\dot{\alpha}}}$ (Section 7.3.4.2)

$$\left(C_{m_{\dot{\alpha}}}\right)_{WB} = [K_{W(B)} + K_{B(W)}]' \left(\frac{S_e'}{S'}\right)\left(\frac{\bar{c}_e'}{\bar{c}'}\right)^2 \left(C_{m_{\dot{\alpha}}}\right)_e' + \left(C_{m_{\dot{\alpha}}}\right)_B \left(\frac{S_b}{S'}\right)\left(\frac{\ell_B}{\bar{c}'}\right)^2$$

(equation 7.3.4.2-a)

$\left(C_{m_{\dot{\alpha}}}\right)_{WB}$ = 1.308 per rad (sample problem, paragraph C, Section 7.3.4.2)

Step 2. Lift-curve slope for the exposed horizontal-tail panel (Section 4.1.3.2)

$\left(C_{N_\alpha}\right)_e''$ = 4.025 per rad (sample problem, paragraph C, Section 7.4.1.1)

Step 3. Tail-body interference factors (Section 4.3.1.2)

$K_{W(B)}'' = 1.315$

$K_{B(W)}'' = 0.4028$

} (sample problem, paragraph C, Section 7.4.1.1)

Step 4. Dynamic pressure ratio (Section 4.4.1)

$\frac{q''}{q_\infty}$ = 0.80 (sample problem, paragraph C, Section 7.4.1.1)

Step 5. Downwash parameter (Section 4.4.1)

$\frac{\partial \bar{\epsilon}}{\partial \alpha}$ = 0.29 (sample problem, paragraph C, Section 7.4.4.1)

Solution:

$$C_{m_{\dot{\alpha}}} = \left(C_{m_{\dot{\alpha}}}\right)_{WB} - 2[K_{W(B)} + K_{B(W)}]'' \left(\frac{S_e''}{S'}\right)\left(\frac{x_{c.g.} - x''}{\bar{c}'}\right)^2 \left(\frac{q''}{q_\infty}\right)\left(\frac{\partial \bar{\epsilon}}{\partial \alpha}\right)\left(C_{N_\alpha}\right)_e''$$

(equation 7.4.4.2-a)

$= 1.308 - 2(1.315 + 0.4028)\,(0.0988)\,(2.26)^2\,(0.80)\,(0.29)\,(4.025)$

$= 1.308 - 1.619$

$= -0.31$ per rad (based on the area and the square of the mean aerodynamic chord of the total forward panel and referred to a moment center at $\bar{c}'/4$)

7.4.4.3 WING-BODY-TAIL DERIVATIVE $C_{D_{\dot{\alpha}}}$

This section presents a method for estimating the wing-body-tail derivative $C_{D_{\dot{\alpha}}}$ at subsonic speeds. This derivative is the change in the drag coefficient due to a change in $\dot{\alpha}$ at a constant pitch rate and is defined as

$$C_{D_{\dot{\alpha}}} = \frac{\partial C_D}{\partial \left(\frac{\dot{\alpha}\bar{c}}{2V}\right)}, \text{ where } C_D \text{ is based on } S_W.$$

In general, this derivative is small and has a negligible effect on longitudinal stability; hence, it is usually neglected.

A. SUBSONIC

The wing contribution to $C_{D_{\dot{\alpha}}}$ can be estimated using unsteady-flow theory. The body contribution is small and has been neglected. The tail contribution is computed from conventional downwash-lag theory. The horizontal-tail lift due to $\dot{\alpha}$ was taken to act normal to the local flow direction at the tail, to produce a force component in the direction of the free-stream.

DATCOM METHOD

The wing-body-tail derivative is given by

$$C_{D_{\dot{\alpha}}} = \left(C_{D_{\dot{\alpha}}}\right)_W + \left(C_{D_{\dot{\alpha}_0}}\right)_H + \left(\frac{\partial C_{D_{\dot{\alpha}}}}{\partial \alpha_F}\right)_H \alpha_F \qquad 7.4.4.3\text{-a}$$

where

$\left(C_{D_{\dot{\alpha}}}\right)_W$ is the wing contribution to $C_{D_{\dot{\alpha}}}$ obtained from Section 7.1.4.3.

$\left(C_{D_{\dot{\alpha}_0}}\right)_H$ is the horizontal-tail contribution independent of angle of attack, obtained by

$$\left(C_{D_{\dot{\alpha}_0}}\right)_H = \frac{1}{57.3} C_{L_{\alpha_H}} \frac{S_H}{S_W} \frac{(\ell_H \cos\alpha_F + z_H \sin\alpha_F)}{\bar{c}/2} \frac{\partial \epsilon}{\partial \alpha} (2\epsilon_0 - i_H) \qquad 7.4.4.3\text{-b}$$

where

$C_{L_{\alpha_H}}$ is the horizontal-tail lift-curve slope (based on S_H) obtained from test data or from Section 4.1.3.2 (per degree).

S_H is the horizontal-tail reference area.

S_W is the wing reference area.

ℓ_H is the distance from the momen reference center to the center-of-pressure location of the horizontal stabilizer, measured parallel to the body center line. For Datcom purposes, the horizontal-tail center-of-pressure location is assumed to be at the quarter-chord point of the MAC of the total added panel.

z_H is the distance from the moment reference center tc the center-of-pressure location of the horizontal stabilizer, measured normal to the body center line, positive for the stabilizer above the body. For Datcom purposes, the horizontal-tail center-of-pressure location is assumed to be at the quarter-chord point of the MAC of the total added panel.

α_F is the fuselage angle of attack.

$\frac{\partial \epsilon}{\partial \alpha}$ is the downwash gradient at $\bar{c}/4$ of the horizontal tail, obtained from test data or from Section 4.4.1.

$\bar{c}$ is the wing MAC.

ϵ_0 is the downwash angle at $\bar{c}/4$ of the horizontal tail at $\alpha_F = 0$.

i_H is the horizontal-tail incidence with respect to the fuselage reference line.

$\left(\frac{\partial C_{D_\alpha}}{\partial \alpha_F}\right)_H$ is the change in horizontal-tail contribution with angle of attack, obtained by

$$\left(\frac{\partial C_{D_\alpha}}{\partial \alpha_F}\right)_H = \frac{1}{57.3} C_{L_{\alpha_H}} \frac{S_H}{S_W} \frac{(\ell_H \cos \alpha_F + z_H \sin \alpha_F)}{\bar{c}/2} \frac{\partial \epsilon}{\partial \alpha} \left(2 \frac{\partial \epsilon}{\partial \alpha} - 1\right) \qquad 7.4.4.3\text{-c}$$

where all of the terms are defined above.

Sample Problem

Given: Same configuration as sample problem of Paragraph A of Section 7.1.4.3.

Tail Characteristics:

$C_{L_{\alpha_H}} = 0.05$ per deg $\qquad S_H = 16$ ft^2

$\ell_H = 8$ ft $\qquad z_H = 0 \qquad \frac{\partial \epsilon}{\partial \alpha} = 0.32$

$\epsilon_0 = 1^o \qquad i_H = 0$

Compute:

$$\left(C_{D_{\alpha_0}}\right)_H = \frac{1}{57.3} C_{L_{\alpha_H}} \frac{S_H}{S_W} \frac{(\ell_H \cos \alpha_F + z_H \sin \alpha_F)}{\bar{c}/2} \frac{\partial \epsilon}{\partial \alpha} (2 \epsilon_0 - i_H) \qquad \text{(Equation 7.4.4.3-b)}$$

$$= \left(\frac{1}{57.3}\right)(0.05)\left(\frac{16.0}{64.0}\right)\frac{[(8.0)(0.9998)+0]}{4/2}(0.32)[2(1.0)-0]$$

$$= 0.000558$$

$$\left(\frac{\partial C_{D_{\dot{\alpha}}}}{\partial \alpha_F}\right)_H = \frac{1}{57.3} C_{L_{\alpha_H}} \frac{S_H}{S_W} \frac{(\ell_H \cos\alpha_F + z_H \sin\alpha_F)}{\bar{c}/2} \frac{\partial \epsilon}{\partial \alpha}\left(2\frac{\partial \epsilon}{\partial \alpha} - 1\right) \qquad \text{(Equation 7.4.4.3-c)}$$

$$= \left(\frac{1}{57.3}\right)(0.05)\left(\frac{16.0}{64.0}\right)\frac{[(8.0)(0.9998)+0]}{4/2}(0.32)[2(0.32)-1]$$

$$= -0.000100$$

Solution:

$$C_{D_{\dot{\alpha}}} = \left(C_{D_{\dot{\alpha}}}\right)_W + \left(C_{D_{\dot{\alpha}_0}}\right)_H + \left(\frac{\partial C_{D_{\dot{\alpha}}}}{\partial \alpha_F}\right)_H \alpha_F \qquad \text{(Equation 7.4.4.3-a)}$$

$\left(C_{D_{\dot{\alpha}}}\right)_W$ = 0.0085 per deg (Sample Problem, Paragraph A, Section 7.1.4.3)

$$C_{D_{\dot{\alpha}}} = 0.0085 + 0.000558 + (-0.000100)\,1.0$$

$$= 0.00896 \text{ per degree}$$

B. TRANSONIC

No method is presented.

C. SUPERSONIC

No method is presented.

7.4.4.4 WING-BODY-TAIL DERIVATIVE $C_{Y_{\dot{\beta}}}$

This section presents a method for estimating the contribution of the vertical tail, in the presence of the wing and body, to the derivative $C_{Y_{\dot{\beta}}}$ at subsonic speeds. This derivative is the change in side-force coefficient with variations in the rate of change of sideslip angle at a constant yaw rate and is defined as

$$C_{Y_{\dot{\beta}}} = \frac{\partial C_Y}{\partial\left(\frac{\dot{\beta} b}{2V}\right)} \text{, where } C_Y \text{ is based on } S_W.$$

In general, at low to moderate angles of attack, this derivative is small and has a negligible effect on lateral stability; hence, it is usually neglected.

A. SUBSONIC

A wing contribution to $C_{Y_{\dot{\beta}}}$ can be evaluated by using unsteady-flow theory, but at low to moderate angles of attack it is generally considered small and is neglected. At low angles of attack and for attached-flow conditions, the largest contributor to $C_{Y_{\dot{\beta}}}$ is the vertical tail. The method herein applies a sidewash-lag theory in an analogous manner to the downwash-lag theory that is used in finding the horizontal-tail contribution to $C_{L_{\dot{\alpha}}}$. The body contribution is small and has been neglected.

For a brief discussion of the physical flow phenomena at high angles of attack, i.e., leading-edge vortex sheets and flow separation, and a comprehensive bibliography on related subject matter, the reader is referred to Reference 1.

DATCOM METHOD

Design charts for predicting the change of wing sidewash angle with the change of sideslip angle are presented as a function of wing geometry, i.e., aspect ratio, sweep, and taper ratio, at Mach numbers 0.2 and 0.8. These design charts were generated from wing loadings in sideslip by using the theory presented in References 2 and 3.

The vertical-tail contribution to the derivative $C_{Y_{\dot{\beta}}}$ at low to moderate angles of attack is given by

$$C_{Y_{\dot{\beta}}} = 2\, C_{L_{\alpha_V}}\, \sigma_\beta \frac{S_V}{S_W} \frac{(\ell_p \cos\alpha_F + z_p \sin\alpha_F)}{b_W} \qquad 7.4.4.4\text{-a}$$

where

$C_{L_{\alpha_V}}$ is the lift-curve slope of the vertical tail obtained from test data or Section 4.1.3.2.

σ_β is the change of sidewash angle (due only to the wing, i.e., no sidewash due to fuselage cross flow) with respect to the change in the sideslip angle. This factor can be estimated by

$$\sigma_\beta = \sigma_{\beta_\alpha}\alpha_F + \frac{\sigma_{\beta_\Gamma}}{57.3}\Gamma - \sigma_{\beta_\theta}\theta + \sigma_{\beta_{WB}} \qquad 7.4.4.4\text{-b}^*$$

where

σ_{β_α} is the sidewash contribution due to angle of attack, obtained from Figures 7.4.4.4-6a through -6p as a function of $\frac{z_V}{b/2}$ and wing geometry. z_V is the distance between the wing $\bar{c}/4$ point and the vertical-stabilizer center-of-pressure location, measured normal to the free-stream direction. For Datcom purposes the vertical-tail center-of-pressure location is assumed to be at the quarter-chord point of the MAC of the total added panel.

$$z_V = z_p \cos\alpha_F - \ell_p \sin\alpha_F \qquad 7.4.4.4\text{-c}$$

where z_p and ℓ_p are defined below.

α_F is the fuselage angle of attack in degrees.

σ_{β_Γ} is the sidewash contribution due to wing dihedral, obtained from Figures 7.4.4.4-22a through -22d as a function of $\frac{z_V}{b/2}$ and wing geometry.

Γ is the wing dihedral in degrees.

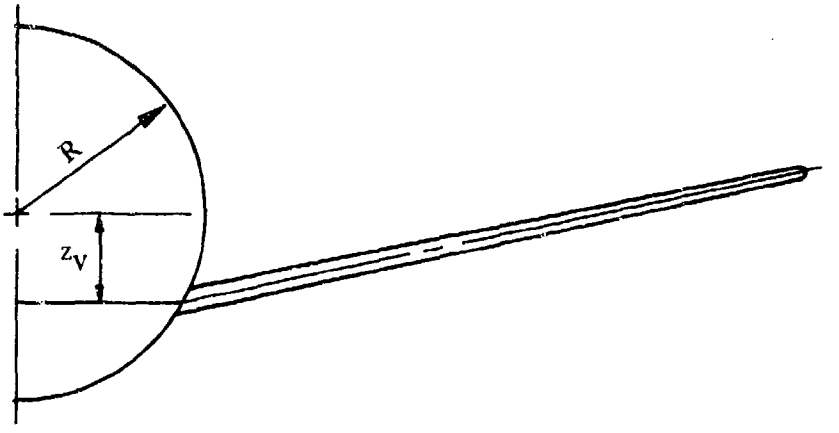
σ_{β_θ} is the sidewash contribution due to wing twist, obtained from Figures 7.4.4.4-26a through -26p as a function of $\frac{z_V}{b/2}$ and wing geometry.

θ is the wing twist in degrees between the root and tip sections, negative for washout (see Figure 5.1.2.1-30b).

$\sigma_{\beta_{WB}}$ is the sidewash contribution due to the body effect on the wing loading. It is presented as a function of $\frac{z_V}{b/2}$ and wing geometry, at three different body-radius-to-wing-span ratios of 0.06, 0.12, and 0.24. In addition, the wing position on the body has an effect on this term. However, for Datcom considerations a low-wing position was assumed as shown in Sketch (a). For a high-wing position as shown in Sketch (b), the sign of $\sigma_{\beta_{WB}}$ in Figures 7.4.4.4-42a through -42p becomes negative.

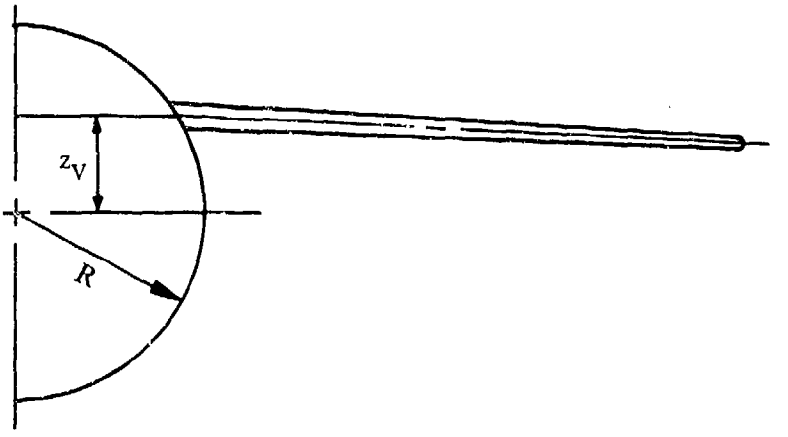
*A more accurate result can be obtained from the equation

$$\sigma_\beta = \frac{1}{S_V}\int_o^{b_V} \sigma_{\beta_{local}} c_V \, dz$$



SKETCH (a)

high-wing position as shown in sketch (b), the sign of $\sigma_{\beta WB}$ in Figures 7.4.4.4-42a through -42p becomes negative.



SKETCH (b)

S_V is the vertical-tail area, consistent with the vertical-tail area used to define $C_{L_{\alpha_V}}$.

S_W is the wing reference area.

ℓ_p is the distance from the wing quarter-chord point to the center-of-pressure location of the vertical stabilizer, measured parallel to the body center line. For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be at the quarter-chord point of the MAC of the total added panel. (See Sketch (a) of Section 7.4.2.1.)

z_p is the distance from the wing quarter-chord point to the center-of-pressure location of the vertical stabilizer, measured normal to the body center line, positive for the stabilizer above the body. For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be at the quarter-chord point of the MAC of the total added panel.

b_W is the wing span.

Sample Problem

Given: The following wing-body-tail configuration

Wing Characteristics:

$A = 7$ $\quad \lambda = 0.25$ $\quad \Lambda_{LE} = 35^o$ $\quad$ Low wing

$S_W = 3500\ ft^2$ $\quad b_W = 156.52\ ft$ $\quad \theta = -5^o$ $\quad \Gamma = 3^o$

Vertical-Tail Characteristics:

$C_{L_{\alpha_V}} = 0.055$ per deg $\quad S_V = 600\ ft^2$

$\frac{z_V}{b/2} = 0.242$

Additional Characteristics:

$\ell_p = 60.0\ ft$ $\quad z_p = 20.0\ ft$ $\quad \alpha_F = 1^o$

$M = 0.8$ $\quad \frac{\text{Body Radius}}{b/2} = 0.12$

Compute:

Determine σ_β

$$\sigma_\beta = \sigma_{\beta_\alpha}\alpha_F + \frac{\sigma_{\beta_\Gamma}}{57.3}\Gamma - \sigma_{\beta_\theta}\theta + \sigma_{\beta_{WB}} \qquad \text{(Equation 7.4.4.4-b)}$$

$\sigma_{\beta_\alpha} = -0.013$ (Figure 7.4.4.4-6ℓ)

$\sigma_{\beta_\Gamma} = -0.56$ (Figure 4.4.4.4-22d)

$\sigma_{\beta_\theta} = -0.0113$ (Figure 7.4.4.4-26ℓ)

$\sigma_{\beta_{WB}} = 0.07$ (Figure 7.4.4.4-42ℓ)

$$\sigma_\beta = (-0.013)(1) + \left(\frac{-0.56}{57.3}\right)3 - (-0.0113)(-5) + (0.07)$$

$$= -0.013 - 0.0293 - 0.0565 + 0.07$$

$$= -0.0288$$

Solution:

$$C_{Y_{\dot\beta}} = 2\,C_{L_{\alpha_V}}\,\sigma_\beta\,\frac{S_V}{S_W}\,\frac{(\ell_p\cos\alpha_F + z_p\sin\alpha_F)}{b_W} \qquad \text{(Equation 7.4.4.4-a)}$$

$$= 2(0.055)(-0.0288)\,\frac{600}{3500}\left[\frac{(60)(0.9998)+(20)(0.01745)}{156.52}\right]$$

$$= -0.000209 \text{ per deg}$$

B. TRANSONIC

No method is presented.

7.4.4.5 WING-BODY-TAIL DERIVATIVE $C_{l_{\dot{\beta}}}$

This section presents a method for estimating the contribution of the vertical tail, in the presence of the wing and body, to the derivative $C_{l_{\dot{\beta}}}$ at subsonic speeds. This derivative is the change in rolling-moment coefficient with variation in the rate of change of sideslip angle at a constant yaw rate and is defined as

$$C_{l_{\dot{\beta}}} = \frac{\partial C_l}{\partial\left(\frac{\dot{\beta} b}{2V}\right)}, \text{ where } C_l \text{ is based on } S_W b_W .$$

In general, at low to moderate angles of attack, this derivative is small and has a negligible effect on lateral stability; hence, it is usually neglected.

A. SUBSONIC

The wing contribution to $C_{l_{\dot{\beta}}}$ can be evaluated by using unsteady-flow theory, but at low to moderate angles of attack it is generally considered small and is neglected. At low angles of attack and for attached-flow conditions, the largest contributor to $C_{l_{\dot{\beta}}}$ is the vertical tail. The rolling moment produced on the airframe by the vertical tail is due to the sidewash time-lag effects from the wing. The body contribution is small and has been neglected.

For a brief discussion of the physical flow phenomena at high angles of attack, i.e., leading-edge vortex sheets and flow separation, and a comprehensive bibliography on related subject matter, the reader is referred to Reference 1. Reference 1 also discusses the inadequacy of oscillating-airfoil theory and sidewash-lag theory for predicting the vertical-tail contribution to $C_{l_{\dot{\beta}}}$ at high angles of attack. However, a modified flow-field-lag theory is discussed in Reference 1 that appears to give qualitative agreement with experimental data for a current twin-jet fighter configuration.

DATCOM METHOD

The vertical-tail contribution to the derivative $C_{l_{\dot{\beta}}}$ at low to moderate angles of attack is given by

$$C_{l_{\dot{\beta}}} = C_{Y_{\dot{\beta}}} \left(\frac{z_p \cos\alpha_F - \ell_p \sin\alpha_F}{b_W}\right) \qquad 7.4.4.5\text{-a}$$

where

$C_{Y_{\dot{\beta}}}$ is the vertical-tail contribution to the derivative $C_{Y_{\dot{\beta}}}$ obtained from Section 7.4.4.4.

z_p is the distance from the wing quarter-chord point to the center-of-pressure location of the vertical stabilizer, measured normal to the body center line, positive for the stabilizer above the body. For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be the quarter-chord point of the MAC of the total added panel.

ℓ_p is the distance from the wing quarter-chord point to the center-of-pressure location of the vertical stabilizer, measured parallel to the body center line. For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be at the quarter-chord point of the MAC of the total added panel. (See Sketch (a) of Section 7.4.2.1.)

α_F is the fuselage angle of attack.

b_W is the wing span.

Sample Problem

Given: Same configuration as sample problem of Paragraph A of Section 7.4.4.4.

Compute:

$$C_{Y_{\dot{\beta}}} = -0.000209 \qquad \text{(Sample Problem, Paragraph A, Section 7.4.4.4)}$$

$$C_{l_{\dot{\beta}}} = C_{Y_{\dot{\beta}}} \left(\frac{z_p \cos \alpha_F - \ell_p \sin \alpha_F}{b_W} \right) \qquad \text{(Equation 7.4.4.5-a)}$$

$$C_{l_{\dot{\beta}}} = (-0.000209) \left[\frac{(20)(0.9998) - (60)(0.0175)}{156.52} \right]$$

$$= -0.0000253 \text{ per deg}$$

B. TRANSONIC

REFERENCE

1. Coe, P. L., Jr., Graham, A. B., and Chambers, J. R.: Summary of Information on Low-Speed Lateral-Directional Derivatives Due to Rate of Change of Sideslip $\dot{\beta}$. NASA TN D-7972, 1975. (U)

7.4.4.6 WING-BODY-TAIL DERIVATIVE $C_{n_{\dot{\beta}}}$

This section presents a method for estimating the contribution of the vertical tail, in the presence of the wing and body, to the derivative $C_{n_{\dot{\beta}}}$ at subsonic speeds. This derivative is the change in yawing-moment coefficient with variation in the rate of change of sideslip angle at a constant yaw rate and is defined as

$$C_{n_{\dot{\beta}}} = \frac{\partial C_n}{\partial\left(\frac{\dot{\beta} b}{2V}\right)}, \text{ where } C_n \text{ is based on } S_W\, b_W .$$

For most configurations at low to moderate angles of attack, $C_{n_{\dot{\beta}}}$ is rather small and can be neglected in lateral dynamic calculations. However, at high angles of attack for swept- and delta-wing configurations, $C_{n_{\dot{\beta}}}$ can approach the magnitude of C_{n_r} and consequently have large effects on the calculated dynamic stability of these configurations.

A. SUBSONIC

The wing contribution to $C_{n_{\dot{\beta}}}$ can be evaluated by using unsteady-flow theory, but at low to moderate angles of attack it is generally considered small and is neglected. At low angles of attack and for attached-flow conditions, the largest contributor to $C_{n_{\dot{\beta}}}$ is the vertical tail. The yawing moment produced on the airframe by the vertical tail is due to the sidewash time-lag effects from the wing. The body contribution is small and has been neglected.

For a brief discussion of the physical flow phenomena at high angles of attack, i.e., leading-edge vortex sheets and flow separation, and a comprehensive bibliography on related subject matter, the reader is referred to Reference 1. Reference 1 also discusses the inadequacy of oscillating-airfoil theory and sidewash-lag theory for predicting the vertical-tail contribution to $C_{n_{\dot{\beta}}}$ at high angles of attack. However, a modified flow-field-lag theory is discussed in Reference 1 that appears to give qualitative agreement with experimental data for a current twin-jet fighter configuration.

DATCOM METHOD

The vertical-tail contribution to the derivative $C_{n_{\dot{\beta}}}$ at low to moderate angles of attack is given by

$$C_{n_{\dot{\beta}}} = -C_{Y_{\dot{\beta}}}\left(\frac{\ell_p \cos\alpha_F + z_p \sin\alpha_F}{b_W}\right) \qquad 7.4.4.6\text{-a}$$

where

$C_{Y_{\dot{\beta}}}$ is the vertical-tail contribution to the derivative $C_{Y_{\dot{\beta}}}$ obtained from Section 7.4.4.4.

ℓ_p is the distance from the moment reference center to the center-of-pressure location of the vertical stabilizer, measured parallel to the body center line. (See Sketch (a) in Section 7.4.2.1.) For Datcom purposes the vertical-tail center-of-pressure location is assumed to be at the quarter-chord point of the MAC of the total added panel.

z_p is the distance from the moment reference center to the center of pressure of the vertical stabilizer, measured normal to the body center line, positive for the stabilizer above the body. For Datcom purposes, the vertical-tail center-of-pressure location is assumed to be at the quarter-chord point of the MAC of the total added panel.

b_W is the wing span.

α_F is the fuselage angle of attack.

Sample Problem

Given: Same configuration as sample problem of Paragraph A of Section 7.4.4.4.

Compute:

$C_{Y_{\dot{\beta}}} = -0.000209$ (Sample Problem, Paragraph A, Section 7.4.4.4)

$$C_{n_{\dot{\beta}}} = -C_{Y_{\dot{\beta}}}\left(\frac{\ell_p \cos\alpha_F + z_p \sin\alpha_F}{b_W}\right) \qquad \text{(Equation 7.4.4.6-a)}$$

$$= -(-0.000209)\left[\frac{(60)(0.9998) + (20)(0.01745)}{156.52}\right]$$

$$= +0.0000805 \text{ per deg}$$

B. TRANSONIC

No method is presented.

C. SUPERSONIC

No method is presented.

8. MASS AND INERTIA

Performance, stability, control, and strength analyses of airborne vehicles depend not only on the mass of the vehicle but on the distribution of the mass within the vehicle. This concept of mass distribution is reflected in the property of the vehicle called moment of inertia. This Section discusses moment of inertia determination for two types of airborne vehicles — manned aircraft and missiles.

8.1 AIRCRAFT MASS AND INERTIA

The purpose of this Section is to furnish the engineer with a method for rapidly but accurately estimating the moment of inertia of manned aircraft during the preliminary-design period. Such inertias are needed in order that dynamic load and stability characteristics of the aircraft may be evaluated.

The following pages present basic moment-of-inertia theory, a discussion of inertia methods in general with the assumptions and conclusions used in evolving the Datcom method, and a discussion of the Datcom method in detail, with a summary showing the step-by-step procedure to follow when using this method.

This method applies to all existing combat and transport aircraft including those of unconventional* design. If radically different airplane configurations evolve, the present methods will have to be altered. The tools needed are a weight-and-balance statement, a three-view drawing, and some knowledge of the design characteristics of the airplane. A total time of approximately three hours for one man is needed to estimate inertia by this method, and the accuracy obtained is within the tolerance required for any preliminary-design project.

Basic Moment-of-Inertia Theory

Moment of inertia is the measure of resistance to angular acceleration, as mass is the measure of resistance to linear acceleration. Moment of inertia may be mathematically derived as follows:

If torque is expressed as the product of force and radius

$$T = Fr$$

and the following substitutions are made:

$$F = ma \quad \text{and} \quad a = \alpha r$$

then

$$T = mar$$

or

$$T = mr^2\alpha \tag{8.1-a}$$

where

a is the linear acceleration
α is the angular acceleration
m is the mass

The term mr^2 is defined as the moment of inertia (I) and equation 8.1-a may be written

$$T = I\alpha \tag{8.1-b}$$

If a body of mass m is caused to rotate about a remote axis y (see sketch (a)) the following relationship exists:

$$I_y = mr^2 = m(x^2 + z^2) \tag{8.1-c}$$

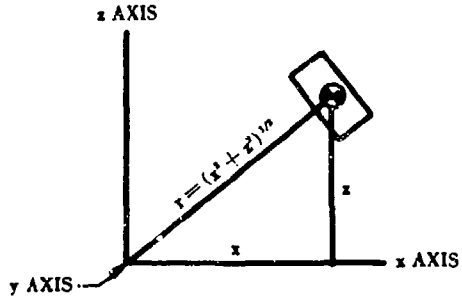
However, since mass m not only offers resistance to rotation about the y axis but also offers resistance to rotation about its own centroidal axis, the total inertia of m about y is

$$I_y = mr^2 + I_{oy} \tag{8.1-d}$$

where I_{oy} is the inertia of m about its own centroidal axis.

---

*The term unconventional as used herein refers chiefly to extreme locations of the wing, fuselage, tail and power plant sections with respect to each other, and to the size and mass of these sections. However, when the shape and mass distribution of any of the sections change considerably over present state of the art design, the method for computing inertia as described herein should be altered accordingly.



SKETCH (s)

If mass m is divided into several parts, $m_1, m_2, \ldots m_n$, then the total inertia of the sum of these parts about y is

$$I_y = m_1 r_1^2 + I_{oy_1} + m_2 r_2^2 + I_{oy_2} + \ldots m_n r_n^2 + I_{oy_n}$$

or

$$I_y = \sum_{i=1}^{n} (m_i r_i^2 + I_{oy_i}) \qquad 8.1\text{-e}$$

Finally, if the total inertia about a remote axis is computed from equation 8.1-e, the inertia of the total mass about its own centroidal axis can be computed from equation 8.1-d, or

$$I_{oy} = I_y - m\bar{r}^2 \qquad 8.1\text{-f}$$

where $\bar{r}$ is the distance from the y axis to the centroid of the total mass.

$$\bar{r} = \frac{\sum_{i=1}^{n} m_i r_i}{\sum_{i=1}^{n} m_i} \qquad 8.1\text{-g}$$

Inertia Methods in General

As equation 8.1-d indicates, the inertia of a body about a remote axis depends on three basic factors: (1) mass, (2) the distance of the mass from the remote axis, and (3) the inertia of the mass about its own centroidal axis. If any one of these factors is ignored, the inertia derived will not be accurate.

A common method is to divide the airplane into many sections, so that the I_o values may be calculated easily and accurately. The total airplane inertia about the remote axis may then be derived by equation 8.1-e, and the total inertia about the aircraft's centroidal axis by equation 8.1-f. Unfortunately, however, this method requires a detail breakdown of the masses and centroids of the components of the aircraft as well as a large time expenditure. Therefore the method does not lend itself to successful application at the preliminary design level.

Another method for computing inertia is one in which the total mass and dimensional data of the aircraft are used as parameters in an empirical inertia equation. However, the equations have to be based on aircraft with mass distribution similar to that of the proposed aircraft, since the mass and locations of the wing, fuselage, tail, and engines can vary greatly between aircraft. This means that a large amount of statistical data has to be available, and this type of method is almost useless for aircraft of unconventional design, where there is a lack of statistical data.

Obviously neither of these two methods fulfills the requirements for one rapid but accurate method independent of airplane type or conventional nature. But consideration of a few facts about inertia methods in general shows which method is preferable in a particular situation. These facts are:

(1) When statistical data are not available —

(a) The time required to compute inertia and the accuracy of the answer are directly proportional to the number of sections into which the airplane is divided.

(b) The number of sections into which the airplane is divided is dependent on the amount of detail information available.

(2) When statistical data are available —

(a) Time is inversely proportional to parametric correlation, which is the mutual relationship of the inertia of the proposed aircraft to statistical data by means of parameters such as size, shape, and mass.

(b) Accuracy is dependent upon the extent to which parametric correlation is applied. This means that, if these correlations are carried beyond the bounds of mass distribution similarity, the accuracy is affected adversely; if carried only as far as these bounds, the accuracy is affected only slightly.

Therefore the method evolved is one that divides the airplane into the least number of sections necessary to maintain sufficient mass distribution similarity to permit valid parametric correlation. Thus the accuracy obtained is within the tolerance required for preliminary-design studies. After careful consideration, these five major sections were chosen:

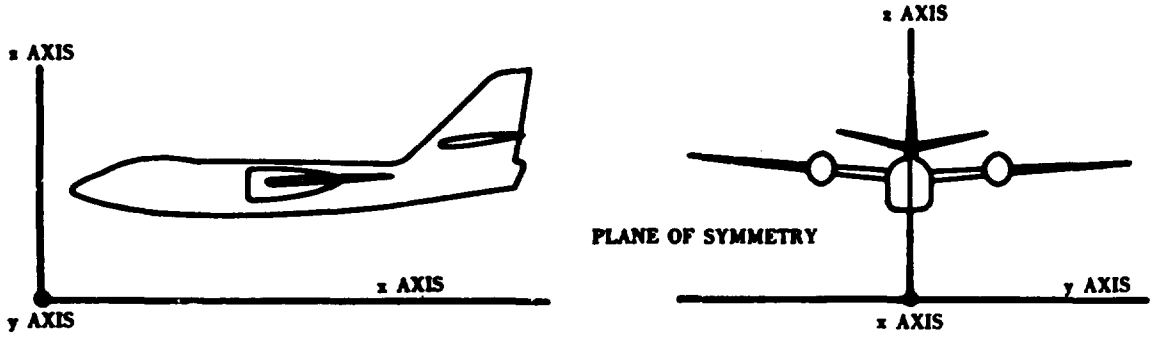
(1) Wing
(2) Fuselage
(3) Horizontal Stabilizer
(4) Vertical Stabilizer
(5) Power Plant (Engine and Nacelle)

The inertias for fuel, cargo, and other variable items may also be added, as shown in the sample problem.

DATCOM METHOD

The method consists of determining the mass and centroids for each of the major sections and then, by equations involving the parameters of size, shape, mass, and centroids, calculating the I_o values for each of these sections. Once this is completed, the inertias about the remote axis may be derived by equation 8.1-e, and hence the inertias about the airplane centroids by equation 8.1-f.

The I_o formulas are based on aircraft in a gear-up configuration with expendable and variable items, such as fuel, cargo, and passengers, deleted. Since it is impossible to predict the aircraft configurations for which inertia will be needed, the inertia for the expendable and variable items comprising these configurations must be added to the basic inertia derived from the method.



SKETCH (b)

Step 1. Selection of remote axes — Three remote axes are chosen so that inertia in pitch, roll, and yaw may be calculated. The origin of these axes should be located so that distances to the centroids of the major sections are positive and should be located on the plane of symmetry of the airplane. This type of location simplifies calculations and minimizes errors. An example of a remote-axis selection is shown in sketch (b). The "x" axis is the axis along which longitudinal distances are measured; the y axis is the axis along which the lateral distances are measured; the z axis is the axis along which vertical distances are measured.

Step 2. Mass and centroid determinations for the major sections — With the aid of a weight-and-balance statement, the three-view drawing, and a knowledge of the locations of the group items, the mass and corresponding centroids for each of the five sections are determined. These values are then recorded on a form similar to the one shown in the sample problem.

For single-engine aircraft with the engine mounted on the aircraft plane of symmetry and with the nacelle structure in part integral with the fuselage, only the engine is considered as a separate section, and the nacelle and other engine items are considered with the fuselage section. Only x and z distances are recorded for all sections mounted on the aircraft plane of symmetry. However, for noncenterline-mounted vertical stabilizers and power-plant sections y distances are recorded in addition to x and z values, since the I_o values are calculated about the centroids of each section For example, the power-plant sections for a four-engine aircraft are analyzed as follows:

The masses of both inboard power-plant sections are added together and recorded. The lateral distance from the aircraft plane of symmetry to the centerline of one of the inboard power plants is recorded along with the distances from the other two axes. The outboard power plants are analyzed similarly, except that the lateral distance recorded is measured from the aircraft plane of symmetry to the centerline of one of the outboard power plant sections.

Care must be taken to use consistent units for mass and distance throughout the entire calculation. Since most group components are listed by pounds, this unit of weight may be used for all calculations. The resulting inertias may then be converted to units involving mass by dividing by the acceleration due to the force of gravity at the desired altitude. An example of such a conversion is included in the sample problem.

Step 3. Calculations of I_o for the major sections — The I_o values for the major sections are determined by first considering an "ideal" formula that closely correlates with the shape of the section. These formulas are labeled "ideal," since they are based on sound mathematical principles, a prerequisite for any school, and since they assume a homogeneous mass distribution throughout the section. The result from the "ideal" formula is then multiplied by a K factor that accounts for deviations in the homogeneous nature of the mass of the section. These factors are based on statistical data. It is found that for some sections a constant factor may be used. For other sections, where the mass distribution may vary considerably, it is found that the K factor varies primarily with the centroid location of the section. Graphs showing the variable K factors, along with substantiating correlation plots, are included as figures. The I_o calculations for each section follow:

(a) Wing Pitching I_o

The wing pitching I_o formulas are listed in the summary. The formulas are based on a consideration of three basic wing shapes (see figure 8.1-22). A constant K factor ($K_o = 0.703$) is used for all wing designs.

(b) Wing Rolling I_o

Because of the large span of the wing with respect to other sections of the aircraft, the wing rolling I_o calculations has the greatest effect on the rolling inertia of the aircraft. The variable K factor (K_I) shown in figure 8.1-23 is based primarily on the lateral centroid of half the wing. As this centroid approaches the aircraft plane of symmetry, more weight must be concentrated in the inboard section of the wing, thereby lowering its I_o value.

(c) Wing Yawing I_o

As is shown by statistical data and by an analysis of the inertias of flat plates, the wing yawing I_o is equal to the sum of the wing pitching and rolling I_o's.

(d) Fuselage Pitching I_o

The fuselage pitching I_o formula is based on that of a combination cylindrical shell and conical shell. The formula provides that as the ratio of the fuselage wetted area to the theoretical wetted area of the fuselage as a two-way cone increases, the inertia approaches that of a cylindrical shell. The fuselage I_o is probably the most difficult to correlate parametrically, since parameters are not available to accurately predict the location of large mass items such as landing gear, electronic equipment, etc. However, statistical data show that the longitudinal centroid location has a definite bearing on the inertia, and therefore the variable K factor (K_x) uses this centroid location as its basic parameter (see figure 8.1-24). It should also be noted that the fuselage pitching I_o has the greatest effect on the pitching inertia of the airplane.

(e) Fuselage Rolling I_o

The formula is based on that of a cylindrical shell of an average diameter determined by consideration of the fuselage wetted area. The fuselage diameter and the ratio of the fuselage structural mass to the total fuselage section mass are the parameters by which K is computed. As the fuselage diameter decreases, the I_o approaches that of a solid cylinder, since the solidity of the equipment items is more effective. Therefore the fuselage diameter is directly proportional to the I_o value since the rolling I_o of the solid circular cylinder is less than that of a cylindrical shell.

The ratio of the fuselage structural mass to the total fuselage-section mass is also directly proportional to the I_o result, since as the value of the ratio decreases, the effect of the solidity of equipment items increases, which decreases the final I_o result. The graph for determining the variable K factor (K_o) is shown as figure 8.1-25.

(f) Fuselage Yawing I_o

As is shown by statistical data and by an analysis of the inertias of cylindrical bodies, the fuselage yawing I_o is equal to the fuselage pitching I_o.

(g) Tail Section I_o

The tail section I_o determinations are similar to those discussed for the wing. Note that the constant K factor used in evaluating tail section I_o's differs from the wing K_o value. For horizontal or vertical stabilizers $K_o = 0.771$.

(h) Power-Plant Pitching and Rolling I_o

The power-plant pitching and rolling formulas are based on that of a solid circular cylinder. The pitching I_o formula accounts for differences in length between the nacelle structure and the engine. Both formulas include a constant factor that may be used for all designs. These formulas are given in the Datcom Summary.

(i) Power-Plant Yawing I_o

As is shown by statistical data and an analysis of the inertias of cylindrical bodies, the power plant yawing I_o is equal to the power plant pitching I_o.

Step 4. Total airplane inertia — When the data discussed above and similar data for the expendable or variable load items have been itemized, the total airplane inertias in pitch, roll, and yaw can be determined from equations 8.1-e and 8.1-f. For further illustration, see the sample problem.

Ten aircraft were analyzed in detail, in order to substantiate the method and the choice of major sections. These aircraft were chosen for their availability of data, for the degree in which they could be analyzed in detail, and for the large cross section of configurations, which include (1) those with a weight empty of from 7,000 to 125,000 pounds, (2) swept and nonswept wing designs, (3) combat, cargo, and passenger types for Air Force, Navy, and commercial uses, (4) reciprocal and jet, both multiple- and single-engine designs, (5) wing and fuselage engine locations, (6) wing and fuselage main-landing-gear locations, (7) fuselage and nonfuselage fuel locations, and (8) all types of tail configurations, including those having wing-mounted elevons instead of horizontal stabilizers.

DATCOM METHOD — SUMMARY

1. Notation*

I_y	pitching moment of inertia about a remote axis
I_x	rolling moment of inertia about a remote axis
I_z	yawing moment of inertia about a remote axis
I_{oy}	pitching moment of inertia about the centroidal axis of the body
I_{ox}	rolling moment of inertia about the centroidal axis of the body
I_{oz}	yawing moment of inertia about the centroidal axis of the body
W_w	weight of wing section including wing carry-through structure
$\bar{y}_w$	lateral centroidal distance of half-wing from aircraft plane of symmetry
C_a, C_b, C_c	wing parameters measured parallel to plane of symmetry (see figure 8.1-22 and page 8.1-7)
c_r	root chord of wing (at ℄)
c_t	tip chord of wing
Λ_{LE}	sweepback angle of wing leading edge
W_f	weight of fuselage section
W_{fs}	weight of fuselage structure
$\bar{x}_f$	longitudinal centroidal distance of fuselage from nose
l_B	length of fuselage
d	average maximum diameter of fuselage $= \frac{\text{max. diameter} + \text{max. width}}{2}$
S_s	fuselage wetted area
W_H	weight of horizontal stabilizer section
$\bar{y}_H$	lateral centroidal distance of half horizontal stabilizer from aircraft plane of symmetry
c_{r_H}	root chord of horizontal stabilizer (at ℄)
c_{t_H}	tip chord of horizontal stabilizer
b_H	span of horizontal stabilizer
Λ_{LE_H}	sweepback angle of horizontal-stabilizer leading edge
W_V	weight of vertical stabilizer
$\bar{z}_V$	vertical centroidal distance of vertical stabilizer from theoretical root chord (at fuselage)
c_{r_V}	root chord of vertical stabilizer (at fuselage)

* Since the values used for W in this section are those of weight instead of mass, the solution of the equations is more general and applicable to any altitude. Consequently, the inertias throughout the problem are in lb-in.^{2}, but are converted at the end of the problem to slug-ft^2 by using the value of gravity at the particular altitude.

c_{t_V} tip chord of vertical stabilizer

b_{v_1} span of vertical stabilizer (tip to fuselage)

Λ_{LE_V} sweepback angle of vertical stabilizer leading edge

W_P weight of power plant section

W_e weight of engine and propeller (if applicable)

l_e length of engine including propeller (if applicable)

d_e average maximum diameter of engine

l_p length of nacelle structure

ρ ratio of weight to chord for wing shapes

2. Select three remote axes and an origin location for these axis.

3. Determine mass and centroids for all sections and applicable expendable and variable load items and record on a convenient form.

4. From the information determined by item 3, calculate and record mass times centroid and mass times centroid squared.

5. Determine the I_o figures for the major sections as follows:

a. Wing pitching I_o (see figure 8.1-22 for development of equations)

if: $$W_W = \frac{\rho}{2}(-C_a + C_b + C_c) \qquad 8.1\text{-h}$$

$$W_W x = \frac{\rho}{6}(-C_a^2 + C_b^2 + C_c C_b + C_c^2) \qquad 8.1\text{-i}$$

$$I = \frac{\rho}{12}(-C_a^3 + C_b^3 + C_c^3 C_b + C_c C_b^2 + C_c^3) \qquad 8.1\text{-j}$$

$$I_{oy} = K_o\left[I - \frac{(W_w x)^2}{W_W}\right] \qquad 8.1\text{-k}$$

where:

$K_o = 0.703$

C_a is the smallest of the following values:

$$c_r \;;\; \frac{b_W \tan \Lambda_{LE}}{2} \;;\; c_t + \frac{b_W \tan \Lambda_{LE}}{2} \qquad 8.1\text{-}\ell$$

C_b is the intermediate value

C_c is the largest value

b. Wing Rolling I_o

$$I_{ox} = \frac{W_w b_W^2 K_1}{24}\left(\frac{c_r + 3c_t}{c_r + c_t}\right) \qquad 8.1\text{-m}$$

where K_1 is obtained from figure 8.1-23.

c. Wing Yawing I_o

$$I_{oz} = I_{oy} + I_{ox} \qquad 8.1\text{-n}$$

d. Fuselage Pitching I_o

$$I_{oy} = \frac{W_f S_s K_2}{37.68}\left(\frac{3d}{2l_B} + \frac{l_B}{d}\right) \qquad 8.1\text{-}o$$

where K_2 is obtained from figure 8.1-24.

e. Fuselage Rolling I_o

$$I_{ox} = \frac{W_f K_3}{4}\left(\frac{S_s}{\pi l_B}\right)^2 \qquad 8.1\text{-}p$$

where K_3 is obtained from figure 8.1-25.

f. Fuselage Yawing I_o

$$I_{oz} = I_{oy} \qquad 8.1\text{-}q$$

g. Horizontal Stabilizer Pitching I_o

Use same equations as wing pitching I_o

$K_o = 0.771$

h. Horizontal Stabilizer Rolling I_o

$$I_{ox} = \frac{W_H b_H^2 K_4}{24}\left(\frac{c_{r_H} + 3c_{t_H}}{c_{r_H} + c_{t_H}}\right) \qquad 8.1\text{-}r$$

where K_4 is obtained from figure 8.1-26.

i. Horizontal Stabilizer Yawing I_o

$$I_{oz} = I_{oy} + I_{ox} \qquad 8.1\text{-}s$$

j. Vertical Stabilizer Rolling I_o

$$I_{ox} = \frac{W_v b_{v_1}^2 K_5}{18}\left[1 + \frac{2c_{r_V} c_{t_V}}{(c_{r_V} + c_{t_V})^2}\right] \qquad 8.1\text{-}t$$

where K_5 is obtained from figure 8.1-27.

k. Vertical Stabilizer Yawing I_o

Use same equations as wing pitching I_o (use twice the vertical stabilizer span as the value of b in the equations for wing pitching I_0)

$K_o = 0.771$

Vertical Stabilizer Pitching I_o

$$I_{oy} = I_{oz} + I_{ox} \qquad 8.1\text{-}u$$

m. Power Plant Pitching I_o

$$I_{oy} = 0.061\left[\frac{3}{4} W_p d_e^2 + W_e l_e^2 + (W_p - W_e) l_p^2\right] \qquad 8.1\text{-}v$$

n. Power Plant Rolling I_o

$$I_{ox} = 0.083\, W_p d_e^2 \qquad 8.1\text{-}w$$

o. Power Plant Yawing I_o

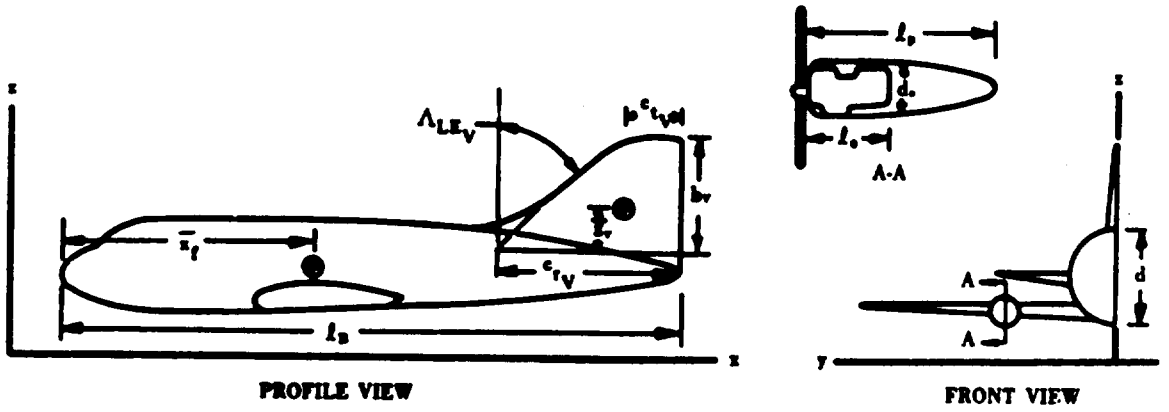
$$I_{oz} = I_{oy} \qquad \text{8.1-x}$$

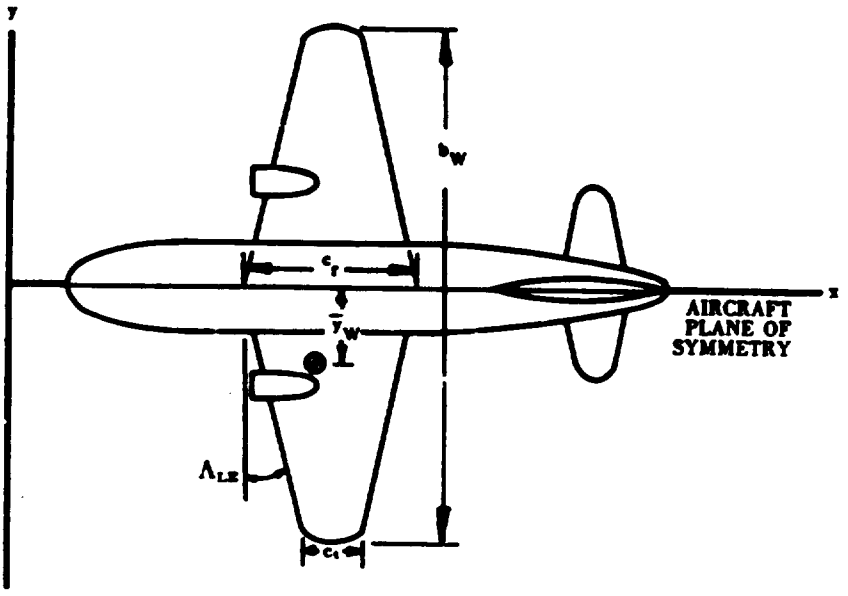
6. Determine the I_o value for the expendable and variable load items by considering the conventional inertia formulas which closely match the shape of these load items. (See sample problem.)

7. Determine the total airplane inertias in pitch, roll, and yaw by using equations 8.1-e and 8.1-f. (See sample problem.)

Sample Problem

Given:





Wing

$\Lambda_{LE} = 12.1°$

$b_W = 10$

$c_r = 300$ in.

$c_t = 100$ in.

$\bar{y}_W = 150$ in.

Hor. Stab.

$\Lambda_{LE_H} = 12°$

$b_H = 400$ in.

$c_{r_H} = 100$ in.

$c_{t_H} = 50$ in.

$\bar{y}_H = 80$ in.

Ver. Stab.

$\Lambda_{LE_V} = 37°$

$b_{V_1} = 200$ in.

$c_{r_V} = 250$ in.

$c_{t_V} = 100$ in.

$\bar{z}_V = 75$ in.

Fuselage

$l_n = 1200$ in.

$d = 150$ in.

$\bar{x}_f = 500$ in.

$S_s = 400{,}000$ sq in.

$W_{f_s} = 8000$ lb

Power Plant

$l_p = 200$ in.

$l_e = 100$ in.

$d_e = 50$ in.

$W_e = 7000$ lb

SECTION	WEIGHT (lbs)	x (in.)	z (in.)	y (in.)
Wing	15,000	650	150	
Fuselage	20,000	600	200	
H. Stab.	1000	1150	200	
V. Stab.	300	1200	300	
P. Plant	10,000	520	150	200
Fuel	20,000	650	150	
Cargo	10,000	500	200	

Compute:

1. Calculate and tabulate the products of weight and centroid location and the products of weight and centroid location squared.

2. Determine the I_o values for the major sections.

   a. Wing pitching I_o

$$C_a = \frac{b_W \tan \Lambda_{LE}}{2} = \frac{(1000) \tan 12.1°}{2} = 107 \text{ in.}$$

$$C_b = c_t + \frac{b_W \tan \Lambda_{LE}}{2} = 100 + 107 = 207 \text{ in.}$$

$$C_c = c_r = 300 \text{ in.}$$

(equation 8.1-ℓ)

$K_o = 0.703$ (constant for any wing)

$$\rho = \frac{W_W}{.5\,(-C_a + C_b + C_c)} \quad \text{(equation 8.1-h)}$$

$$= \frac{15{,}000}{.5\,(-107 + 207 + 300)} = 75 \text{ lb/in.}$$

$$W_W x = \frac{\rho}{6}[-C_a^2 + C_b^2 + C_c C_b + C_c^2] \quad \text{(equation 8.1-i)}$$

$$= 12.5\,[-(107)^2 + (207)^2 + (300)(207) + (300)^2] = 2{,}293{,}750 \text{ lb-in.}$$

$$I = \frac{\rho}{12}[C_r^3 + C_r^2 C_t + C_r C_t^2 + C_t^3] \quad \text{(equation 8.1-j)}$$

$$= 0.23[(107)^3 + (207)^2 + (300)^2(207) + (300)(207)^2 + (300)^3] = 413,308,750 \text{ lb-in.}^2$$

$$I_{oy} = K_o\left[I - \frac{(W_w \bar{x})^2}{W_w}\right] \text{(equation 8.1-k)}$$

$$= (0.703)\left[413,308,750 - \frac{(2,293,750)^2}{15,000}\right] = 43,976,971 \text{ lb-in.}^2$$

b. Wing Rolling I_o

$$\frac{\bar{y}_w}{\frac{b_w}{6}\frac{c_r + 2c_t}{c_r + c_t}} = \frac{150}{208} = 0.72$$

$K_1 = 0.67$ (figure 8.1-23)

$$I_{ox} = \frac{W_w b_w^2 K_1}{24}\left(\frac{c_r + 3c_t}{c_r + c_t}\right) \quad \text{(equation 8.1-m)}$$

$$= \frac{(15,000)(1000)^2(0.67)}{24}\left(\frac{300 + 300}{300 + 100}\right) = 628,125,000 \text{ lb-in.}^2$$

c. Wing Yawing I_o

$$I_{oz} = I_{oy} + I_{ox} \quad \text{(equation 8.1-n)}$$

$$= 43,976,971 + 628,125,000 = 672,101,971 \text{ lb-in.}^2$$

d. Fuselage Pitching I_o

$$\frac{\left|\frac{\ell_B}{2} - \bar{x}_f\right|}{\frac{\ell_B}{2}} = \frac{|600 - 500|}{600} = 0.17$$

$K_2 = 0.83$ (figure 8.1-24)

$$I_{oy} = \frac{W_f S_o K_2}{37.68}\left(\frac{3d}{2\ell_B} + \frac{\ell_B}{d}\right) \quad \text{(equation 8.1-o)}$$

$$= \frac{(20,000)(400,000)(0.83)}{37.68}\left(\frac{450}{2400} + \frac{1200}{150}\right) = 1,442,807,855 \text{ lb-in.}^2$$

e. Fuselage Rolling I_o

$$\frac{(d)^{1/2}(W_{fs})}{W_f} = \frac{(150)^{1/2}(8,000)}{20,000} = 4.9$$

$K_3 = 0.97$ (figure 8.1-25)

$$I_{ox} = \frac{W_f K_3}{4}\left(\frac{S_1}{\pi \ell_B}\right)^2 \quad \text{(equation 8.1-p)}$$

$$= \frac{(20,000)(0.97)}{4}\left(\frac{400,000}{1200\pi}\right)^2 = 54,600,860 \text{ lb-in.}^2$$

f. Fuselage Yawing I_o

$$I_{oz} = I_{oy} = 1,422,807,855 \text{ lb-in.}^2$$

g. Horizontal Stabiliser Pitching I_α

$$C_a = \frac{b_H \tan \Lambda_{LE_H}}{2} = \frac{(400) \tan 12°}{2} = 43 \text{ in.}$$

$$C_b = c_{t_H} + \frac{b_H \tan \Lambda_{LE_H}}{2} = 50 + 43 = 93 \text{ in.}$$

$$C_c = c_{t_H} = 100 \text{ in.}$$

(equation 8.1-*l*)

$K_\alpha = 0.771$ (constant for any tail surface)

$$\rho = \frac{W_H}{.5(-C_a + C_b + C_c)} \quad \text{(equation 8.1-h)}$$

$$= \frac{1000}{.5(-43 + 93 + 100)} = 13.3 \text{ lb/in.}$$

$$Wx = \frac{\rho}{6}[-C_a^2 + C_b^2 + C_cC_b + C_c^2] \quad \text{(equation 8.1-i)}$$

$$W_Hx = 2.2[-(43)^2 + (93)^2 + (100)(93) + (100)^2] = 57{,}420 \text{ lb-in.}$$

$$I = \frac{\rho}{12}[-C_a^3 + C_b^3 + C_c^2C_b + C_cC_a^2 + C_c^3] \quad \text{(equation 8.1-j)}$$

$$= 1.1[-(43)^3 + (93)^3 + (100)^2(93) + (100)(93)^2 + (100)^3] = 3{,}871{,}725 \text{ lb-in.}^2$$

$$I_{\alpha y} = K_\alpha\left[I - \frac{W_Hx^2}{W_H}\right] \quad \text{(equation 8.1-k)}$$

$$= (0.771)\left[3{,}871{,}725 - \frac{(57{,}420)^2}{1000}\right] = 443{,}070 \text{ lb-in.}^2$$

h. Horizontal Stabiliser Rolling I_α

$$\frac{\bar{y}_H}{\frac{b_H}{6}\left(\frac{c_{r_H} + 2c_{t_H}}{c_{r_H} + c_{t_H}}\right)} = \frac{80}{\frac{400}{6}\left(\frac{100 + 100}{100 + 50}\right)} = 0.90$$

$K_\alpha = 0.740$ (figure 8.1-26)

$$I_{\alpha x} = \frac{W_H b_H^2 K_\alpha}{24}\left(\frac{c_{r_H} + 3c_{t_H}}{c_{r_H} + c_{t_H}}\right) \quad \text{(equation 8.1-r)}$$

$$= \frac{(1000)(400)^2(0.74)}{24}\left(\frac{100 + 150}{100 + 50}\right) = 8{,}222{,}222 \text{ lb-in.}^2$$

i. Horizontal Stabiliser Yawing I_α

$$I_{\alpha z} = I_{\alpha y} + I_{\alpha x} \quad \text{(equation 8.1-s)}$$

$$= 443{,}070 + 8{,}222{,}222 = 8{,}665{,}292 \text{ lb-in.}^2$$

j. Vertical Stabiliser Rolling I_α

$$\frac{\bar{z}_V}{\frac{b_V}{3}\left(\frac{c_{r_V} + 2c_{t_V}}{c_{r_V} + c_{t_V}}\right)} = \frac{75}{\frac{200}{3}\left(\frac{250 + 200}{250 + 100}\right)} = 0.87$$

$K_\alpha = 0.930$ (figure 8.1-27)

$$I_{\alpha z} = \frac{W_V b_V^2 K_\alpha}{18}\left[1 + \frac{2c_{r_V}c_{t_V}}{(c_{t_V} + c_{t_V})^2}\right] \quad \text{(equation 8.1-t)}$$

$$= \frac{(300)(200)^2(0.93)}{18}\left[1 + \frac{2(250)(100)}{(250+100)^2}\right] = 872{,}960 \text{ lb-in.}^2$$

k. Vertical Stabilizer Yawing I_o

$$\left.\begin{aligned} C_a &= b_{V_1} \tan \Lambda_{LE_V} = (200) \tan 37^\circ = 150 \text{ in.} \\ C_b &= c_{t_V} + b_{V_1} \tan \Lambda_{LE_V} = 100 + 150 = 250 \text{ in.} \\ C_c &= c_{t_V} = 250 \text{ in.} \end{aligned}\right\} \text{ (equation 8.1-}\ell\text{)}$$

$K_o = 0.771$ (constant for any tail surface)

$$\rho = \frac{W_V}{.5(-C_a + C_b + C_c)} \text{ (equation 8.1-h)}$$

$$= \frac{300}{.5(-150+250+250)} = 1.7 \text{ lb/in.}$$

$$W_V x = \frac{\rho}{6}[-C_a^2 + C_b^2 + C_c C_b + C_c^2] \text{ (equation 8.1-i)}$$

$$= 0.28[-(150)^2 + (250)^2 + (250)(250) + (250)^2] = 46{,}200 \text{ lb-in.}$$

$$I = \frac{\rho}{12}[-C_a^3 + C_b^3 + C_c^2 C_b + C_c C_b^2 + C_c^3] \text{ (equation 8.1-j)}$$

$$= 0.14[-(150)^3 + (250)^3 + (250)^2(250) + (250)(250)^2 + (250)^3] = 8{,}277{,}500 \text{ lb-in.}^2$$

$$I_{ox} = K_o\left[I - \frac{(W_V x)^2}{W_V}\right] \text{ (equation 8.1-k)}$$

$$= (0.771)\left[8{,}277{,}500 - \frac{(46{,}200)^2}{300}\right] = 896{,}442 \text{ lb-in.}^2$$

l. Vertical Stabilizer Pitching I_o

$$I_{oy} = I_{ox} + I_{oz} \text{ (equation 8.1-u)}$$

$$= 872{,}960 + 896{,}442 = 1{,}769{,}402 \text{ lb-in.}^2$$

m. Power Plant Pitching I_o

$$I_{oy} = 0.061\left[\frac{3}{4} W_e d_o^2 + W_e \ell_e^2 + (W_p - W_e)\ell_p^2\right] \text{ (equation 8.1-v)}$$

$$= 0.061\left[\frac{3}{4}(10{,}000)(50)^2 + (7000)(100)^2 + (10{,}000-7000)(200)^2\right]$$

$$= 12{,}733{,}750 \text{ lb-in.}^2$$

n. Power Plant Rolling I_o

$$I_{oz} = 0.083 W_p d_o^2 \text{ (equation 8.1-w)}$$

$$= (0.083)(10{,}000)(50)^2 = 2{,}075{,}000 \text{ lb-in.}^2$$

o. Power Plant Yawing I_o

$$I_{ox} = I_{oy} = 12{,}733{,}750 \text{ lb-in.}^2 \text{ (equation 8.1-x)}$$

3. Determine the I_o values for the expendable and variable loads items

a. Fuel I_o

Estimate fuel volume as a rectangular flat plate

Span = 600 in. Chord = 150 in. Thickness = 8 in.

Using the conventional inertia formula for a rectangular parallelopiped

$$I_{oy} = \frac{W}{12}(c^2 + t^2) = \frac{20{,}000}{12}[(150)^2 + (8)^2] = 37{,}606{,}667 \text{ lb-in.}^2$$

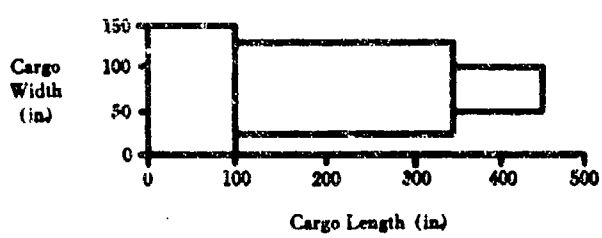
$$I_{ox} = \frac{W}{12}(b^2 + t^2) = \frac{20{,}000}{12}[(600)^2 + (8)^2] = 600{,}106{,}667 \text{ lb-in.}^2$$

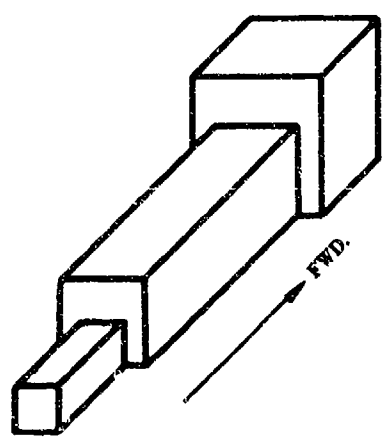
$$I_{oz} = \frac{W}{12}(c^2 + b^2) = \frac{20{,}000}{12}[(150)^2 + (600)^2] = 637{,}500{,}000 \text{ lb-in.}^2$$

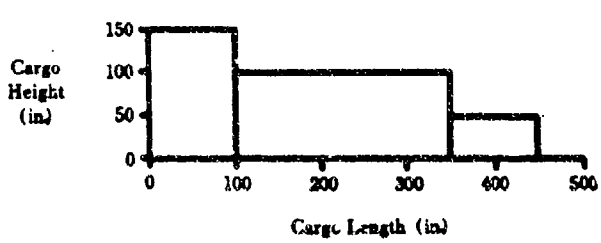
where W is the fuel weight

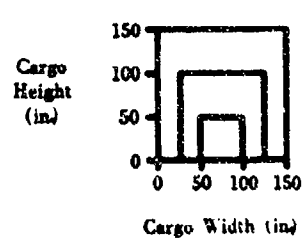
b. Cargo I_o

*Cargo Distribution

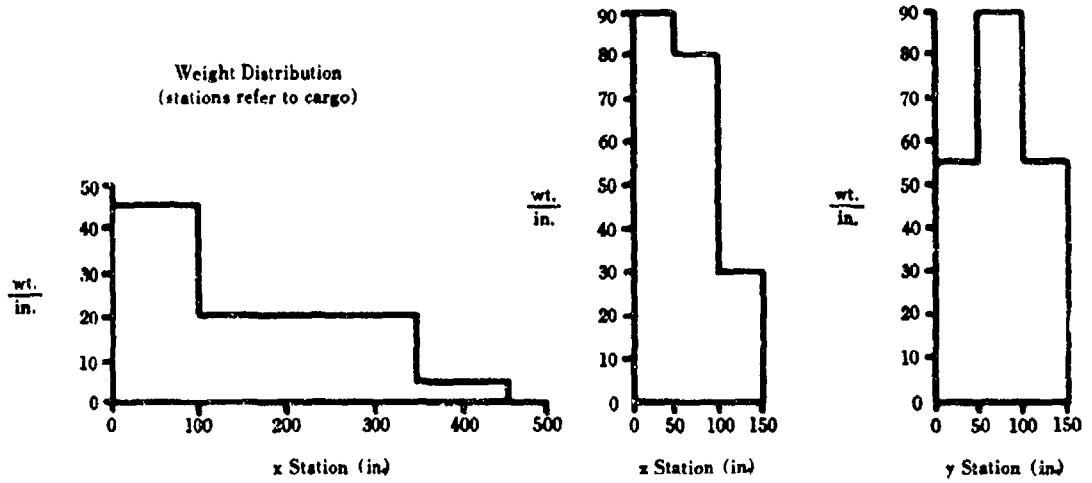








*Indicated as a sample only to show an approach to cargo inertia determinations, and may not reflect actual cargo distributions.



Centroids:*

$$\bar{x} = \frac{\int_0^{100} 45\,x\,dx + \int_{100}^{350} 20\,x\,dx + \int_{350}^{450} 5\,x\,dx}{10{,}000} = 155.0$$

$$\bar{z} = \frac{\int_0^{50} 90\,z\,dz + \int_{50}^{100} 80\,z\,dz + \int_{100}^{150} 30\,z\,dz}{10{,}000} = 60.0$$

$$\bar{y} = \frac{\int_0^{50} 55\,y\,dy + \int_{50}^{100} 90\,y\,dy + \int_{100}^{150} 55\,y\,dy}{10{,}000} = 75.0$$

Second Moments:*

$$Wx^2 = \int_0^{100} 45\,x^2dx + \int_{100}^{350} 20\,x^2dx + \int_{350}^{450} 5\,x^2dx = 374{,}583{,}333$$

$$Wz^2 = \int_0^{50} 90\,z^2dz + \int_{50}^{100} 80\,z^2dz + \int_{100}^{150} 30\,z^2dz = 50{,}833{,}333$$

$$Wy^2 = \int_0^{50} 55\,y^2dy + \int_{50}^{100} 90\,y^2dy + \int_{100}^{150} 55\,y^2dy = 72{,}083{,}333$$

$I_{oy} = I_y - W\bar{r}^2$ (equation 8.1-f)

$= Wx^2 - W\bar{x}^2 + Wz^2 - W\bar{z}^2$ (Substituting equation 8.1-c in 8.1-f)

$= 374{,}583{,}333 - (10{,}000)(155)^2 + 50{,}833{,}333 - (10{,}000)(60)^2$

$= 149{,}166{,}666$ lb-in.^{2}

* The x, y, and z distances, as well as the Wx^2, Wz^2, and Wy^2 terms in the equations for Centroids and Second Moments, refer only to these calculations and are not to be confused with the distances and moment terms in Table 8.1-A.

$$I_{ox} = I_x - W\bar{r}^2 \quad \text{(equation 8.1-f)}$$

$$= Wx^2 - W\bar{z}^2 + Wy^2 - W\bar{y}^2$$

$$= 50{,}833{,}334 - (10{,}000)(60)^2 + 72{,}083{,}335 - (10{,}000)(75)^2$$

$$= 30{,}666{,}666 \text{ lb-in.}^2$$

$$I_{oz} = I_z - W\bar{r}^2 \quad \text{(equation 8.1-f)}$$

$$= Wy^2 - W\bar{y}^2 + Wx^2 - W\bar{x}^2$$

$$= 72{,}083{,}333 - (10{,}000)(75)^2 + 374{,}583{,}333 - (10{,}000)(155)^2$$

$$= 150{,}166{,}666 \text{ lb-in.}^2$$

4. Determine the total airplane inertias in pitch, roll, and yaw. All of the values calculated in 1, 2, and 3 are tabulated in Table 8.1-A and each column is totaled.

   a. Inertia about the remote axis

$$I_y = \sum (Wr^2 + I_{oy}) \quad \text{(equation 8.1-e)}$$

$$= \sum [W(x^2 + z^2) + I_{oy}]$$

$$= (28{,}946{,}000 + 2{,}279{,}500)\,10^3 + (1{,}688{,}505)\,10^3$$

$$= 32{,}914{,}005 \times 10^3 \text{ lb-in.}^2$$

$$I_x = \sum (Wr^2 + I_{ox}) \quad \text{(equation 8.1-e)}$$

$$= \sum [W(y^2 + z^2) + I_{ox}]$$

$$= (400{,}000 + 2{,}279{,}500)\,10^3 + (1{,}324{,}670)\,10^3$$

$$= 4{,}004{,}170 \times 10^3 \text{ lb-in.}^2$$

$$I_z = \sum (Wr^2 + I_{oz}) \quad \text{(equation 8.1-e)}$$

$$= \sum [W(y^2 + x^2) + I_{oz}]$$

$$= (400{,}000 + 28{,}946{,}000)\,10^3 + (2{,}924{,}872)\,10^3$$

$$= 32{,}270{,}872 \times 10^3 \text{ lb-in.}^2$$

   b. Inertia about the airplane centroid

Pitching $I_o = I_y - W\bar{r}^2$ (equation 8.1-f)

where $\bar{r} = \dfrac{\sum Wr}{\sum W}$ (equation 8.1-g)

$$I_o = I_y - \left[\frac{\sum (Wx)^2 + \sum (Wz)^2}{\sum W}\right]$$

$$= 32{,}914{,}005 \times 10^3 - \left[\frac{(46{,}460{,}000)^2 + (13{,}040{,}000)^2}{76{,}300}\right]$$

$$= 2{,}395{,}352 \times 10^3 \text{ lb-in.}^2$$

Rolling $I_o = I_x - W\bar{r}^2$ (equation 8.1-f)

$$= I_x - \left[\frac{\sum (Wy)^2 + \sum (Wz)^2}{\sum W}\right]$$

$$= 4{,}004{,}170 \times 10^3 - \frac{(2{,}000{,}000)^2 + (13{,}040{,}000)^2}{76{,}300}$$

$$= 1{,}723{,}153 \times 10^3 \text{ lb-in.}^2$$

Yawing $I_w = I_z - Wf^2$ (equation 8.1-f)

$$= I_z - \left[\frac{\sum (Wx)^2 + \sum (Wy)^2}{\sum W}\right]$$

$$= 32{,}270{,}872 \times 10^3 - \frac{(46{,}460{,}000)^2 + (2{,}000{,}000)^2}{76{,}300}$$

$$= 3{,}928{,}387 \times 10^3 \text{ lb-in.}^2$$

See Table 8.1-A for tabulated results and conversion to units of mass times distance squared.

TABLE 8.1-A

SECTION	WEIGHT (lbs)	x (in.)	z (in.)	y (in.)	$Wx \times 10^{-3}$ (lb-in.)	$Wz \times 10^{-3}$ (lb-in.)	$Wy \times 10^{-3}$ (lb-in.)	$Wx^2 \times 10^{-3}$ (lb-in.^{2})	$Wz^2 \times 10^{-3}$ (lb-in.^{2})	$Wy^2 \times 10^{-3}$ (lb-in.^{2})

8.2 MISSILE MASS AND INERTIA

Two methods of estimating missile mass and inertia, each limited by the initial assumptions and input data, are presented in this section. The method selected will depend on the desired accuracy related to the problem at hand.

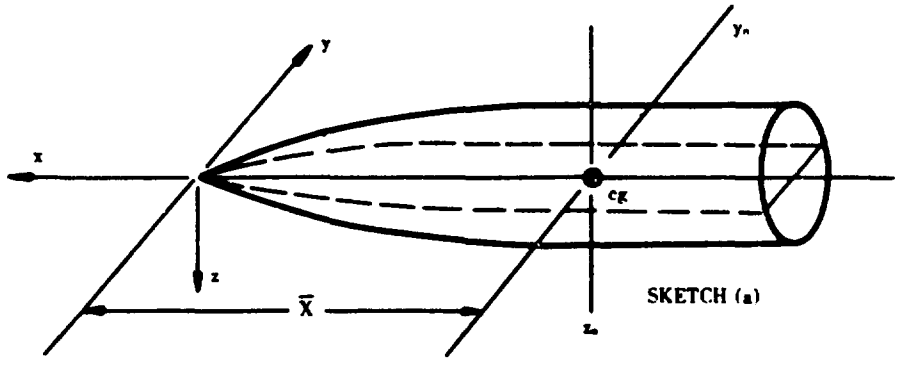
The first method, more sophisticated than the second, requires an estimated weight and center-of-gravity breakdown of the vehicle. Although the results are presented in the Datcom for hand calculations, they are most expeditiously programed for a small-capacity computer. The hand computations may be long and tedious, but they are not complicated.

The second method presents the procedure, based on estimates of gross stage weight and profile, for determining the order of magnitude of pitch and roll moments of inertia of a vehicle.

DATCOM METHODS

Method 1

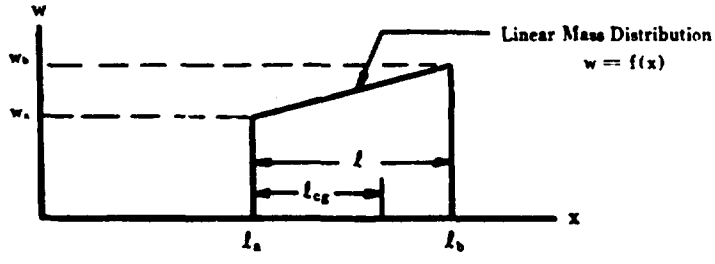
This method assumes that the basic body being analyzed is symmetrical about one axis, as illustrated in the axis-system diagram of sketch (a). This leads to the assumption that the center of gravity of the body lies on the longitudinal axis of the vehicle. However, this assumption does not eliminate handling of missile components that are not symmetrical.



SKETCH (a)

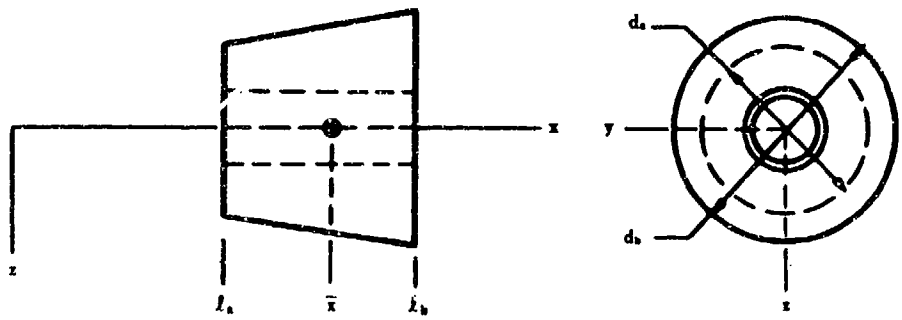
A second assumption is that the moment of inertia with respect to the z_o axis is equal to the moment of inertia with respect to the y_o axis. (yaw moment of inertia = pitch moment of inertia). This assumption is reasonable for most missile bodies and will be in the range of accuracy desired for moment-of-inertia values of vehicles in the preliminary-design phase.

A third assumption is that all components can be approximated by a linear mass distribution along the longitudinal axis as shown in sketch (b). This assumption forces the following limitation: $l/3 \leq l_{c.g.} \leq 2l/3$, where l is the length of the component and l_{cg} is the center of gravity of the component measured from the beginning station of the component. The weight per unit length of element is denoted by w.



SKETCH (b)

A fourth assumption is that the diameters of any component can be approximated by a linear distribution along the longitudinal axis as shown in sketch (c).



SKETCH (c)

It will be assumed that W, $\bar{x}$, ℓ_a, ℓ_b, d_a and d_b are given or can be estimated and tabulated for each symmetrical component of the missile, where W is the weight of a given component and $\bar{x}$ is the longitudinal station of the center of gravity of that component with respect to the missile nose apex.

The values w_a and w_b are then estimated for each component from the equations

$$w_a = \frac{W}{\ell_b - \ell_a}\left[4 - \frac{6(\bar{x} - \ell_a)}{\ell_b - \ell_a}\right] \qquad 8.2\text{-a}$$

$$w_b = \frac{W}{\ell_b - \ell_a}\left[\frac{6(\bar{x} - \ell_a)}{\ell_b - \ell_a} - 2\right] \qquad 8.2\text{-b}$$

The pitch and yaw moments of inertia (I_{yy}' and I_{zz}') of each solid (nonliquid) component can then be estimated from

$$I_{yy}' = I_{zz}' = (\ell_b^4 - \ell_a^4)\left(\frac{m}{4} + \frac{mT^2}{4K}\right) + (\ell_b^3 - \ell_a^3)\left(\frac{b}{3} + \frac{2mTN + bT^2}{3K}\right) + (\ell_b^2 - \ell_a^2)\left(\frac{mN^2 + 2bTN}{2K}\right) + (\ell_b - \ell_a)\frac{bN^2}{K} - W\bar{x}^2 \qquad 8.2\text{-c}$$

where

$$m = \frac{w_b - w_a}{\ell_b - \ell_a}$$

$$T = \frac{d_b - d_a}{\ell_b - \ell_a}$$

$$b = w_a - \ell_a\left(\frac{w_b - w_a}{\ell_b - \ell_a}\right)$$

$$N = d_a - \ell_a\left(\frac{d_b - d_a}{\ell_b - \ell_a}\right)$$

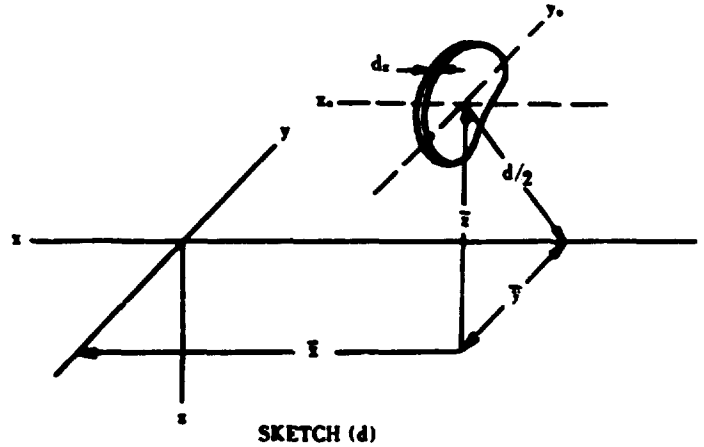
$K = \dfrac{16}{1 + \left(\dfrac{d_o}{d}\right)^2}$ for elements symmetrical about the longitudinal axis (use figure 8.2-5)

$= \dfrac{1}{\left(\dfrac{\bar{z}}{d}\right)^2 + \left(\dfrac{\rho_{y_o}}{d}\right)^2}$ for unsymmetrical solid elements in pitch (use figure 8.2-6)

$$= \frac{1}{\left(\frac{\bar{y}}{d}\right)^2 + \left(\frac{\rho_{z_o}}{d}\right)^2}$$ for unsymmetrical solid elements in yaw (use figure 8.2-6)

$\bar{x}, \bar{y}, \bar{z}$ are measured to the c.g. of the element as shown in sketch (d)

$\rho_{x_o}, \rho_{y_o}, \rho_{z_o}$ are the radii of gyration of the element



SKETCH (d)

The corresponding roll moment of inertia of a given solid element is

$$I_{xx}' = \frac{2}{C}\left[(l_b^4 - l_a^4)\frac{mT^2}{4} + (l_b^3 - l_a^3)\left(\frac{2mTN + bT^2}{3}\right) + (l_b^2 - l_a^2)\frac{mN^2 + 2bTN}{2} + (l_b - l_a)\,bN^2\right] \qquad 8.2\text{-d}$$

where

$$C = \frac{16}{1 + \left(\frac{d_o}{d}\right)^2}$$ for symmetrical elements (same as K, use figure 8.2-5)

$$= \frac{2}{\frac{1}{4} + \left(\frac{\rho_{x_o}}{d}\right)^2}$$ for unsymmetrical elements (use figure 8.2-7)

and the other symbols are as defined for equation 8.2-c.

For liquid components, the pitch and yaw moments of inertia are

$$I_{yy}' = I_{zz}' = K_L\left[(l_b^4 - l_a^4)\left(\frac{m}{4} + \frac{mT^2}{64}\right) + (l_b^3 - l_a^3)\left(\frac{b}{3} + \frac{2mTN + bT^2}{48}\right) + (l_b^2 - l_a^2)\frac{mN^2 + 2bTN}{32} + (l_b - l_a)\frac{bN^2}{16} - W\bar{x}^2\right] \qquad 8.2\text{-e}$$

where

K_L is given by figure 8.2-8 as a function of the fineness ratio of the element.

The corresponding roll moment of inertia of a liquid element is assumed to be zero.

$$I_{xx}' = 0 \qquad 8.2\text{-f}$$

The pitch and yaw moments of inertia of the complete vehicle are obtained by using the parallel-axis theorem to sum the contribution of each element. Thus

$$I_{yy} = I_{zz} = \sum I_{yy}' + \sum W\bar{x}^2 - (\sum W)\bar{X}^2 \qquad 8.2\text{-g}$$

where the sums are taken over the entire set of elements comprising the configuration and $\bar{X}$ is the longitudinal position of the vehicle center of gravity. This latter term is obtained from the equation

$$\bar{X} = \frac{\sum \bar{x} W}{\sum W} \qquad 8.2\text{-h}$$

The corresponding roll moment of inertia for the complete vehicle is

$$I_{xx} = \sum I_{xx}' \qquad 8.2\text{-i}$$

where again the sum extends over all components.

Certain common vehicle components not satisfying the basic assumptions can be handled exactly by replacing them by equivalent shapes that do satisfy the assumptions.

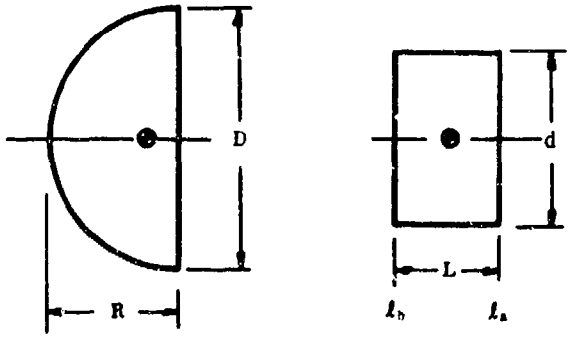
The spherical segment shell, which does not have a linear diameter variation, can be replaced by an equivalent cylindrical shell as illustrated in figure 8.2-9. The moment of inertia of the cylindrical shell can be computed by the derived equations.

The dimensions of an equivalent solid cylinder for a hemispherical solid are given as

$$d = 0.894\ D \qquad \ell_a = \bar{x} - 0.2105\ D$$

$$L = 0.421\ D \qquad \ell_b = \bar{x} + 0.2105\ D$$

where the symbols are defined in sketch (e).



SKETCH (e)

Method 2

For order-of-magnitude determinations, figures 8.2-10 and 8.2-11 summarize the pitch (and yaw) and roll radii of gyration, respectively, of a number of actual missile configurations. This information will allow a determination of these parameters within perhaps ±20 percent. The moments of inertia are then

$$I_{y_{c.g.}} = I_{yy} = I_{zz} = \rho_P^2 \sum W \qquad 8.2\text{-j}$$

$$I_{x_{c.g.}} = I_{xx} = \rho_R^2 \sum W \qquad 8.2\text{-k}$$

where $\sum W$ is the total weight of the vehicle

ρ_P and ρ_R are obtained from figures 8.2-10 and 8.2-11, respectively.

9. CHARACTERISTICS OF VTOL-STOL AIRCRAFT

The interest in a wide variety of aircraft having VTOL-STOL capability has created the need for establishing preliminary-design methods for the prediction of the aerodynamic characteristics of such vehicles.

The terms VTOL, STOL, and V/STOL appear many times in the literature. VTOL means "vertical take-off and landing." STOL means "short take-off and landing," and vehicles of this classification do not have vertical take-off and landing capability. V/STOL means the capability to perform both vertical and short take-offs and landings. The many ways of achieving VTOL-STOL capability are exhibited in the proposed and existing vehicles of this family. There are four basic VTOL-STOL principles involved for accomplishing the conversion from hovering to cruise flight; namely, aircraft tilting, thrust tilting, thrust deflection, and dual-propulsion. These four conversion principles are coupled with four different propulsion methods; namely, rotor, propeller, fan, and jet, to give the family of basic V/STOL types. In the broad sense the material presented in this section does not include all V/STOL concepts. Specifically, the methods presented in Section 9 are applicable to predicting the forces and moments on free propellers (Section 9.1), power-on lift and drag forces of propeller-wing combinations (Section 9.2), and the forces and moments on isolated ducted propellers as functions of power and angle of attack (Section 9.3). No discussion or methodology is presented for rotor-type V/STOL aircraft. In addition to the material presented in this section, there are additional methods pertaining to STOL aircraft given in Section 6. Specifically, these methods pertain to jet-flap configurations; i.e., both internally-blown flaps (IBF) and externally-blown flaps (EBF).

Because of the unusual low-speed configurations and the effects of power and high angles of attack in the low-speed flight regime, which are typical of VTOL-STOL vehicles, conventional methods of predicting aerodynamic characteristics at low speeds are not applicable in most cases. In cruise flight, VTOL-STOL vehicles can usually be analyzed by conventional methods. Therefore, the primary problem is the prediction of characteristics that exist as a result of high-velocity slipstreams, high angles of attack, and geometry variations in the hover and transition flight regimes.

Because of the scope of VTOL-STOL aerodynamics and the scarcity of verified theoretical methods and design charts, a literature summary is presented as Table 9-A, accompanied by a subject index on page 9-34, a "key" to the summary table on page 9-35, and a bibliography on pages 9-3 through 9-33.

V/STOL aircraft are characterized by the following four basic and unique characteristics:

1. High power requirements in hover and transition
2. High-velocity slipstreams in hover and transition
3. Inherent deficiencies in aerodynamic stability and control in hover and low-speed flight
4. Special provisions for performing the conversion from the hovering to the cruise configuration

The high power required in hovering and transition is not of primary concern to the stability and control engineer and is not considered in the Datcom. However, it should be noted that the engine-operation problems are extremely significant in the design of a V/STOL vehicle. The high power required in hovering and transition results in both higher fuel consumption and greater noise.

The magnitude of these increases depends on the type of propulsion system used. Both fuel consumption and noise level progressively increase from the rotor to the propeller, the fan, and the jet.

The high-velocity slipstream required in hovering and transition flight introduces problems due to surface erosion, recirculation of dust and debris, ingestion of foreign objects, and slipstream recirculation, which can result in adverse aerodynamic effects and ingestion of hot gases into the engine, resulting in a serious reduction in engine thrust. Only the aerodynamic effects of the slipstream are considered in this section. Slipstream recirculation can affect the pressure on the airframe, which can cause significant changes in the vertical lift. When a single high-velocity slipstream exhausts in still air, suctions are generated on the surrounding surface because of the entrainment into the high-velocity slipstream. This "suckdown" effect is a pressure reduction and reduces the vertical lift. This lift loss is evident during hovering near the ground for a configuration with a single vertical slipstream or a close cluster of vertical slipstreams. On the other hand, when several vertical slipstreams are dispersed over the planform, the high-velocity slipstreams tend to meet on the ground between the exits, and the consequent upflow can produce positive-pressure regions between the exits to counterbalance the "suckdown" generated by the entrainment. Unfortunately, this upward flow of air is not very steady or symmetrical and can result in random upsetting motions. In addition, for configurations with a tail behind the slipstreams, additional interference effects on longitudinal trim and stability can occur during transition flight. (Strong downwash and sidewash fields can develop in the region aft of the exits as a result of the rearward deflection and distortion of the slipstreams together with the entrainment of the free-stream flow.) References pertaining to the aerodynamic effects of high-velocity slipstreams are listed under one or more of the following specialized categories in table 9-A:

5.5 Ground Effects

5.10 Jet-Wake or Propeller-Slipstream Effects

5.11 Jet-Induced Effects

An important aspect of V/STOL hovering and low-speed flight is the inherently low level of aerodynamic stability and control. Aerodynamic control and static and dynamic stability vary with dynamic pressure in the free stream, and they all drop off rapidly as the flight speed is decreased. In hovering there is no aerodynamic control effectiveness (unless the control surface is in a high-velocity slipstream), and it is usually necessary to provide an additional control system for hovering and low-speed flight. In hovering flight the static stability is neutral (no stability of attitude) for all V/STOL types. The dynamic stability in hover is about neutral for jet-V/STOL types, but other types are usually dynamically unstable in the form of unstable pitching and rolling oscillations. Almost any system that will provide control for the pilot under these conditions can also be used to augment stability. However, the way in which this should be accomplished has not been clearly settled for any V/STOL type. The cost, complexity, reliability, and maintainability of any augmentation system must be weighed against the improvements in handling qualities and the potential reductions in control requirements. The problem immediately becomes more complex, since there is still a great deal of controversy regarding control-system requirements and handling-quality criteria. References pertaining to the aerodynamic stability and control deficiencies in hovering and low-speed flight may be found

under one or more of the following specialized categories in table 9-A:

5.1 General Static Stability and Control

5.2 Dynamic Stability

5.3 Handling Criteria

5.4 Handling Qualities

5.7 Stabilization

5.8 Zero or Low-Airspeed Control and/or Control Systems

Although wind-tunnel tests cover a wide variety of V/STOL configurations, they are often of questionable accuracy because of wall interference effects and/or data-accuracy limitations at the low tunnel velocities required to simulate low-speed flight. Large flow-deflection angles are required for flight at very low speeds, and when these conditions are duplicated by a powered model in a wind tunnel, the presence of the tunnel walls have a first-order effect on tunnel flow conditions. Most existing low-speed wind tunnels are inadequate for the simulation of powered-lift low-speed flight because of their size limitations. The test section must be large compared to model dimensions to minimize the adverse effects of the wind-tunnel walls on the flow field. Simply testing models of smaller scale in an effort to avoid wall-interference effects often has not proved satisfactory, because of the significant errors in test data associated with low Reynolds number and the problems encountered in the design and manufacture of a powered model to a small scale. There appears to be a limit, which is a function of the tunnel test-section size and shape, model size, flow deflection angle, and model configuration, at which the tunnel-wall constraint causes a complete flow breakdown. The effects of all these variables on the accuracy of the wind-tunnel data are quite complex and some are not yet clearly understood. However, one fact has become very clear, and that is that most existing wind tunnels are simply too small for simulation of V/STOL flight.* References pertaining to wind-tunnel test techniques are listed under category 5.12 in table 9-A.

VTOL-STOL SUBJECT INDEX

1. Propeller-Driven Aircraft and Component Combinations

    1.1 Boundary-Layer Control
    1.2 Tilting Wing
    1.3 Deflected Slipstream
    1.4 Ducted Propeller
    1.5 Tilting Propeller
    1.6 Tailsitter

2. Jet-Driven Aircraft and Component Combinations

    2.1 Deflected Jet (Vectored Jet)
    2.2 Lift Plus Propulsion
    2.3 Tailsitter
    2.4 Tilting Engine
    2.5 Boundary-Layer Control

3. Fan-Driven (Lifting System) Aircraft and Component Combinations

    3.1 Fan in Wing
    3.2 Fan in Fuselage

4. Individual Components

    4.1 Free Propeller
    4.2 Ducted Propeller
    4.3 Plane Wing
    4.4 Annular Wing
    4.5 Jet Flaps or Jet-Augmented Flaps

5. Specialized Categories

    5.1 General Static Stability and Control
    5.2 Dynamic Stability
    5.3 Handling Criteria
    5.4 Handling Qualities
    5.5 Ground Effects
    5.6 Gyroscopic Effects
    5.7 Stabilization
    5.8 Zero or Low-Airspeed Control and/or Control Systems
    5.9 Propeller-Rotation-Direction Effects
    5.10 Jet-Wake or Propeller-Slipstream Effects
    5.11 Jet-Induced Effects
    5.12 Wind-Tunnel Test Techniques
    5.13 Miscellaneous Effects

6. Bibliographies and Compilations

KEY TO VTOL-STOL SUMMARY TABLE

Column Heading	Abbreviation	Definition
V/STOL Concept	BLC	Boundary-Layer Control
	DJ	Deflected Jet (Vectored Jet)
	DP	Ducted Propeller
	DSS	Deflected Slipstream
	FIF	Fan in Fuselage
	FIW	Fan in Wing
	FP	Free Propeller
	HL	High Lift (Flaps, Slots, Slats)
	JF	Jet Flap or Jet-Augmented Flap
	L+P	Lift-Plus-Propulsion Engine
	RF	Rotating Flap

9.1 FREE-PROPELLER CHARACTERISTICS

The methods of this Section are for estimating forces and moments on propellers. The primary purpose of this work is to provide information for analysis of direct propeller effects during the transition flight phase of V/STOL aircraft.

Operation of a propeller in an unsymmetrical flow field results in unsymmetrical loading on the blades as a function of their rotational position, which, in turn, produces forces normal to the thrust axis resulting in pitching and yawing moments. Flow field asymmetries result from either thrust-axis tilt or from flow angles induced by the airplane lifting surfaces. The propellers on V/STOL aircraft will encounter greater asymmetries than those of conventional aircraft because of the greater thrust-axis tilt and greater induced upwash of more effective high-lift devices.

Methods for the prediction of forces and moments on propellers inclined with respect to the free stream are developed by DeYoung in reference 1. DeYoung has generalized existing small-incidence theory (references 2 and 3) using a propeller solidity based on average blade chord. Simple expressions are thus developed for propeller normal (or side) force and some of the principal derivatives. DeYoung develops these expressions by first determining approximate equations of propeller geometry and operating parameters from the theory presented by Ribner in references 2 and 3, and then establishing by statistical means the equation constants and slightly altered functions from computed data of given blade shapes.

DeYoung also derives expressions for the ratio of normal force at high incidence to normal-force derivative at zero incidence, and the ratios of thrust, torque, and power at high incidence to the zero-incidence values.

Reference 5 presents results of a propeller test for three full-scale propellers of different design at nine angles of incidence ranging from 0 to 85 degrees. The operating conditions were selected to simulate the take-off, landing, and transition regimes of V/STOL aircraft. From the data of this reference certain generalizations can be made regarding propeller characteristics likely to be encountered in transition flight. It is shown that the thrust coefficients for given values of blade angle and advance ratio are nearly constant over a large range of thrust-axis angles of attack and that this range decreases with increasing advance ratio. Furthermore, it is shown that, over the same range of thrust-axis angles, the variations of propeller normal force and pitching moment are nearly linear. Using these generalizations it is possible to present approximate methods for the estimation of propeller forces and moments at large angles of inclination from experimental data at small angles of inclination for certain transition programs.

A general notation list is included in this Section for all free-propeller Sections.

The positive direction of forces and moments is shown in figure 9.1-4.

Notation List

A	wing aspect ratio
a_o	blade section lift-curve slope, per rad
B	number of blades

Notation List (continued)

b'	propeller blade chord, ft
$\bar{b}'$	average blade chord, ft
$b'_{.25}, _{.50}, \cdots$	blade chord at $\frac{r}{R} = .25, .50, \cdots$, ft
C_N'	normal-force coefficient based on free-stream velocity and propeller disk area, $\frac{N}{q_\infty S_p}$
C_N	normal-force coefficient, $\frac{N}{\rho n^2 D^4} = \frac{\pi J^2}{8} C_N'$
C_T	thrust coefficient, $\frac{T}{\rho n^2 D^4} = \frac{\pi J^2}{8} T_c$
c_r	wing root chord, ft
D	propeller diameter, ft
J	advance ratio, $\frac{V_\infty}{nD}$
J'	modified advance ratio, $J \cos \alpha$
J_{0T}	advance ratio at zero thrust
J_{0P}	advance ratio at zero power
N	propeller normal force, lb
n	propeller rotational speed, rps
q_∞	free-stream dynamic pressure, lb/sq ft
R	propeller radius, ft
R_{fus}	maximum fuselage radius forward of propeller plane
r	radial distance to blade element, ft
S_p	propeller disk area, $\frac{\pi}{4} D^2$, sq ft
T	propeller thrust, lb
T_c	thrust coefficient based on free-stream velocity and propeller disk area, $\frac{T}{q_\infty S_p} = \frac{8}{\pi J^2} C_T$
x	longitudinal coordinate measured positive forward from wing leading edge, ft
y	lateral coordinate measured positive to right of plane of symmetry, f
Δ_y	lateral distance from thrust axis of one propeller blade to element of another, ft

Notation List (continued)

V_∞	free-stream velocity, ft/sec
α	wing angle of attack measured from zero lift, deg
α_{in}	inflow angle at propeller disk, deg
β	blade angle at .75R blade station, deg
$\epsilon_{z_{slip}}$	upwash induced by propeller slipstream, positive downward, deg
σ	propeller solidity, ratio of blade element area to annulus area at .75R
σ_e	effective propeller solidity (propeller solidity based on average blade chord)
δ_f	force phase angle, deg

Subscripts

α_{in}	differentiation with respect to inflow angle, α_{in}
$L_{.75}$	left blade position at three-quarters radius point
$R_{.75}$	right blade position at three-quarters radius point
fus	fuselage

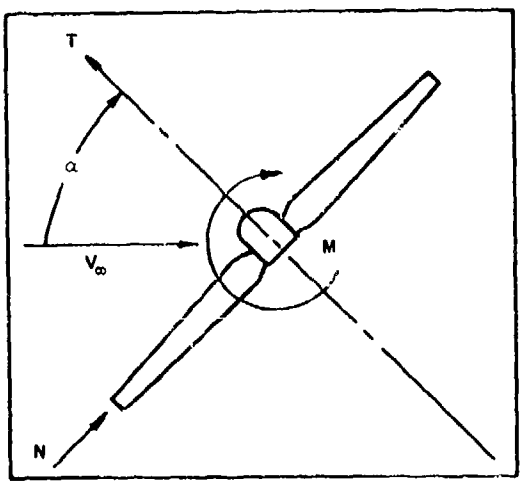

FIGURE 9.1-4 CONVENTIONS USED TO DEFINE POSITIVE SENSE OF FORCES AND MOMENTS

9.1.1 PROPELLER THRUST VARIATION WITH ANGLE OF ATTACK

Two methods are presented in this Section for estimating the thrust of a propeller at high angles of incidence. The first method is that of reference 1 and provides thrust relative to the zero-incidence value. This ratio is approximately proportional to the square of the tangent of the angle of incidence with a constant advance ratio, determined from the velocity normal to the propeller disk. In the theory the thrust is represented by the phase-angle change of the resultant velocity at the blade and takes into account both the angle-of-attack changes and the dynamic-pressure changes. A 90-degree incidence level is formulated from helicopter theory to provide a relatively small correction to the propeller theory. This thrust ratio is dependent on blade angle and advance ratio but, except for a small dependence on solidity, is independent of propeller geometry.

In the absence of complete data on a particular propeller, a second method is given that can be used to approximate the thrust at large incidence angles from experimental data at small incidence angles. This approach is formulated in reference 2, wherein it is demonstrated that certain VTOL transition programs can lie within the region of linear slope of the propeller forces and moments.

The methods presented herein are for an isolated propeller where the thrust-axis angle of attack is the angle between the free-stream velocity and the propeller thrust axis. For airplane installations this angle is often affected by flow induced by the wing, fuselage, and other propellers; however, the results of references 3 and 4 indicate that the major effects of induced flow on propeller thrust occur under conditions that are not likely to be of practical interest (high forward speed at high angles of attack).

DATCOM METHODS

Method 1

The variation of propeller thrust with angle of attack is given relative to the value at zero angle of attack, provided equal advance ratios exist as determined from the velocity normal to the propeller disk. This thrust ratio is given in reference 1 as

$$\frac{C_T(\alpha,J')}{C_T(0,J')} = 1 + \frac{3\left(\frac{J'}{J_{\alpha_T}}\right)^2}{4\left(1-\frac{J'}{J_{\alpha_T}}\right)} \sin(\beta+5)\left[\tan(\beta+5) + \sigma_e\left(1+\sqrt{1+\frac{2}{\sigma_e}\tan(\beta+5)}\right)(1-\cos\alpha)\right]\tan^2\alpha \qquad 9.1.1\text{-a}$$

where all parameters are defined in the general notation list of Section 9.1 and the positive direction of forces and angles is shown in figure 9.1-4.

The procedure to be followed in evaluating equation 9.1.1-a is outlined in the following steps.

Step 1. Determine the propeller effective solidity σ_e by

$$\sigma_e = \frac{\bar{b}'}{b'_{.75}} \sigma = \frac{4B\bar{b}'}{3\pi D} \qquad 9.1.1\text{-b}$$

where

$\bar{b}' = \frac{1}{0.8} \int_{.2}^{1} b' \, dx'$, which may be approximated by

$$\bar{b}' = 0.16 \left(\frac{5}{4} b'_{.25} + 2b'_{.50} + 2b'_{.75} + b'_{.95} \right) \qquad 9.1.1\text{-c}$$

$b'_{.25, .50, \ldots}$ are obtained from the propeller blade planform curve at $\frac{r}{R} = 0.25, 0.50, \ldots$

Step 2. The advance ratio at zero-thrust J_{O_T} is obtained from figure 9.1.1-7 as a function of β. This functional relationship is given in reference 1 as

$$J_{O_T} = 2.2 \tan(\beta + 5) \qquad 9.1.1\text{-d}$$

Step 3. Using equation 9.1.1-a obtain $\frac{C_T(\alpha,J')}{C_T(0,J')}$ with the σ_e and J_{O_T} values obtained in Steps 1 and 2. With this result values of the thrust ratio can be computed for a range of angles of attack and modified advance ratios.

Step 4. Determine the propeller thrust coefficient at selected angles of attack and modified advance ratios by

$$C_T(\alpha,J') = \frac{C_T(\alpha,J')}{C_T(0,J')} C_T(0,J')$$

where $C_T(0,J')$ is the propeller thrust coefficient at zero angle of attack, but with the velocity equal to $V_\infty \cos\alpha$. This parameter will normally be a known quantity.

Figures 9.1.1-8a-g and 9.1.1-11a-d present a comparison of experimental data from reference 2 with the Datcom method as computed from equation 9.1.1-a.

Method 2

This method is suggested in reference 2 for estimating propeller thrust at high angles of attack when experimental data at zero angle of attack are available.

The experimental data of reference 2 show that the thrust coefficient for given values of blade angle and advance ratio is practically constant over a wide angle-of-attack range at low advance ratios, and that this range diminishes with increasing advance ratio. Using these observations, it is possible to identify these ranges in VTOL transition programs.

The boundary of this region, presented in figure 9.1.1-13, has been determined on the basis of five-percent thrust-coefficient increases from the zero-angle-of-attack values for two propellers at a constant blade angle, tested in reference 2. The region varies with blade angle. The boundary curve of figure 9.1.1-13 is defined for a 12-degree blade angle, typical for maximum propeller efficiency in very low-speed flight. The characteristics of the two test propellers are presented in table 9.1.1-A.

As a simple rule of thumb, the propeller thrust at high angles of attack may be assumed to equal the value at zero angle of attack if the modified advance ratio falls below the boundary of figure 9.1.1-13.

A 1-g transition program for a hypothetical airplane described in reference 3 is also shown in figure 9.1.1-13. This program is based on the data obtained for propeller 1 of reference 2. The modified advance ratio lies well below the boundary curve. However, for conditions of steep descent or rapidly decelerating transition the boundary could be exceeded.

Sample Problem

Method 1

Given: The three-bladed propeller designated as propeller number 1 of reference 2. The following example is based on four values of the modified advance ratio over a thrust-axis angle-of-attack range from 0 to 85°.

$B = 3$ $\quad D = 12$ ft $\quad \beta = 12^{\circ}$

r/R	0.25	0.50	0.75	0.95
b', ft	0.89	1.115	1.175	1.18

J'	0.1	0.2	0.4	0.6
$C_T(0,J')$	0.132	0.121	0.083	0.032

Compute:

Step 1. Determine the effective propeller solidity σ_e.

$$\bar{b}' = 0.16\left[\frac{5}{4}b'_{.25} + 2b'_{.50} + 2b'_{.75} + b'_{.95}\right] \quad \text{(equation 9.1.1-c)}$$

$$= 0.16\left[\frac{5}{4}(0.89) + (2)(1.115) + (2)(1.175) + 1.18\right]$$

$$= 0.16\,(6.87) = 1.10$$

$$\sigma_e = \frac{4B\bar{b}'}{3\pi D} = \frac{(4)(3)(1.10)}{(3)(12)\pi} = 0.117 \quad \text{(equation 9.1.1-b)}$$

Step 2. Determine the advance ratio at zero-thrust J_{O_T} from figure 9.1.1-7 at $\beta = 12^o$.

$$J_{O_T} = 0.6725$$

Solution:

Determine the ratio of the thrust coefficient at inclination to the thrust coefficient at zero angle of incidence.

$$\frac{C_T(\alpha,J')}{C_T(0,J')} = 1 + \frac{3\left(\frac{J'}{J_{O_T}}\right)^2}{4\left(1 - \frac{J'}{J_{O_T}}\right)} \sin(\beta + 5)\left|\tan(\beta + 5)\right.$$

$$+ \sigma_e \left(1 + \sqrt{1 + \frac{2}{\sigma_e}\tan(\beta + 5)}\right)(1-\cos\alpha)\left|\right. \tan^2\alpha$$

(equation 9.1.1-a)

$$= 1 + \frac{3\left(\frac{J'}{0.6725}\right)^2}{4\left(1 - \frac{J'}{0.6725}\right)} \sin(17)\left|\tan(17)\right.$$

$$+ 0.117\left(1+\sqrt{1+\frac{2}{0.117}\tan(17)}\right)(1-\cos\alpha)\left|\right. \tan^2\alpha$$

$$= 1 + \frac{6.64\,J'^2}{4 - 5.95J'}\,(0.2924)\left|0.3057 + 0.409(1-\cos\alpha)\right|\tan^2\alpha$$

$$= 1 + \frac{1.939J'^2}{4 - 5.95J'}\left|0.3057 + 0.409\,(1-\cos\alpha)\right|\tan^2\alpha$$

Using this result obtain $\frac{C_T(\alpha,J')}{C_T(0,J')}$ as a function of J' and α. This is calculated below for seven angles of attack. Note that at $J' = 0$, $\frac{C_T(\alpha,J')}{C_T(0,J')} = 1.0$; and at $J' = J_{O_T}$, $\frac{C_T(\alpha,J')}{C_T(0,J')} \longrightarrow \infty$

				$\left[C_T(\alpha,J')/C_T(0,J')\right]$ -1						
①	②	③	④	$\alpha=85^\circ$	79.5°	75°	67.5°	60°	45°	30°
J'	4-5.95J'	1.939J'^{2}	③ / ②	88.68 ④	18.63 ④	8.465 ④	3.252 ④	1.531 ④	.4255 ④	.1206 ④

The calculated values of the thrust ratio are compared with the experimental results from reference 1 in figure 9.1.1-14.

The thrust coefficient at angle of inclination and given advance ratio is then

$$C_T(\alpha,J') = C_T(0,J') \frac{C_T(\alpha,J')}{C_T(0,J')}$$

	$C_T(\alpha,J')$			
α	J'=.1	J'=.2	J'=.4	J'=.6
0	0.132	0.121	0.083	0.032
30	0.1321	0.1214	0.0849	0.0383

9.1.2 PROPELLER PITCHING-MOMENT VARIATION WITH POWER AND ANGLE OF ATTACK

At the present there are no theoretical or semi-empirical methods available in the literature for the prediction of propeller pitching moments at high angles of attack. The method presented herein is empirical and requires experimental data at two moderate angles of attack.

Experimental data indicate that there is an appreciable direct pitching moment on the propeller during operation at angle of attack. This pitching moment may be regarded as being due to the fact that the center of thrust is some distance away from the center of rotation. Figures 9.1.2-3 and 9.1.2-4 show the direct propeller pitching moment expressed as an effective thrust-axis shift for the propeller and the propeller-wing combination of reference 1 and for propeller 1 of reference 2, respectively. These data indicate an increase in propeller pitching moment with increasing angle of attack and a more pronounced shift of the effective thrust axis at the lower thrust coefficients. The data of figure 9.1.2-3 further show that the propeller pitching moment was approximately doubled when the propeller was operated in the presence of the wing because of the upwash induced by the wing.

The Datcom method which follows is based on observations of the large body of test data presented in reference 2.

DATCOM METHOD

This method is suggested in reference 2 for estimating propeller pitching moment at high thrust-axis angles of attack when experimental data are available at two angles of attack, such as zero and 15 degrees.

The experimental data of reference 2 show that the propeller pitching moment for given values of blade angle and advance ratio have nearly a constant slope over wide angle-of-attack ranges at low advance ratio and that the width of these ranges diminishes with increasing advance ratio.

It is not possible to define the limits of the regions of linearity of propeller pitching moments from the experimental data as was done for the propeller thrust in Section 9.1.1. However, in view of the fact that the angle-of-attack ranges of pitching-moment linearity are essentially those over which the thrust is constant, it is assumed that, to a first approximation, the boundary, defined in figure 9.1.1-13, also applies to pitching moments. As noted in Section 9.1.1, this boundary varies with blade angle. It is defined for a blade angle typical of maximum propeller efficiency in very low-speed flight.

As a simple rule of thumb, the propeller pitching moment at high angles of attack may be obtained with accuracy acceptable for preliminary design analysis by a linear extrapolation of experimental data at moderate angles of attack, provided the modified advance ratio falls below the boundary of figure 9.1.1-13 .

9.1.3 PROPELLER NORMAL-FORCE VARIATION WITH POWER AND ANGLE OF ATTACK

Two methods are presented in this Section for estimating the propeller normal force at high angles of attack .

The first method, developed by DeYoung in reference 1, provides the normal-force coefficient at high angles of attack relative to the linear relation $\left(\frac{dC_N}{d\alpha}\right)_{\alpha=0}$ This ratio is equal to the tangent of the angle of attack, provided equal advance ratios, as determined from the velocity normal to the propeller disk, exist. In theory, the normal force is considered to be proportional to the torque difference due to angle of incidence between the down-going blade and the up-going blade.

The essential part of Datcom method 1 is the estimation of $\left(\frac{dC_N}{d\alpha}\right)_{\alpha=0}$. This involves determining the normal-force derivative with respect to the local angle of attack, the local angle-of-attack gradient, and a correction for phase-angle shift.

DeYoung, in reference 1, has obtained a simple relationship for the normal-force derivative with respect to local angle of attack in the manner described in Section 9.1. A general expression for this derivative as a function of propeller geometry and operating parameters is obtained from the analysis of Ribner in references 2 and 3 and the assumption of a blade section lift-curve slope of $c_{l_\alpha} = 0.95(2\pi)$ per radian. The constants of the resulting expression are evaluated by statistical means from the computed data of the given blade shapes of reference 4.

The normal-force derivative with respect to wing angle of attack is given as the product of the normal-force derivative with respect to the local propeller angle of attack and the local angle-of-attack gradient $\frac{d\alpha_{in}}{d\alpha}$, obtained in reference 1 by an analysis of the upwash due to the wing, fuselage, and other propellers.

Propellers operating at high angles of attack experience appreciable angle-of-attack variation on the blades. Lift increases and decreases in a harmonic fashion. As the angle of attack is increased, circulation increases, and a starting vortex is shed which induces a downwash and changes the buildup of circulation. This unsteady motion causes the lift cycle to be out of phase with the angle-of-attack cycle; consequently, the propeller forces and moments have components in both the lateral and vertical directions. The normal force at incidence is then the product of the normal force computed for zero phase angle and the cosine of the phase angle. In Datcom method 1 the effect of this phase-angle shift is applied to the computed linear relation $\left(\frac{dC_N}{d\alpha}\right)_{\alpha=0}$.

In the theory of reference 1 the propeller phase angle is approximated by an analogous wing unsteady solution, assuming that the propeller forces and blade angle of attack are analogous to those of a wing that is harmonically pitching about its quarter-chord line.

A second method is given which, in the absence of complete data on a particular propeller, can be used to approximate the normal force at large angles of attack from experimental data at small angles of attack. This approach is formulated in reference 5, wherein it is demonstrated that certain VTOL transition programs can lie within the region of linear slope of the propeller forces and moments.

DATCOM METHODS

Method 1

The variation of propeller normal force with angle of attack is given relative to $\left(\frac{dC_N}{d\alpha}\right)_{\alpha=0}$, provided equal advance ratios, as determined from the velocity normal to the propeller disk, exist. This ratio is given in reference 1 as

$$\frac{C_N(\alpha,J')}{C_{N_\alpha}(0,J')} = \tan\alpha \qquad 9.1.3\text{-a}$$

The positive normal-force and angle-of-attack senses are shown in figure 9.1-4, and the required parameters are defined in the general notation list of Section 9.1.

This method is essentially one of determining the denominator values in the form of C_{N_α}' where

$$C_{N_\alpha}' = C_{N_{\alpha_{in}}}' \frac{d\alpha_{in}}{d\alpha} \text{ per rad} \qquad 9.1.3\text{-b}$$

In computing these values the J or thrust in the relation for $C_{N_{\alpha_{in}}}'$ must be taken at J' and velocity at $V_\infty \cos\alpha$.

The derivatives C_{N_α}' and C_{N_α} are related by

$$C_{N_\alpha}(0,J') = \frac{\pi}{8}(J')^2 C_{N_\alpha}'(0,J') \text{ per rad} \qquad 9.1.3\text{-c}$$

The procedure to be followed in evaluating the normal force is outlined in the following steps.

Step 1. Determine at zero phase angle the propeller normal-force derivative with respect to the local angle of attack at the propeller disk by

$$C_{N_{\alpha_{in}}}' = \frac{4.25\,\sigma_e}{1+2\,\sigma_e}\sin(\beta+8)\left(1+\frac{3T_c}{8\sqrt{1+(2/3)T_c}}\right) \text{ per rad} \qquad 9.1.3\text{-d}$$

for single-rotation propellers, and by

$$C_{N_{\alpha_{in}}}' = \frac{3.86\,\sigma_e}{1+\sigma_e}\sin(\beta+14)\left(1+\frac{3T_c}{8\sqrt{1+(2/3)T_c}}\right) \text{per rad} \qquad 9.1.3\text{-d}'$$

for counter-rotating propellers;

where σ_e is obtained as outlined in Step 1 of Datcom method 1 of Section 9.1.1 and the thrust values are taken at J', with velocity equal to $V_\infty \cos\alpha$. The thrust values will normally be known.

Step 2. Determine the local angle-of-attack gradient $\frac{d\alpha_{in}}{d\alpha}$ by

$$\frac{d\alpha_{in}}{d\alpha} = \frac{1 + \frac{2A}{9(A+10)}\left(\frac{1}{\frac{x_{L\ .75}}{c_r} + \frac{1}{10}} + \frac{1}{\frac{x_{R\ .75}}{c_r} + \frac{1}{10}}\right) + \frac{1}{2}\left[\left(\frac{R_{fus}}{y_{L\ .75}}\right)^2 + \left(\frac{R_{fus}}{y_{R\ .75}}\right)^2\right]}{1 - \frac{1}{4}\sum_{\text{other props}}\left[\left(\frac{R}{\Delta y_{L\ .75}}\right)^2 + \left(\frac{R}{\Delta y_{R\ .75}}\right)^2\right]\frac{d\epsilon_{z\ slip}}{d\alpha_{in}}} \qquad 9.1.3\text{-e}$$

where the first two terms in the numerator are the average upwash at the propeller .75R station due to the wing, and the third term in the numerator is the average upwash at the propeller .75R station due to the fuselage.

The summation term in the denominator is the average downwash in the propeller slipstream at the propeller .75R station. For propellers operating near each other this downwash must be considered in predicting the local angle-of-attack gradient. This downwash may be neglected if a fuselage separates the propellers or if adjacent propellers are sufficiently far apart so that $\Delta y > 2R$. The slipstream gradient is given by

$$\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}} = \frac{T_c}{4 + \frac{8}{7}T_c} + \frac{\left(C_{N'_{\alpha_{in}}}\right)_{T_c=0}\sqrt{1 + 1.3\,T_c}}{4 + 2T_c} \qquad 9.1.3\text{-f}$$

Step 3. Determine the propeller normal-force derivative with respect to wing angle of attack at zero phase angle using the terms obtained in Steps 1 and 2 and equation 9.1.3-b

$$C_{N'_\alpha} = C_{N'_{\alpha_{in}}}\frac{d\alpha_{in}}{d\alpha} \text{ per rad}$$

Step 4. Correct the $C_{N'_\alpha}$ value obtained for zero phase angle (Step 3) for phase-angle shift by

$$C_{N'_\alpha}(\delta) = C_{N'_\alpha}\cos\delta_f \text{ per rad} \qquad 9.1.3\text{-g}$$

The phase angle is determined by

$$\delta_f = 0.825 \tan^{-1} \frac{15\ \sigma_e}{B\sqrt{2\ J_{o_P}\ J' - (J')^2}} \qquad 9.1.3\text{-h}$$

where

$$J_{o_P} = J_{o_T} + \frac{16}{\sin(\beta + 5)\cos^4(\beta + 5)} \left(\frac{\sigma_e}{B}\right)^2 \qquad 9.1.3\text{-i}$$

and J_{o_T} is obtained as a function of β from Figure 9.1.1-7.

Step 5. Convert the C_{N_α}' results of Step 4 to C_{N_α} using equation 9.1.3-c.

$$C_{N_\alpha}(0,J') = \frac{\pi}{8} (J')^2\ C_{N_\alpha}'(0,J') \quad \text{per rad}$$

Step 6. Determine the normal force at selected wing angles of attack and modified advance ratios using

$$C_N(\alpha,J') = C_{N_\alpha}(0,J') \tan\alpha$$

A comparison of normal-force derivative at zero thrust, computed using equations 9.1.3-d and 9.1.3-d', with the theory of reference 4 is presented in Table 9.1.3-A. The percentage difference shown has been taken with respect to the values of reference 4. The comparison includes data with two blade shapes and wide variations of solidity, blade pitch angles, and number of blades. The percentage difference is considered to be within the accuracy of detailed propeller theory.

The normal-force ratio given by equation 9.1.3-a is compared with experimental data from reference 5 in figure 9.1.3-14.

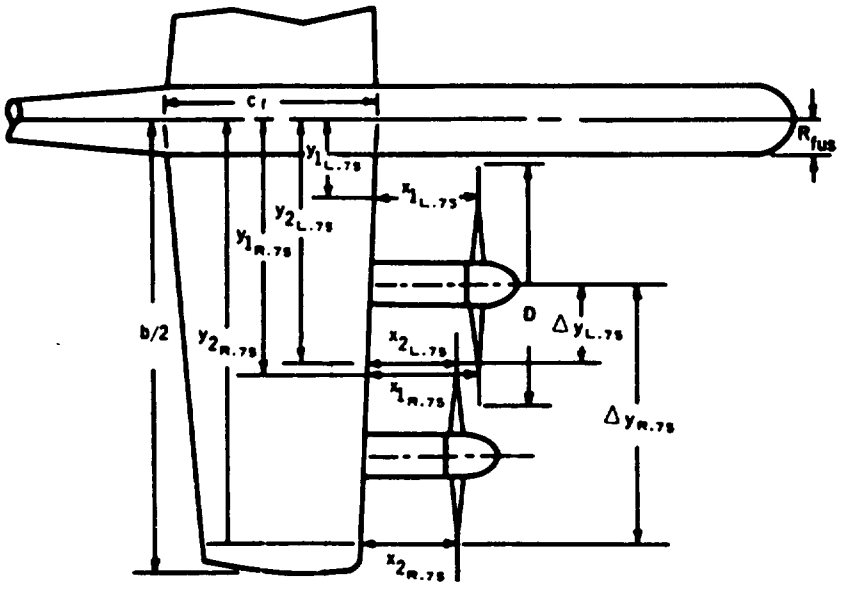
Method 2

This method is suggested in reference 5 for estimating the propeller normal force at high angles of attack when experimental data are available at two angles of attack, such as zero and 15 degrees. This is an empirical method based on observations of a large body of test data in reference 5. The method is analogous to the method of Section 9.1.2 for estimating propeller pitching moments and provides acceptable accuracy for preliminary-design analysis. The method merely states that the propeller normal force at high angles of attack may be obtained by linear extrapolation of experimental data, provided the modified advance ratio falls below the boundary of figure 9.1.1-13.

Sample Problem

Method 1

Given: The hypothetical four-propeller, tilt-wing airplane of reference 6 with linear dimensions six times those of the model. The propellers are those designated as propeller 1 of reference 5. The following example is computed for four values of the modified advance ratio over an angle-of-attack range from 0 to 80 degrees.



Propeller Characteristics

The propellers are the same as those of the sample problem of Section 9.1.1.

B = 3 D = 12 ft $\beta = 12^{\circ}$ $\sigma_e = 0.117$ $J_{OT} = 0.6725$

J'	0.1	0.2	0.4	0.6
T_c (0, J')	33.61	7.703	1.321	0.2267

These T_c (0,J') values have been obtained from the C_T (0,J') values given in the sample problem of Section 9.1.1 by

$$T_c\ (0,J') = \frac{8}{\pi\ (J')^2}\ C_T\ (0,J')$$

Airplane Characteristics

c_r = 10.0 ft A = 4.89 R_{fus} = 1.25 ft

Propeller 1 (Inboard)		Propeller 2 (Outboard)	
$x_{L\ .75}$ = 5.25 ft	$y_{L\ .75}$ = 3.25 ft	$x_{L\ .75}$ = 4.50 ft	$y_{L\ .75}$ = 11.75 ft
$x_{R\ .75}$ = 5.60 ft	$y_{R\ .75}$ = 12.25 ft	$x_{R\ .75}$ = 4.80 ft	$y_{R\ .75}$ = 20.75 ft

$\Delta y_{L\ .75}$ = 4.0 ft

$\Delta y_{R\ .75}$ = 13.0 ft

Compute:

Step 1. Determine the propeller normal-force derivatives at zero phase angle with respect to the local angle of attack at the propeller disk $C_{N'_{\alpha_{in}}}$

$$C_{N'_{\alpha_{in}}} = \frac{4.25\ \sigma_e}{1 + 2\ \sigma_e} \sin(\beta + 8) \left(1 + \frac{3T_c}{8\sqrt{1 + (2/3)T_c}}\right) \text{per rad}$$

(equation 9.1.3-d)

$$= \frac{(4.25)(0.117)}{1 + 2\ (0.117)} \sin(12 + 8) \left(1 + \frac{3T_c}{8\sqrt{1 + (2/3)T_c}}\right)$$

$$= 0.138 + \frac{0.0517T_c}{\sqrt{1 + (2/3)T_c}}$$

TABLE I

①	②	③	④	⑤	⑥
J'	T_c	$0.0517T_c$ / 0.0517 ②	$\sqrt{1 + (2/3)\ T_c}$ / $\sqrt{1 + (2/3)}$ ②	$C_{N'_{\alpha_{in}}}$ -0.138 ③/④	$C_{N'_{\alpha_{in}}}$ (1/rad) 0.138 + ⑤
0.1	33.61	1.74	4.84	0.3600	0.498
0.2	7.703	0.398	2.48	0.1600	0.298
0.4	1.321	0.0683	1.371	0.0498	0.1878
0.6	0.2267	0.0117	1.072	0.0109	0.1489

Step 2. Determine the local angle-of-attack gradient $d\alpha_{in}/d\alpha$.

For this configuration $\Delta y < 2R$ and the propeller downwash effect on the local angle-of-attack gradient must be considered.

$$\frac{d\alpha_{in}}{d\alpha} = \frac{1 + \frac{2A}{9(A+10)}\left(\frac{1}{\frac{x_{L\ .75}}{c_r} + \frac{1}{10}} + \frac{1}{\frac{x_{R\ .75}}{c_r} + \frac{1}{10}}\right) + \frac{1}{2}\left[\left(\frac{R_{fus}}{y_{L\ .75}}\right)^2 + \left(\frac{R_{fus}}{y_{R\ .75}}\right)^2\right]}{1 - \frac{1}{4}\sum_{prop\ 1}^{prop\ 2}\left[\left(\frac{R}{\Delta y_{L\ .75}}\right)^2 + \left(\frac{R}{\Delta y_{R\ .75}}\right)^2\right]\frac{d\epsilon_{z\ slip}}{d\alpha_{in}}} \qquad \text{(equation 9.1.3-e)}$$

Propeller 1 (Inboard)

$$\left(\frac{d\alpha_{in}}{d\alpha}\right)_1 = \frac{1 + \frac{2(4.89)}{9(4.89+10)}\left(\frac{1}{\frac{5.25}{10} + \frac{1}{10}} + \frac{1}{\frac{5.60}{10} + \frac{1}{10}}\right) + \frac{1}{2}\left[\left(\frac{1.25}{3.25}\right)^2 + \left(\frac{1.25}{12.25}\right)^2\right]}{1 - \frac{1}{4}\left[\left(\frac{6.0}{4.0}\right)^2 + \left(\frac{6.0}{13.0}\right)^2\right]\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$$= \frac{1 + 0.073\left(\frac{1}{0.625} + \frac{1}{0.660}\right) + \frac{1}{2}(0.148 + 0.0104)}{1 - 0.25\ (2.25 + 0.213)\ \frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$$= \frac{1 + 0.073\ (3.115) + 0.0792}{1 - 0.25\ (2.463)\ \frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$$= \frac{1.3067}{1 - (0.616)\ \frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

Propeller 2 (Outboard)

$$\left(\frac{d\alpha_{in}}{d\alpha}\right)_2 = \frac{1 + 0.073\ \left(\frac{1}{\frac{4.50}{10} + \frac{1}{10}} + \frac{1}{\frac{4.80}{10} + \frac{1}{10}}\right) + \frac{1}{2}\left[\left(\frac{1.25}{11.75}\right)^2 + \left(\frac{1.25}{20.75}\right)^2\right]}{1 - (0.616)\ \frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$$= \frac{1 + 0.073\left(\frac{1}{0.550} + \frac{1}{0.580}\right) + \frac{1}{2}(0.0113 + 0.0036)}{1 - (0.616)\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$$= \frac{1 + 0.073\ (3.542) + 0.00745}{1 - (0.616)\ \frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$$= \frac{1.266}{1 - (0.616)\ \frac{d\epsilon_{z_{slip}}}{d\alpha_{in}}}$$

$\left(C_{N_{\alpha'_{in}}}\right)_{T_c=0} = 0.138$ (step 1 with $T_c=0$)

$$\frac{d\epsilon_{z_{slip}}}{d\alpha_{in}} = \frac{T_c}{4 + \frac{8}{7}T_c} + \frac{\left(C_{N'_{\alpha_{in}}}\right)_{T_c=0}\sqrt{1 + 1.3\ T_c}}{4 + 2\ T_c}$$ (equation 9.1.3-f)

$$= \frac{T_c}{4 + \frac{8}{7}T_c} + \frac{0.138\sqrt{1 + 1.3\ T_c}}{4 + 2\ T_c}$$

TABLE II

①	②	③	④	⑤	⑥	⑦	⑧

0.4	0.1878	0.295	0.286
0.6	0.1489	0.206	0.199

Step 4. Correct the $C_{N'_\alpha}$ values obtained in step 3 for phase-angle shift.

$$J_{o_P} = J_{o_T} + \frac{16}{\sin(\beta + 5)\cos^4(\beta + 5)} \left(\frac{\sigma_e}{B}\right)^2 \quad \text{(equation 9.1.3-i)}$$

$$= 0.6725 + \frac{16}{\sin(17)\cos^4(17)} \left(\frac{0.117}{3}\right)^2$$

$$= 0.6725 + \frac{16}{(0.2924)(0.9563)^4} (0.00152)$$

$$= 0.6725 + 0.0995$$

$$= 0.772$$

$$\delta_f = 0.825 \tan^{-1} \frac{15\ \sigma_e}{B\sqrt{2\ J_{o_p}\ J' - (J')^2}} \qquad \text{(equation 9.1.3-h)}$$

$$= 0.825 \tan^{-1} \frac{15(0.117)}{3\sqrt{2(0.772)(J') - (J')^2}}$$

$$= 0.825 \tan^{-1} \frac{0.585}{\sqrt{1.544\ J' - (J')^2}}$$

TABLE V

①	②	③	④	⑤	⑥	⑦	⑧
J'	$(J')^2$ ①^2	1.544 J' 1.544 ①	1.544 $J' - (J')^2$ ③ − ②	$\sqrt{④}$	0.585 ⑤	$\tan^{-1}$ ⑥ (deg)	δ_f (deg) 0.825 ⑦

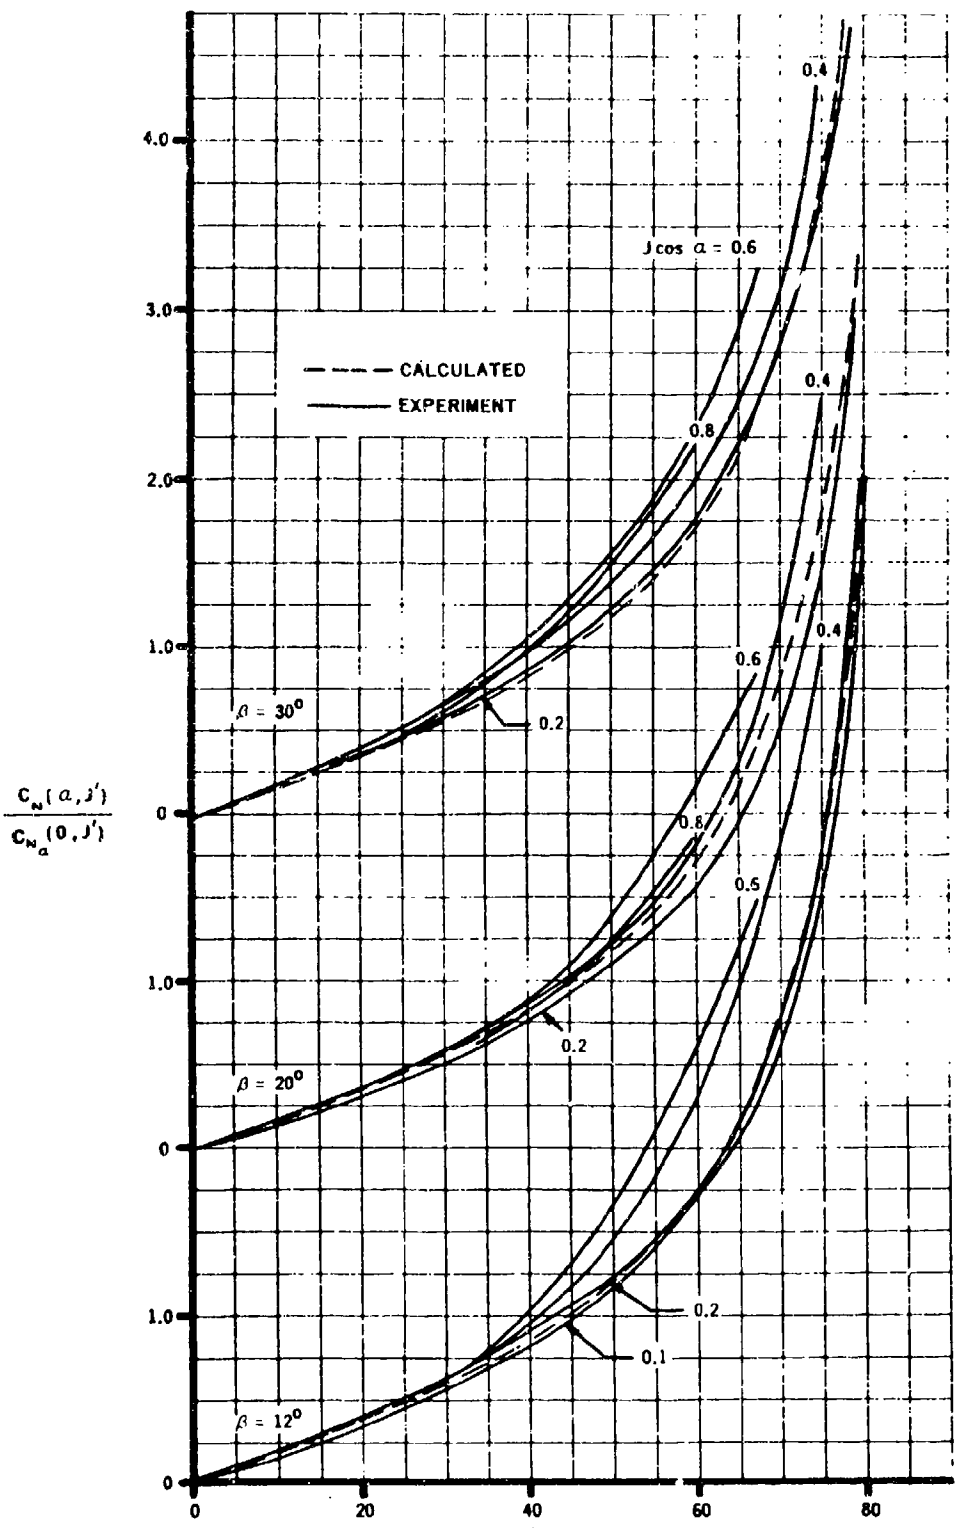

FIGURE 9.1.3-14 COMPARISON OF CALCULATED AND EXPERIMENTAL NORMAL-FORCE RATIO WITH PROPELLER THRUST-AXIS ANGLE OF ATTACK FOR PROPELLER 1 OF REFERENCE 5

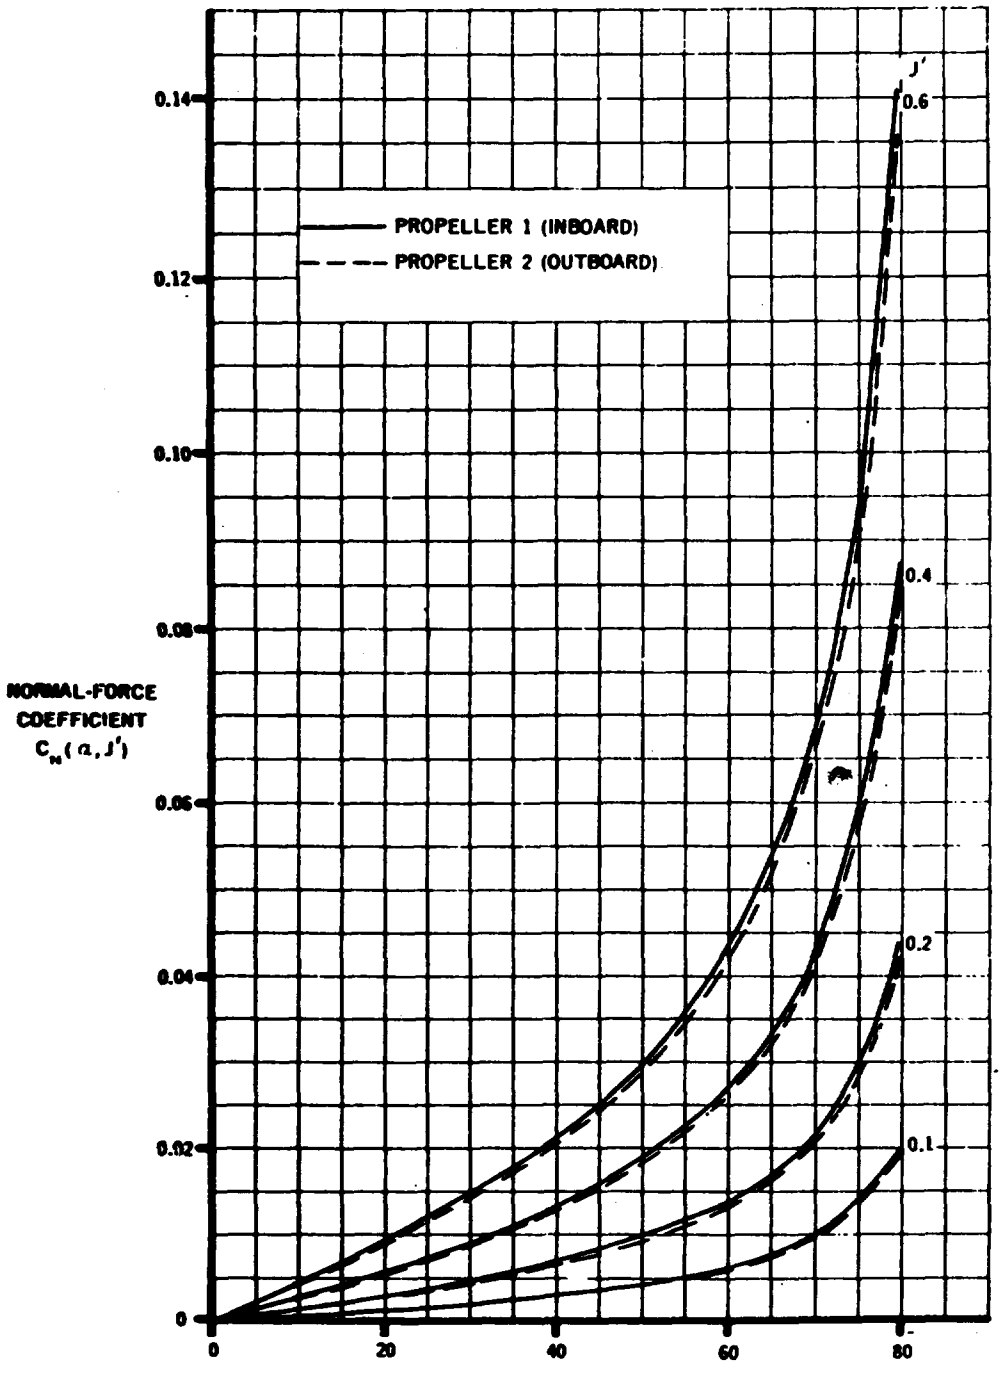

FIGURE 9.1.3-15 VARIATION OF PROPELLER NORMAL-FORCE COEFFICIENT WITH ANGLE OF ATTACK AND MODIFIED ADVANCE RATIO FOR INBOARD AND OUTBOARD PROPELLERS OF A HYPOTHETICAL 4-PROPELLER TILT-WING AIRPLANE. SAMPLE PROBLEM, METHOD 1

9.2 PROPELLER-WING CHARACTERISTICS

The methods of this section are for prediction of the power-on lift and drag forces of propeller-wing combinations of V/STOL aircraft and deal primarily with the low-speed, high-power flight regime where wing stalling tendencies at high angles of attack are delayed by power effects.

The usual approach to attaining V/STOL capabilities is to use power plant thrust to obtain lift at low speeds. Propeller-driven V/STOL configurations, other than those employing ducted propellers, consist basically of three types:

1. Deflected slipstream
2. Tilt wing
3. Combination tilt wing–deflected slipstream

These configurations differ in detail, but each employs interacting wing and thrust systems. In treating such configurations in the low-speed, high-power flight regime we must abandon the familiar distinction between lifting and thrusting systems and combine them.

Several factors dealing with propeller slipstream flow over a wing are of special significance. The local angles of attack of a propeller-wing combination in transition are determined by vector addition of the free-stream and propeller slipstream velocities. The propeller slipstream is a strong factor in reducing the local angles of attack and thereby minimizing the tendency of wing stall. Stalls may occur even in the presence of the slipstream if the slipstream velocity is low.

Since the velocity of the slipstream relative to that of the free stream is increased by increased disk loading, stalling tendencies are decreased by increasing the propeller disk loading. Wing stall can be avoided entirely by immersing the entire wing in the propeller slipstream, provided sufficient thrust is generated by the propellers.

Experimental studies have been conducted to determine the spanwise distribution of the lift increase due to the slipstream at different angles of attack with various free-stream-to-slipstream velocity ratios. The results of these tests, reported in reference 7, indicate that the lift increment due to the passage of a slipstream over a wing consists of two parts:

1. A direct lift gain which can be accurately predicted by potential flow theory.
2. A lift increment due to a "destalling" or boundary-layer-control effect. This "destalling" effect extends to portions of the wing outside the propeller slipstream and improves the wing stalling behavior.

The results also indicate that the limits of the direct slipstream influence are sharply defined and do not vary with wing angle of attack and slipstream strength.

Both references 7 and 61 indicate that the rotation of the propeller slipstream causes an upwash over the wing behind the upward moving blade. This area will generally be the first to stall on a wing that is fully immersed in propeller slipstreams. The effect of propeller rotation on maximum lift was investigated in reference 20, wherein it is concluded that slightly larger values of maximum lift can be generated when propellers rotate with the inboard tips moving up. This lift increase is attributed to a reduction in tip losses resulting from the propeller rotating in such a manner as to oppose the wing-tip vortex and to the fact that the upwash behind the upward moving blade is not entirely cancelled by the downflow at the wing tip.

Propeller-wing combinations in the transition region do not lend themselves to theoretical analysis. The Datcom methods for the prediction of lift and drag forces at forward speed with power on comprise semiempirical expressions from reference 52. These methods employ momentum theory as a starting point. They are based on power-off data and a correlation of slipstream-deflection data at zero forward speed. The correlation of slipstream-deflection data is based on numerous static investigations of a limited number of wing-flap systems. Effects of various parameters on the slipstream-deflection characteristics are summarized in reference 52.

The methods are applicable only in the unstalled flight regime. Comparison of experimental results with calculations made using the Datcom methods indicate that, in general, the estimation procedures give reasonably good results for steady level flight and for climbing flight. Through judicious use of the Datcom methods the lift and drag forces can be estimated for deflected-slipstream, tilt-wing, and combination tilt-wing – deflected-slipstream configurations. At the present time there are no methods available for the prediction of the pitching moment of a propeller-wing configuration in the transition flight regime.

Numerous static and forward speed investigations have been conducted on propeller-driven V/STOL configurations. However, the number of specific designs tested has been so limited that the substantiation of any semiempirical method developed for the prediction of forces and moments has not been possible. Furthermore, excessive wind-tunnel wall effects during simulated low-speed, high-power flight conditions invalidate many investigations.

A comprehensive tabulation of pertinent propeller-wing experimental data is presented as table 9.2-A. This table provides a brief outline of the test data contained in each report and indicates the basic parametric changes made. Additional reports, dealing with complete configurations, can be found in the VTOL-STOL summary table of Section 9.

A general notation list is included in this section for all propeller-wing combination sections. Coefficients are based on the dynamic pressure in the propeller slipstream unless otherwise noted. The conversion from coefficients based on slipstream dynamic pressure to coefficients based on free-stream dynamic pressure is presented at the end of the notation list.

The positive direction of forces and angles is shown in figure 9.2-9.

NOTATION

c	average wing chord, ft
ΔC_D	zero-lift drag increment due to flap deflection based on free-stream velocity
C_{D_f}	power-off zero-lift drag coefficient based on free-stream velocity
C_{D_o}	power-off drag coefficient based on free-stream velocity, $\frac{\text{Drag}}{q_\infty S}$
c_f	average flap chord, ft
C_{F_x}	negative-drag coefficient based on free-stream velocity, $\frac{F_x}{q_\infty S}$
C_{F_x}''	negative-drag coefficient based on slipstream velocity, $\frac{F_x}{q'' S}$
C_{L_o}	power-off lift coefficient based on free-stream velocity, $\frac{L}{q_\infty S}$
C_L''	lift coefficient based on slipstream velocity, $\frac{L}{q'' S}$
D	propeller diameter, ft
e	span efficiency factor
F	resultant force, lb
F_x	horizontal force, lb
$\frac{F}{T}$	thrust-recovery factor
i_W	wing incidence measured between thrust axis and wing chord plane, deg
J	advance ratio, $\frac{V_\infty}{nD}$
K	number of propellers

L lift, lb

q_∞ free-stream dynamic pressure, lb/sq ft

q'' slipstream dynamic pressure, $q_\infty + \frac{T}{S_p}$, lb/sq ft

S wing area, sq ft

S_p propeller disk area, $\frac{\pi}{4} D^2$, sq ft

T thrust per propeller or total thrust when used in thrust-recovery factor, lb

T_c propeller thrust coefficient based on free-stream velocity and wing area, $\frac{KT}{q_\infty S}$

T_c'' propeller thrust coefficient based on slipstream velocity and propeller disk area, $\frac{T}{q'' S_p}$

α angle of attack measured between free stream and thrust axis, deg

δ flap deflection, deg

δ_e equivalent flap deflection due to wing camber and incidence, deg

θ slipstream turning angle measured from thrust axis, deg

θ_f slipstream turning angle adjusted to the condition of zero camber and zero incidence, deg

$\Delta\theta$ increment of slipstream turning angle due to wing camber and incidence, deg

Conversion between systems:

(Unprimed coefficients are based on free-stream dynamic pressure.)

$$C_D = \frac{-C_{F_x}''}{1 - T_c''} \qquad C_{F_x}'' = \frac{-C_D}{1 + T_c \frac{S}{KS_p}} \qquad T_c = \frac{T_c''}{1 - T_c''} \frac{KS_p}{S}$$

$$C_L = \frac{C_L''}{1 - T_c''} \qquad C_L'' = \frac{C_L}{1 + T_c \frac{S}{KS_p}} \qquad T_c'' = \frac{T_c}{T_c + \frac{KS_p}{S}}$$

$$q_\infty = q'' (1 - T_c'')$$

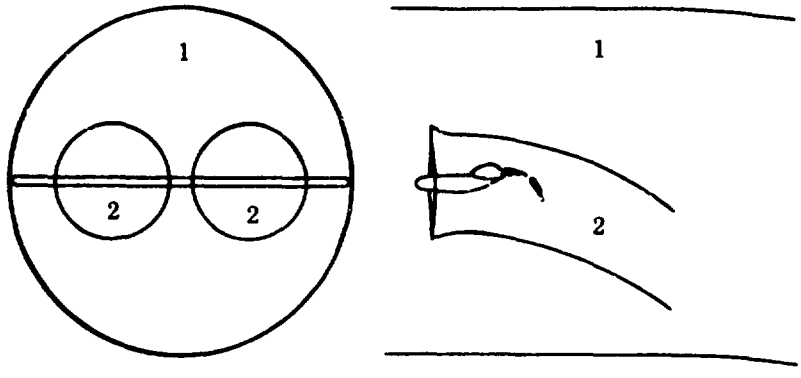
9.2.1 PROPELLER-WING-FLAP LIFT VARIATION WITH POWER AND ANGLE OF ATTACK

The methods for calculating power-on lift and drag forces of tilt-wing and deflected-slipstream configurations are those developed by Kuhn in reference 1. The methods treat the flow system of a propeller-wing-flap configuration as two separate mass flows, each deflected through a different angle by the wing. The two mass flows are (1) the mass flow deflected downward by the wing through small to moderate angles and (2) the mass flow in slipstreams created by the action of the propellers and deflected downward through large angles by either tilting the thrust axis or deflecting the flaps. These flow systems are illustrated in sketch (a).



SKETCH (a)

The forces generated in deflection of these mass flows are the familiar lift, induced drag, and profile drag of a wing in a free stream; the propeller thrust which accelerates the propeller slipstream; and a force which accounts for deflection of the propeller slipstream by the wing. Kuhn has analyzed the forces arising from the deflection of each mass flow separately and combined them to arrive at a semiempirical method based on simple momentum theory to estimate the lift and drag forces of propeller-wing-flap configurations. The method uses static slipstream deflection data and power-off wing-flap data as the basis for the calculations.

Kuhn develops expressions for both the lift and drag forces in cruising and high-speed flight by neglecting the forces due to the propeller slipstream and treating the deflection of the mass flow affected by the wing within the assumption of simple momentum thoery. Using this assumption at very low cruising speeds requires that the stream tube be deflected through large angles with a minimum loss in order to produce enough lift to support the airplane. Although the validity of extrapolation of simple momentum theory to large angles appears to be a rather gross assumption, the theory gives reasonable results as long as stall can be avoided.

At zero forward speed, only the propeller slipstreams are available to produce thrust and lift. At this end of the speed range Kuhn develops expressions for the lift and drag forces from available static experimental data on the effectiveness of wing-flap systems in deflecting propeller slipstreams. These expressions are presented in terms of propeller thrust, slipstream characteristics, and the turning effectiveness parameters θ and $\frac{F}{T}$. The slipstream characteristics are obtained using simple momentum theory as applied to propellers.

At transition speeds both flow regions are considered. The resulting expressions approach the power-off wing expressions as velocity is increased and thrust reduced to zero, and approach the zero-forward-speed expressions as the speed is reduced to zero. The method thus provides a logical means of interpolating between these end points.

In treating the flow in the two systems, the fact that the propeller slipstreams occupy space within the large wing stream tube is compensated for by assuming the propeller slipstream to be fully contracted at the wing and that the contraction does not alter the diameter of the stream tube affected by the wing.

To determine the velocity increments necessary to calculate momentum changes, Kuhn assumes that the propeller slipstreams are deflected through the turning angle θ obtained at zero forward speed, that the stream tube affected by the wing is deflected through the downwash angle ϵ obtained under power-off conditions, and that both θ and ϵ remain constant with changes in speed and power.

In order to apply the Datcom methods, it is necessary to have experimental results for or to be able to estimate power-off lift and drag-force characteristics of the wing, as well as slipstream deflection characteristics of the propeller-wing-flap configuration at zero forward speed. The slipstream deflection characteristics for a given propeller-wing-flap configuration require experimental static-thrust data, which will more than likely not be available during the preliminary design phase. Therefore design charts, taken from reference 1, for the slipstream deflection characteristics are provided.

The method presented in this Section is for estimation of the lift of propeller-wing-flap configurations at combined forward speed and power-on conditions. The method is applicable only in the unstalled region of flight.

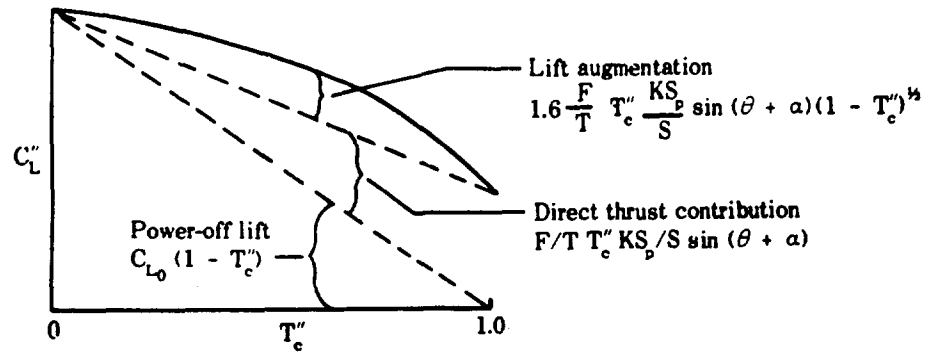
DATCOM METHOD

The lift of a propeller-wing-flap configuration at combined forward speed and power-on conditions is given in reference 1 as

$$C_L'' = C_{L_o} (1 - T_c'') + \frac{F}{T} T_c'' \frac{KS_p}{S} \sin(\theta + \alpha) \left[1 + 1.6 (1 - T_c'')^{1/2} \right] \quad 9.2.1\text{-a}$$

where all the parameters are defined in the general notation list of Section 9.2. The coefficients, except for C_{L_o}, are based on the dynamic pressure in the propeller slipstream, and the positive direction of forces and angles is shown in Figure 9.2-6.

The first term of equation 9.2.1-a represents the power-off lift contribution. The last term represents both the direct propeller thrust contribution and the lift augmentation of the wing due to the propeller slipstream. The significance of these terms is illustrated in sketch (b).



SKETCH (b)

The procedure to be followed in evaluating equation 9.2.1-a is outlined in the following steps.

Step 1. Determine the slipstream turning angle θ by

$$\theta = \theta_f + \Delta\theta \qquad 9.2.1\text{-b}$$

where

θ_f is the slipstream turning angle under conditions of zero incidence and zero camber

$\Delta\theta$ is the slipstream turning-angle increment due to wing camber and incidence between the wing-chord plane and the thrust axis

θ_f is obtained by

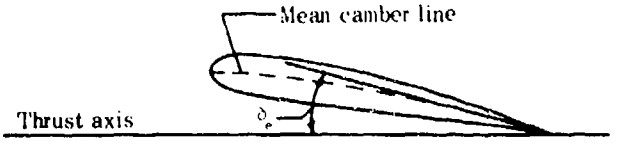
$$\theta_f = \frac{\theta}{\delta}\,\delta \qquad 9.2.1\text{-c}$$

where $\frac{\theta}{\delta}$ is obtained from figure 9.2.1-18a as a function of the ratio of the total extended flap chord to the propeller diameter $\frac{c_f}{D}$, and δ is the total flap deflection. For a multiple-flapped configuration the total flap deflection is the sum of the flap deflection of each individual flap.

$\Delta\theta$ is obtained by

$$\Delta\theta = \frac{\theta}{\delta}\,\delta_e \qquad 9.2.1\text{-d}$$

where $\frac{\theta}{\delta}$ is obtained from Figure 9.2.1-18a as a function of the ratio of the wing chord to the propeller diameter $\frac{c}{D}$, and δ_e is an equivalent flap deflection angle defined as the angle between the thrust axis and the mean camber line at the wing trailing edge (see sketch (c)).



SKETCH (c)

In using this procedure to determine the slipstream turning angle, it is necessary that the value be obtained over the linear part of the curve of variation of turning angle with flap deflection.

In order to define the region of linearity for a given flap configuration, a curve of the variation of the maximum turning angle θ_{max} with the ratio of the total flap chord to the propeller diameter $\frac{c_f}{D}$ is given as figure 9.2.1-18b. A comparison of Figures 9.2.1-18a and 9.2.1-18b indicates that the slope $\frac{\theta}{\delta}$ is dependent only on the total flap chord; whereas the maximum turning angle is dependent upon both the total flap chord and the type of flap. The slope $\frac{\theta}{\delta}$ will become nonlinear as θ_{max} for a given flap configuration is approached. For the purpose of the Datcom the range of the linear variation of θ with δ is defined as

$$\frac{\theta_f}{\theta_{max}} \leq 0.95$$

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$ from figure 9.2.1-19 as a function of the turning angle θ (obtained in Step 1), the flap configuration, and the propeller arrangement.

Step 3. Determine the power-off lift coefficient C_{L_o}.

A wing which is stalled in the power-off condition would frequently be unstalled at some moderate to high propeller thrust coefficient. In order to estimate the power-on data in this region, it is necessary to use the lift values that would exist if the wing were unstalled in the power-off condition. Where possible, experimental power-off data should be used and extrapolated for this purpose. Under these conditions the power-off lift coefficient can be estimated by

$$C_{L_o} = C_{L_{\alpha_o}} 57.3 \sin (\alpha - \alpha_o) \qquad 9.2.1\text{-e}$$

where $C_{L_{\alpha_o}}$ is the extrapolated power-off lift-curve slope of the wing-flap configuration, per degree, and α_o is the extrapolated power-off zero-lift angle of attack.

If power-off data for the given configuration are not available or if the power-off data do not exhibit any region of unstalled flow, the following procedure can be used:

(a) Determine the unflapped wing zero-lift angle of attack from Section 4.1.3.1.

(b) Determine the wing-flap incremental lift from Section 6.1.4.1.

(c) Determine the power-off lift-curve slope of the flapped wing from Section 6.1.4.2.

(d) Using the parameters determined in (a), (b), and (c) construct the power-off lift curve of the flapped wing to obtain α_o.

(e) The power-off lift coefficient of the flapped wing at angle of attack is then obtained using equation 9.2.1-e.

Step 4. The propeller thrust coefficient T_c'' will usually be specified; however, if necessary this parameter can be estimated using the method of Section 9.1.1. $\left(\text{Note that } T_{c_{9.2.1}} = T_{c_{9.1.1}} \frac{S_p}{S}, \text{ and } T_c'' = \frac{T_{c_{9.1.1}}}{T_{c_{9.1.1}} + K}.\right)$

Step 5. The lift coefficient is then obtained from equation 9.2.1-a.

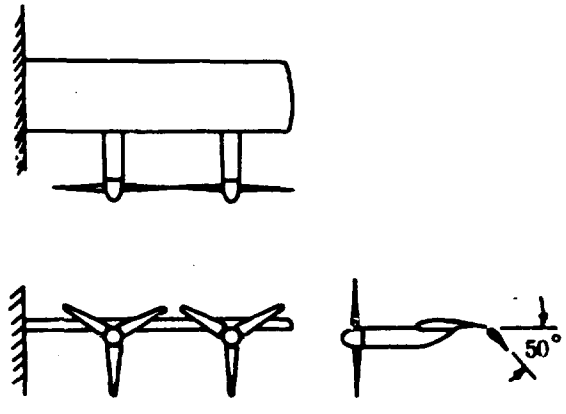
The sample problems illustrate the use of the Datcom method in estimating the lift coefficients of both deflected-slipstream and tilt-wing configurations.

Comparison of experimental data, in the unstalled flight regime, with calculations made using the Datcom method is presented for deflected-slipstream and tilt-wing configurations in Table 9.2.1-A.

Sample Problems

1. Deflected-Slipstream Configuration

Given: A propeller-wing-flap deflected-slipstream configuration of reference 2.



Wing Characteristics

$S = 10.96$ sq ft $A = 7.66$ NACA 4415 airfoil section

$i_w = 0^\circ$ $c = 1.2$ ft (flap retracted) $c = 1.68$ ft (Fowler flap extended)

Flap Characteristics

Fowler flap $\frac{c_f}{c} = 0.286$ (flap extended) $\delta = 50^\circ$

Propeller Characteristics

$K = 4$ (2 propellers per semispan, no overlap) $D = 2.0$ ft

$S_p = 3.14$ sq ft

Additional Characteristics

$T_c" = 0.90$ $\delta_e = 7.4^\circ$

Compute:

Step 1. Determine the slipstream turning angle θ.

$$\frac{c_f}{D} = \frac{c_f}{c}\,\frac{c}{D} = (0.286)\left(\frac{1.68}{2.0}\right)$$

$$= 0.24$$

$\frac{\theta}{\delta} = 0.50$ (figure 9.2.1-18a at $\frac{c_f}{D} = 0.24$)

$\theta_f = \frac{\theta}{\delta}\,\delta = (0.50)(50)$ (equation 9.2.1-c)

$= 25^\circ$

Assuming the wing to be a large-chord flap

$\frac{c}{D} = \frac{1.2}{2.0} = 0.60$

$\frac{\theta}{\delta} = 0.803$ (figure 9.2.1-18a at $\frac{c}{D} = 0.6$)

$\Delta\theta = \frac{\theta}{\delta}\,\delta_e = (0.803)(7.4)$ (equation 9.2.1-d)

$= 5.94$

$\theta = \theta_f + \Delta\theta = 25 + 5.94$ (equation 9.2.1-b)

$= 30.94^\circ$

Determine if the $\frac{\theta}{\delta}$ value for this wing-flap configuration is in the linear range.

$\theta_{max} = 26.5^{o}$ (figure 9.2.1-18b at $\frac{cf}{D} = 0.24$)

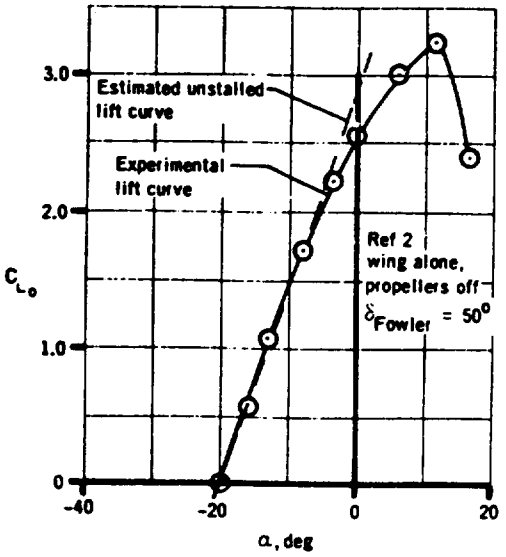
$\frac{\theta_f}{\theta_{max}} = \frac{25}{26.5} = 0.943$ which is within the range of the linear variation of θ with δ as defined by the Datcom.

Step 2. Determine the thrust-recovery $\frac{F}{T}$.

$\frac{F}{T} = 0.96$ (figure 9.2.1-19)

Step 3. Determine the power-off lift coefficient C_{L_o}.

The experimental power-off lift curve is extrapolated to obtain



$\alpha_o = -20^{o}$

$C_{L_{\alpha_o}} = 0.145$ per deg

The lift curve that would exist if the wing were unstalled in the power-off condition is estimated by

$C_{L_o} = C_{L_{\alpha_o}} 57.3 \sin(\alpha - \alpha_o)$ (equation 9.2.1-e)

α deg	$(\alpha - \alpha_o)$ deg	$\sin(\alpha - \alpha_o)$	C_{L_o}
-20	0	0	0
-10	10	0.1736	1.442
0	20	0.3420	2.842
10	30	0.5000	4.154
20	40	0.6428	5.341

Solution:

$$C_L'' = C_{L_o}(1 - T_c'') + \frac{F}{T} T_c'' \frac{KS_p}{S} \sin(\theta + \alpha) \left[1 + 1.6(1 - T_c'')^{1/2}\right] \text{(equation 9.2.1-a)}$$

$$= C_{L_o}(1 - 0.9) + (0.96)(0.9) \frac{(4)(3.14)}{(10.96)} \sin(\theta + \alpha) \left[1 + 1.6(1 - 0.9)^{1/2}\right]$$

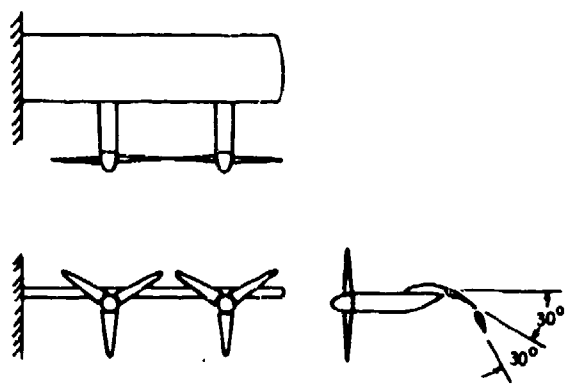
$$= 0.10\, C_{L_o} + 1.491 \sin(\theta + \alpha)$$

①	②	③	④	⑤	⑥	⑦
α deg	C_{L_o}	$(\theta + \alpha)$ deg	sin $(\theta + \alpha)$ sin ③	0.10 C_{L_δ} 0.10 ②	1.491 ④	$C_{L''}$ ⑤ + ⑥
-20	0	10.94	0.1898	0	0.2830	0.2830
-10	1.442	20.94	0.3574	0.1442	0.5329	0.6771
0	2.842	30.94	0.5141	0.2842	0.7665	1.0507
10	4.154	40.94	0.6553	0.4154	0.9771	1.3925
20	5.341	50.94	0.7764	0.5341	1.1576	1.6917

These results are compared with experimental data in table 9.2.1-A.

2. Deflected-Slipstream Configuration

Given: A propeller-wing-flap deflected-slipstream configuration of reference 2.



Wing Characteristics

S = 10.96 sq ft A = 7.66 NACA 4415 airfoil section

i_W = 0 c = 1.2 ft (flaps retracted)

c = 1.68 ft (sliding flap and Fowler flap extended)

Flap Characteristics

Combination sliding and Fowler flap

$\frac{c_f}{c}$ = 0.566 (sliding flap and Fowler flap extended; effective chord of sliding flap measured to flap knee)

$\left.\begin{aligned} \delta_{sliding} &= 30^o \\ \delta_{Fowler} &= 30^o \end{aligned}\right\} \delta = \delta_{sliding} + \delta_{Fowler} = 60^o$

Propeller Characteristics

K = 4 (2 propellers per semispan, no overlap) D = 2.0 ft

S_p = 3.14 sq ft

Additional Characteristics

$T_c" = 0.90$ $\delta_e = 7.4^\circ$

Compute:

Step 1. Determine the slipstream turning angle θ.

$$\frac{c_f}{D} = \left(\frac{c_f}{c}\right)\left(\frac{c}{D}\right) = (0.566)\left(\frac{1.68}{2.0}\right)$$

$$= 0.475$$

$\frac{\theta}{\delta} = 0.72$ (figure 9.2.1-18a at $\frac{c_f}{D} = 0.475$)

$\theta_f = \frac{\theta}{\delta}\,\delta = (0.72)(60)$ (equation 9.2.1-c)

$= 43.2^\circ$

Assuming the wing to be a large-chord flap

$\frac{c}{D} = \frac{1.2}{2.0} = 0.60$

$\frac{\theta}{\delta} = 0.803$ (figure 9.2.1-18a at $\frac{c}{D} = 0.60$)

$\Delta\theta = \frac{\theta}{\delta}\,\delta_e$ (0.803)(7.4) (equation 9.2.1-d)

$= 5.94^\circ$

$\theta = \theta_f + \Delta\theta = 43.2 + 5.94$ (equation 9.2.1-b)

$= 49.14^\circ$

Determine if the $\frac{\theta}{\delta}$ value for this wing-flap configuration is in the linear range.

$\theta_{max} = 53.5^\circ$ (upper curve of figure 9.2.1-18b at $\frac{c_f}{D} = 0.475$)

$\frac{\theta_f}{\theta_{max}} = \frac{43.2}{53.5} = 0.807$ which is within the range of linear variation of θ with δ as defined by the Datcom.

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$.

$\frac{F}{T} = 0.90$ (figure 9.2.1-19)

Step 3. Determine the power-off lift coefficient C_{L_o}.

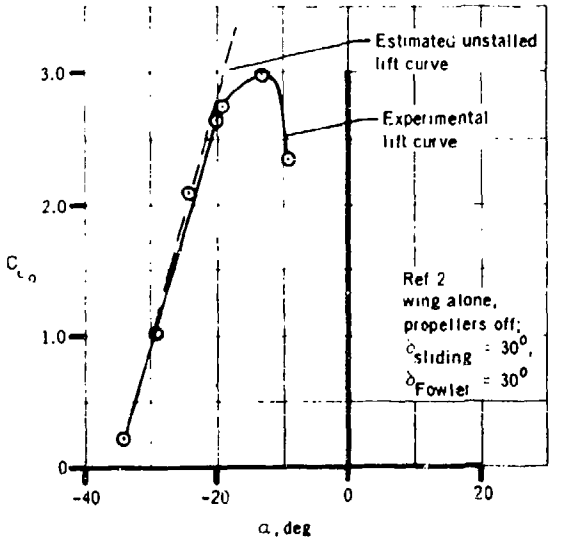
The experimental power-off lift curve is extrapolated to obtain

$\alpha_o = -35^o$

$C_{L_{\alpha_o}} = 0.180$ per deg

The lift curve that would exist if the wing were unstalled in the power-off condition is estimated by

$$C_{L_o} = C_{L_{\alpha_o}} 57.3 \sin (\alpha - \alpha_o)$$ (equation 9.2.1-e)



α deg	$\alpha - \alpha_o$ deg	$\sin (\alpha - \alpha_o)$	C_{L_o}
-40	-5	-0.0872	-0.8990
-35	0	0	0
-20	15	0.2588	2.6693
-10	25	0.4226	4.3587
0	35	0.5736	5.9161
10	45	0.7071	7.2930
20	55	0.8192	8.4492

Solution:

$$C_L'' = C_{L_o} (1 - T_c'') + \frac{F}{T} T_c'' \frac{KS_p}{S} \sin (\theta + \alpha) \left[1 + 1.6(1 - T_c'')^{1/2}\right]$$ (equation 9.2.1-a)

$$= C_{L_o} (1 - 0.9) + (0.90)(0.90) \frac{(4)(3.14)}{(10.96)} \sin (\theta + \alpha) \left[1 + 1.6(1 - 0.9)^{1/2}\right]$$

$$= 0.10\, C_{L_o} + 1.3978 \sin (\theta + \alpha)$$

① α deg	② C_{L_o}	③ $(\theta + \alpha)$ deg	④ sin ③	⑤ 0.10 ②	⑥ 1.3978 ④	⑦ ⑤ + ⑥ C_L''
-40	-0.8990	9.14	0.1588	-0.0899	0.2220	0.1321

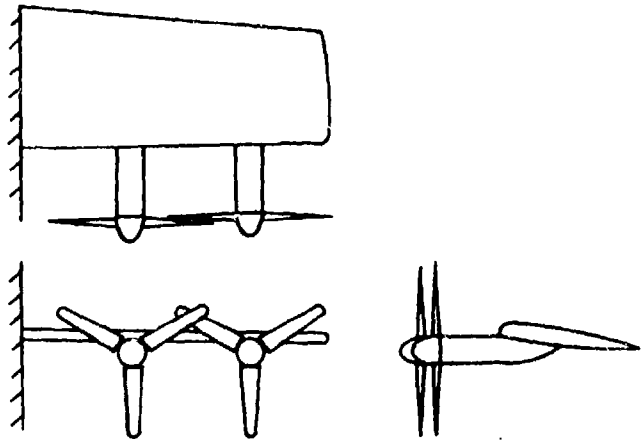
10	7.2930	59.14	0.8585	0.7293	1.2000	1.929
20	8.4492	69.14	0.9344	0.8449	1.3061	2.151

These results are compared with experimental data in table 9.2.1-A.

3. Tilt-Wing Configuration

Given: The propeller-wing configuration of reference 5.



Wing Characteristics

$S = 11.0$ sq ft $\quad A = 4.89 \quad i_w = 5^\circ \quad$ NACA 4415 airfoil section

$c = 1.5$ ft

Propeller Characteristics

$K = 4$ (2 propellers per semispan, overlapped) $\quad D = 2.0$ ft

$S_p = 3.14$ sq ft

Additional Characteristics

$T_c'' = 0.69 \quad \delta_e = 12.4^\circ$

Compute:

Step 1. Determine the slipstream turning angle θ.

$\theta_f = 0$

$\frac{c}{D} = \frac{1.5}{2.0} = 0.75$

$\frac{\theta}{\delta} = 0.89$ (figure 9.2.1-18a at $\frac{c}{D} = 0.75$)

$\Delta\theta = \frac{\theta}{\delta}\delta_e = (0.89)(12.4)$ (equation 9.2.1-d)

$= 11.0^\circ$

$\theta = \theta_f + \Delta\theta$ (equation 9.2.1-b)

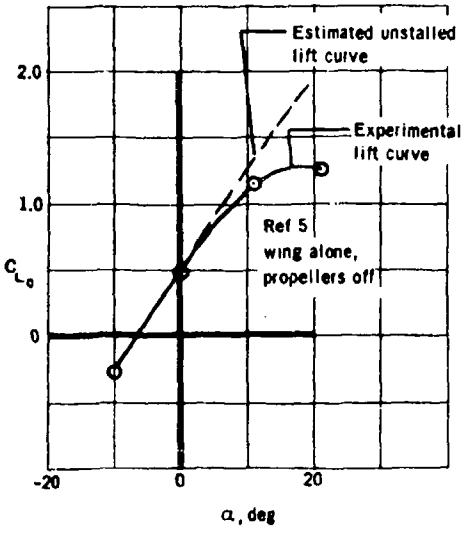
$= 11.0^\circ$

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$.

$\frac{F}{T} = 1.0$ (figure 9.2.1-19)

Step 3. Determine the power-off lift coefficient C_{L_o}.

The experimental power-off lift curve is extrapolated to obtain



$\alpha_o = -6.5^\circ$

$C_{L_{\alpha_o}} = 0.075$ per deg

The lift curve that would exist if the wing were unstalled in the power-off condition is estimated by

$C_{L_o} = C_{L_{\alpha_o}} 57.3 \sin(\alpha - \alpha_o)$ (equation 9.2.1-

α deg	$(\alpha - \alpha_o)$ deg	$\sin(\alpha - \alpha_o)$	C_{L_o}
-10	-3.5	-0.0611	-0.2624
-6.5	0	0	0
0	6.5	0.1132	0.4865
10	16.5	0.2840	1.2205
20	26.5	0.4462	1.9175

Solution:

$$C_L'' = C_{L_o}(1 - T_c'') + \frac{F}{T} T_c'' \frac{KS_p}{S} \sin(\theta + \alpha) \quad 1 + 1.6(1 - T_c'')^{1/2} \quad \text{(equation 9.2.1-a}$$

$$= C_{L_o}(1 - 0.69) + (1.0)(0.69) \frac{(4)(3.14)}{(11.0)} \sin(\theta + \alpha) \quad 1 + 1.6(1-0.69)^{1/2}$$

$$= 0.31\, C_{L_o} + 1.4897 \sin(\theta + \alpha)$$

① α deg	② C_{L_o}	③ $(\theta + \alpha)$ deg	④ $\sin(\theta + \alpha)$ $\sin$ ③	⑤ $0.31\, C_{L_o}$ 0.31 ②	⑥ 1.4897 ④	⑦ C_L'' ⑤ + ⑥

9.2.3 PROPELLER-WING-FLAP DRAG VARIATION WITH POWER AND ANGLE OF ATTACK

This Section presents a method for estimating the drag force of propeller-wing-flap configurations at combined forward speed and power-on conditions. The method is applicable only in the unstalled region of flight. The discussion in Section 9.2.1 is directly applicable to this Section, and the reader is referred to that discussion for a general description of the fundamental phenomena.

DATCOM METHOD

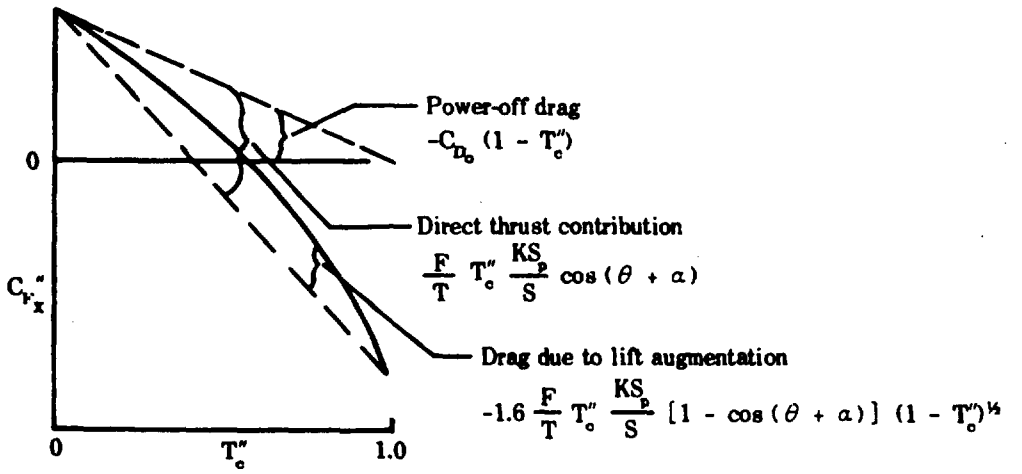
The negative drag force of a propeller-wing-flap configuration at combined forward speed and power-on conditions is given in reference 1 as

$$C_{F_X}'' = -C_{D_o}(1 - T_c'') + \frac{F}{T} T_c'' \frac{KS_p}{S} \cos(\theta + \alpha)$$

$$-1.6 \frac{F}{T} T_c'' \frac{KS_p}{S} \left|1 - \cos(\theta + \alpha)\right| (1 - T_c'')^{1/2} \qquad 9.2.3\text{-a}$$

where all the parameters are defined in the general notation list of Section 9.2. The coefficients, except for C_{D_o}, are based on the dynamic pressure in the propeller slipstream, and the positive direction of forces and angles is shown in Figure 9.2-6.

The first term of equation 9.2.3-a represents the power-off drag contribution, the second term represents the component of thrust opposing the drag, and the third term represents the drag resulting from the lift augmentation due to the propeller slipstream. The significance of these terms is illustrated in sketch (a).



SKETCH (a)

The procedure to be followed in evaluating equation 9.2.3-a is outlined in the following steps.

Step 1. Determine the slipstream turning angle θ as in Step 1 of the method outline of Section 9.2.1.

In using this procedure to determine the slipstream turning angle it is necessary that the value be obtained over the linear part of the curve of variation of turning angle with flap deflection. The range of linear variation is defined in Step 1 of the method outline of Section 9.2.1.

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$ as in Step 2 of the method outline of Section 9.2.1.

Step 3. Determine the power-off drag coefficient C_{D_o}.

A wing which is stalled in the power-off condition would frequently be unstalled at some moderate to high propeller thrust coefficient. In order to estimate the power-on data in this region, it is necessary to use the drag values that would exist if the wing were unstalled in the power-off condition. Where possible, experimental power-off data should be used for this purpose. Under these conditions the power-off drag coefficient can be estimated by

$$C_{D_o} = C_{D_f} + \frac{C_{L_o}^2}{\pi A e} \qquad 9.2.3\text{-b}$$

where

C_{D_f} is the power-off zero-lift drag coefficient. (For the purpose of the Datcom this coefficient is taken as the minimum experimental power-off drag coefficient in order to simplify the definition of the drag polar.)

C_{L_o} is the power-off lift coefficient obtained as in Step 3 of the method outline of Section 9.2.1

e is the span efficiency factor for the configuration. For the purpose of the Datcom e = 0.85.

If power-off data for the given configuration are not available or if power-off test data do not exhibit any region of unstalled flow, the following procedure should be used:

(a) Determine the power-off lift variation and α_o as in Step 3 of the method outline of Section 9.2.1.

(b) Determine the power-off zero-lift drag coefficient for the unflapped wing from Section 4.1.5.1.

(c) Determine the zero-lift drag increment due to flap deflection from Section 6.1.7.

then

$$C_{D_f} = C_{D_{f(4.1.5.1)}} + (\Delta C_D)_{(6.1.7)} \qquad 9.2.3\text{-c}$$

(d) The power-off drag coefficient of the flapped wing at angle of attack is then obtained from equation 9.2.3-b.

Step 4. The propeller thrust coefficient T_c'' will usually be specified; however, if necessary this parameter can be estimated using the method of Section 9.1.1.

$$\left(\text{Note that } T_{c_{9.2.1}} = T_{c_{9.1.1}} \frac{S_p}{S}, \text{ and } T_c'' = \frac{T_{c_{9.1.1}}}{T_{c_{9.1.1}} + K}.\right)$$

Step 5. The drag force coefficient is then obtained from equation 9.2.3-a.

The sample problems illustrate the use of the Datcom method in estimating the horizontal-force coefficients of both deflected-slipstream and tilt-wing configurations.

Comparison of experimental data, in the unstalled flight regime, with calculations made using the Datcom method is presented for deflected-slipstream and tilt-wing configurations in Table 9.2.3-A.

Sample Problems

1. Deflected-Slipstream Configuration

Given: A propeller-wing-flap deflected-slipstream configuration of reference 2. This is the same configuration as that of sample problem 1 of Section 9.2.1. The characteristics are repeated below.

Wing Characteristics

$S = 10.96$ sq ft $A = 7.66$ NACA 4415 airfoil section

$i_w = 0$ $c = 1.2$ ft (flap retracted) $c = 1.68$ ft (Fowler flap extended)

Flap Characteristics

Fowler flap $\frac{c_f}{c} = 0.286$ (flap extended) $\delta = 50^\circ$

Propeller Characteristics

$K = 4$ (2 propellers per semispan, no overlap) $D = 2.0$ ft

$S_p = 3.14$ sq ft

Additional Characteristics

$T_c'' = 0.90$ $\delta_e = 7.4^\circ$

Compute:

Step 1. Determine the slipstream turning angle θ.

$\theta = 30.94^\circ$ (sample problem 1, Section 9.2.1)

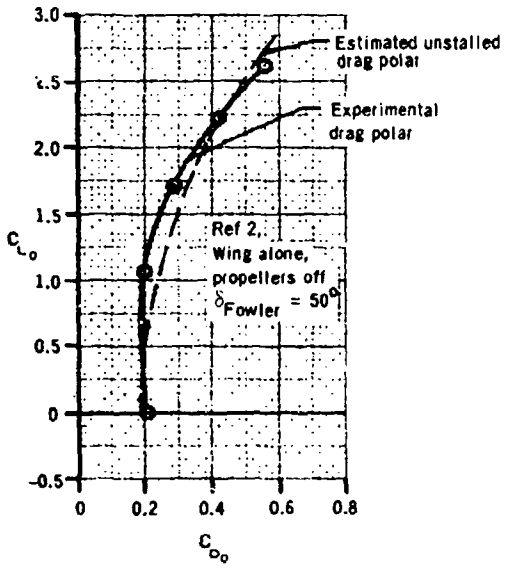
Also note that the variation of θ with δ for this wing-flap configuration was shown to be within the range of linear variation as defined by the Datcom.

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$.

$\frac{F}{T} = 0.96$ (sample problem 1, Section 9.2.1)

Step 3. Determine the power-off drag coefficient C_{D_o}.

The power-off drag coefficient is obtained using the experimental zero-lift drag coefficient, and the power-off lift coefficient at angle of attack as determined in sample problem 1 of Section 9.2.1.



$C_{D_f} = 0.19$ (minimum experimental power-off drag coefficient)

The drag polar that would exist if the wing were unstalled in the power-off condition is estimated by

$$C_{D_o} = C_{D_f} + \frac{C_{L_o}^2}{\pi Ae} \quad \text{(equation 9.2.3-b)}$$

α deg	C_{L_o} Problem 1 9.2.1	$\frac{C_{L_o}^2}{\pi Ae}$	C_{D_o}
-20	0	0	0.1900
-10	1.422	0.1017	0.2917

These results are compared with experimental data in table 9.2.3-A.

2. Deflected-Slipstream Configuration

Given: A propeller-wing-flap deflected-slipstream configuration of reference 2. This is the same configuration as that of sample problem 2 of Section 9.2.1. The characteristics are repeated below.

Wing Characteristics

$S = 10.96$ sq ft $\quad A = 7.66$ $\quad$ NACA 4415 airfoil section

$i_w = 0$ $\quad c = 1.2$ ft (flaps retracted) $\quad c = 1.68$ ft (sliding flap and Fowler flap extended)

Flap Characteristics

$\frac{c_f}{c} = 0.566$ (sliding flap and Fowler flap extended; effective chord of sliding flap measured to flap knee)

$$\left.\begin{aligned} \delta_{sliding} &= 30^\circ \\ \delta_{Fowler} &= 30^\circ \end{aligned}\right\} \delta = \delta_{sliding} + \delta_{Fowler} = 60^\circ$$

Propeller Characteristics

$K = 4$ (2 propellers per semispan, no overlap) $\quad D = 2.0$ ft

$S_p = 3.14$ sq ft

Additional Characteristics

$T_c" = 0.90 \qquad \delta_e = 7.4^\circ$

Compute:

Step 1. Determine the slipstream turning angle θ.

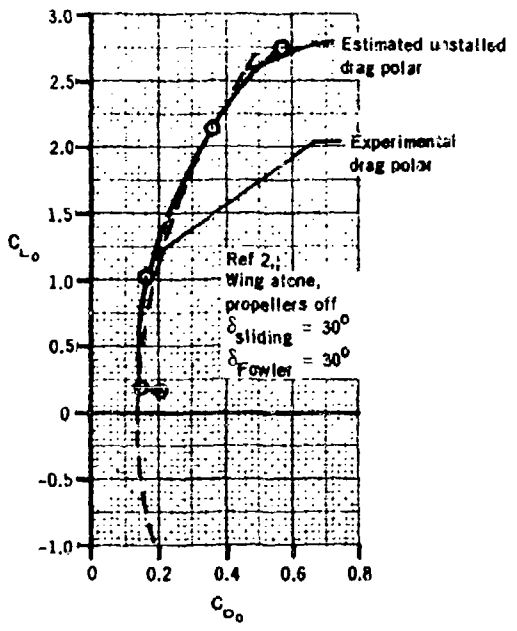
$\theta = 49.14^\circ$ (sample problem 2, Section 9.2.1) Also note that the variation of θ with δ for this wing-flap configuration was shown to be within the range of linear variation as defined by the Datcom.

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$.

$\frac{F}{T} = 0.90$ (sample problem 1, Section 9.2.1)

Step 3. Determine the power-off drag coefficient C_{D_o}.

The power-off drag coefficient is obtained using the experimental zero-lift drag coefficient, and the power-off lift coefficient at angle of attack determined in sample problem 2 of Section 9.2.1.



$C_{D_f} = 0.14$ (minimum experimental power-off drag coefficient)

The drag polar that would exist if the wing were unstalled in the power-off condition is estimated by

$$C_{D_o} = C_{D_f} + \frac{C_{L_o}^2}{\pi Ae} \quad \text{(equation 9.2.3-b)}$$

These results are compared with experimental data in table 9.2.3-A

3. Tilt-Wing Configuration

Given: The propeller-wing configuration of reference 5. This is the same configuration as that of sample problem 3 of Section 9.2.1. The characteristics are repeated below.

Wing Characteristics

$S = 11.0$ sq ft $\quad A = 4.89 \quad i_w = 5^\circ$ NACA 4415 airfoil section

$c = 1.5$ ft

Propeller Characteristics

$K = 4$ (2 propellers per semispan, overlapped) $\quad D = 2.0$ ft

$S_p = 3.14$ sq ft

Additional Characteristics

$T_c'' = 0.69 \quad \delta_e = 12.4^\circ$

Compute:

Step 1. Determine the slipstream turning angle θ.

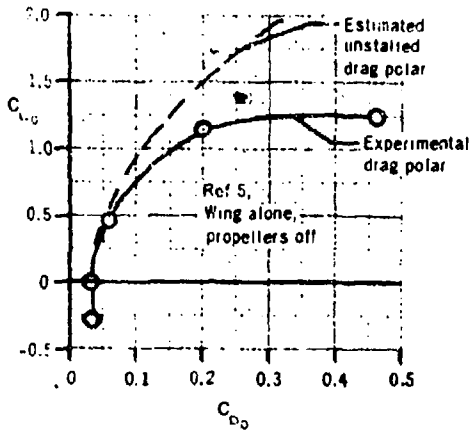
$\theta = 11.0^\circ$ (sample problem 3, Section 9.2.1)

Step 2. Determine the thrust-recovery factor $\frac{F}{T}$.

$\frac{F}{T} = 1.0$ (sample problem 3, Section 9.2.1)

Step 3. Determine the power-off drag coefficient C_{D_o}

The power-off drag coefficient is obtained using the experimental zero-lift drag coefficient, and the power-off lift coefficient at angle of attack determined in sample problem 3 of Section 9.2.1.



$C_{D_f} = 0.035$

The drag polar that would exist if the wing were unstalled in the power-off condition is estimated by

$$C_{D_o} = C_{D_f} + \frac{C_{L_o}^2}{\pi Ae} \quad \text{(equation 9.2.3-b)}$$

9.3 DUCTED-PROPELLER CHARACTERISTICS

The estimation of ducted-propeller aerodynamics can be approached in three phases, each representing a VTOL aircraft flight regime. These are static operation (hovering), axial flow (approximately zero duct angle of attack as in cruise or vertical climb), and nonaxial flow (high duct angles of attack as in transition). The most important and most difficult problem is the prediction of the aerodynamic characteristics in the presence of strong power effects at high angles of attack and low speeds during transition.

The methods presented in this section are for predicting forces and moments on isolated ducted propellers as functions of power and angle of attack. The static and axial-flow regimes are trivial, and no attempt is made to deal with the characteristics in these regimes. It is virtually impossible to present quantitative information on the effects of the various geometric and aerodynamic variables involved because of the complexity of the problem and the general lack of appropriate data. However, a qualitative discussion of the ducted-propeller problem is given with primary emphasis on the nonaxial flow regime.

A ducted propeller consists of a propeller enclosed in an axially symmetric duct as shown in figure 9.3-12. The purpose of the duct is to increase the thrust-generating capability of the entire unit in the static and low subsonic speed regimes for a given propeller diameter and power input. If the chordwise cross section of the duct is reasonably faired, the unit can function as a ring wing as well as a thrusting propeller.

Differing from flying platforms or "flying jeeps," ducted-propeller units are typically mounted on the tips of low-aspect-ratio wings with the capability of rotating from 0 to 90 degrees. Since much of the ducted-propeller work has been the application to particular vehicle designs, the emphasis has been on propeller design and development of auxiliary devices to augment thrust and to provide control moments. This work is thus of little interest here because the lift and pitching moments are not affected significantly. The development of various auxiliary devices is reported in reference 84, and additional information pertaining to experimental investigations is given in table 9.3-A.

The duct complicates the problem of predicting the aerodynamic characteristics because of the strong mutual interference effects and the increased number of geometric variables. A preliminary list of geometric variables includes duct aspect ratio, duct section parameters (thickness ratio, camber, leading-edge radius, etc.), diffuser angle, propeller activity factor, propeller pitch setting, propeller solidity, propeller section parameters (twist, camber, taper, thickness, etc.), blade tip clearance, center-body location relative to the duct, center-body shape, ratio of hub diameter to propeller diameter, and propeller location within the duct. Aside from this seemingly endless list of geometric variables, there are the aerodynamic variables of angle of attack, Reynolds number, advance ratio, and Mach number.

The ducted propeller in the nonaxial flow regime has received very little theoretical attention in comparison to that given to the static and axial-flow regimes. The theoretical work available in the literature is generally classified under one of three general categories of analysis: (1) method of singularities, (2) momentum considerations, and (3) methods which seek to avoid the

mathematical complexities of the method of singularities and yet yield more detailed results than simple momentum theory. The method of singularities is relatively complex, and almost all solutions in the literature are restricted to special classes of duct profiles. The method involves replacing the annular airfoil by a vortex distribution on its camber line, determining the axial and radial velocity components induced by this vortex distribution, and relating these velocity components to the shape of the airfoil by satisfying the potential flow streamline condition. Two approaches to the problem can be defined: (1) given the vortex distribution, find the corresponding shape and determine its aerodynamic characteristics, and (2) given the shape, find the corresponding vortex distribution, from which the aerodynamic characteristics can be determined. In either case, an iteration process is required if other than a first approximation is desired. The effects of geometric parameters and propellers are induced by the use of additional distributed singularities. The theoretical basis on which the method of singularities rests is developed and discussed in reference 57.

An approximate theory for nonaxial flow, based on the method of singularities, is developed by Burggraf in reference 1. Burggraf represents the ducted propeller as a short, thin, cylindrical duct with a uniformly loaded actuator disk across its exit plane. Each section of the duct is treated as a thin two-dimensional airfoil, and solutions are obtained by means of conformal transformations. An analysis with less restricted geometry has been made by Kriebel and summarized in reference 55. Kriebel treats the duct as a thin cylinder (but not necessarily short) and represents the propeller as a uniformly loaded actuator disk located at the duct inlet. The vorticity distribution bound to the duct and trailing from it is found in terms of a Fourier series by the method of singularities. The results are obtained by solving for the coefficients of the Fourier series representing the duct-bound vorticity distribution. Both Burggraf and Kriebel include the nonaxial flow case by assuming the vorticity shed by both the actuator disk and the duct to be concentrated on a circular cylinder which extends axially downstream, even at angles of attack. Because of this assumption, the exit velocity must be large relative to the cross-flow component of the free-stream velocity, i.e.,

$$V_e >> V_\infty \sin \alpha_D ,$$

a restriction which requires high actuator disk loadings at high angles of attack.

Momentum theory in itself is not sufficient to predict the performance of a ducted propeller, since the relationships between thrust and power are in terms of the area and velocity of the final wake. At the present time, there appears to be no available way of relating wake characteristics to duct design without using the method of singularities. To avoid this difficulty some assumption must be made which relates the duct exit characteristics to the final wake. The most common assumption, forming what is generally termed "simple momentum theory," is that the final wake area is equal to the duct exit area. This implies that the exit velocity profile is uniform and the static pressure at the exit is equal to that at infinity. The nonaxial flow case is generally based on the additional assumption that the internal mass flow exits parallel to the duct axis, an assumption which is valid only for low duct aspect ratios and high exit-velocity ratios. Examples of simple momentum theory as applied to nonaxial flow are given in references 85 and 58.

Moser and Livingston, in reference 70, develop semiempirical expressions for the aerodynamic characteristics of ducted propellers in nonaxial flow by adapting blade element theory and modifications to it to take some account of duct influence. This method is shown to be reasonable for analyzing ducted-propeller characteristics where the deflection of the airstream is relatively small.

Minassian, in reference 65, treats the ducted propeller in nonaxial flow as a ring wing. He assumes that the propeller causes the internal pressures on the duct to cancel one another and then applies two-dimensional airfoil characteristics to predict normal-force variation with angle of attack. This work is restricted to rough approximations at low angles of attack and high advance ratios.

Wind-tunnel tests cover a wide variety of ducted propellers in the nonaxial flow regime; however, the data are often of questionable accuracy because of wall-interference effects and data accuracy limitations at the tunnel speeds required to simulate low-speed flight. Testing small models in an effort to avoid wall-interference effects has not proved satisfactory because of the errors associated with low Reynolds numbers and balance-system sensitivity. The uncertainties of wind-tunnel test data, coupled with the geometric and aerodynamic variables involved, preclude generalization and verification of any valid prediction methods. Although a large number of experimental investigations have been conducted, it is still difficult to draw any general conclusions pertaining to the effects of geometric or aerodynamic variations. However, the results that are available can serve at least to give a practical orientation to some aspects of the ducted propeller problem. Accordingly, a qualitative discussion of the effects of a number of the important variables is given.

Duct Leading-Edge Radius

The duct leading-edge radius is critical in that it must be large enough to prevent inlet flow separation at high power and/or angle of attack and yet not so large as to produce an excessive drag penalty in cruise flight. Leading-edge lip stall reduces lift and pitching moment and increases the power required.

Diffuser

A properly designed diffuser increases the diameter of the fully developed stream tube, thereby increasing the static thrust and efficiency of a given ducted propeller. Tests of two unpowered ducts (reference 36) in nonaxial flow indicate that diffusion of the duct afterbody results in an appreciable increase in lift-curve slope and maximum-lift stall angle of attack. Reference 36 also indicates that diffusion causes the center of pressure to move forward. These effects can be attributed to the increased internal mass flow through the duct resulting from increased positive circulation.

Although substantial diffusion may be beneficial in the static flow regime, it can lead to internal flow separation during essentially axial flow with an attendant drag increase.

Exit Stators

In addition to providing a structural tie between the center body and the duct, exit stators, because of twist and camber, also serve as guide vanes to eliminate the slipstream rotation resulting from the high thrust loading of the ducted propeller. This flow straightening converts the rotational kinetic energy to pressure and increased axial velocity. If flow straightening is not provided, the propeller efficiency is severely reduced.

Propeller Twist

The effect of propeller twist on static performance has been a source of controversy. The results reported in references 12 and 64 indicate that a relatively flat, untwisted blade is best for static and low-speed operation, because of the better match with the theoretical ring vortex circulation about the duct, resulting in gains in static efficiency. However, these reports make no statement regarding blade pitch optimization, and it is difficult to distinguish between the effects of blade twist and those of blade pitch. On the other hand, the results reported in references 19 and 56, which did use blade pitch optimization, show no such corresponding improvement and indicate that blade twist is relatively unimportant. Moser and Livingston, in reference 70, also indicate that the effects of blade twist are relatively unimportant except at the highest collective pitch tested.

Propeller Tip Clearance

Ducted-propeller efficiency increases with decreasing tip clearance. Excessive tip clearance will aggravate a condition of flow reversal that occurs on the duct in the propeller plane even for small tip clearances. At moderate to high angles of attack, the flow reversal condition on the lower inside surface of the duct can cause premature inlet lip separation, resulting in reductions in both lift and pitching moment accompanied by increased power requirements.

Propeller Position

The effect of propeller position on ducted-propeller forces and moments in nonaxial flow is relatively undefined. Reference 19 indicates that at a given thrust level, moving the propeller forward reduces the lift and pitching-moment coefficients. However, data of reference 57 indicate that forward movement of the propeller plane increases the radial variation in duct velocity distribution (greater velocities near the duct), which would be expected to increase the pitching moments in nonaxial flow.

It is stated in reference 55 that analytical results indicate that in axial flow the pressure jump acting upon the internal duct surface downstream of the propeller plane is maximum when the propeller plane is located at the minimum duct internal cross-sectional area. For this location of the propeller in axial flow, the disk area and disk thrust are minimum for a given disk loading, and the duct-to-disk thrust ratio and the propulsive efficiency are maximum.

Exit-Velocity Ratio and Angle of Attack

The exit-velocity ratio and angle of attack determine the basic flow pattern for a given ducted propeller. As the duct angle of attack is increased beyond the unpowered stall angle, the exit-velocity ratio must be increased to prevent stalling of the duct lower leading edge. Because of the predominance of power effects as duct angle of attack is increased, the separation that occurs on the top aft portion of the duct usually has a minor effect on force and moment data.

Reynolds Number

Reynolds-number effects are of extreme importance in ducted-propeller design because of the low airspeed of operation and the short streamwise lengths of ducted-propeller elements. The separation that occurs on the lower inside surface of the duct leading edge at high angles of attack and low exit-velocity ratios is a low Reynolds-number characteristic. At low Reynolds number, laminar flow is followed by separation rather than by attached turbulent flow, resulting in substantial losses in both lift and pitching moment at a given power setting.

A comprehensive tabulation of pertinent ducted-propeller experimental data in the nonaxial flow regime is presented as table 9.3-A. This table provides a brief outline of the test data contained in each report and indicates the basic parametric changes. Similar tables pertaining to the static- and axial-flow regimes are given in reference 84. It should be recognized that the ducted propeller problem cannot be satisfactorily handled by treating isolated effects with all other variables fixed. The effect of a geometric or aerodynamic variation on the characteristics of a ducted propeller of different design will very likely be quite different from that indicated by the test results of available reports.

A general notation list is included in this section for all ducted propeller sections. Figures 9.3-12 and 9.3-13 illustrate the geometric data required by the methods of these sections. Figure 9.3-13 also illustrates the positive sense of forces, moments, and angles.

NOTATION

A_D duct aspect ratio, $\frac{d_e}{c}$

c duct chord, ft

C_{D_e} external duct drag coefficient, $\frac{-F_{x_e}}{q_\infty S_D}$

C_{F_x} duct negative-drag coefficient, $\frac{F_x}{q_\infty S_D}$

$C_{F_{x_e}}$ external duct negative-drag coefficient, $\frac{F_{x_e}}{q_\infty S_D}$

C_L duct lift coefficient, $\frac{L}{q_\infty S_D}$

9.3.1 DUCTED-PROPELLER LIFT VARIATION WITH POWER AND ANGLE OF ATTACK

The primary purpose of enclosing a propeller in a duct is to increase the thrust-generating capability in the static and low subsonic speed regimes for a given propeller diameter and power input. Because of strong mutual interference effects, the ducted-propeller aerodynamic characteristics are vastly different from those of a free propeller and an annular airfoil. The forces and moments acting on a ducted propeller may be considered as arising from the propeller forces, the duct forces, and the mutual interference of the duct and propeller.

As a consequence of the input of mechanical energy to a propeller delivering positive thrust, there is a pressure rise at the propeller disk, which is subsequently transformed into kinetic energy in the slipstream. If the propeller is enclosed within a fairing, a further velocity increment is produced at the propeller, which must be superimposed on the propeller flow. If this velocity increment is positive, the mass flow and consequently the total thrust are increased. This increase in force acts on the duct, and its magnitude depends upon the velocity increment due to the duct and the propeller loading. In addition, the mutual interference of the duct and propeller and other bodies which may be present results in an induced circulation, which may either increase or decrease the internal mass flow.

The Datcom methods presented for estimating forces and moments on ducted-propeller configurations require knowledge of only the total internal axial thrust rather than the thrust due to the propeller and to the duct at angle of attack. However, the fundamental phenomenon of ducted-propeller aerodynamics may be clarified somewhat by an analysis of the division of loads between the duct and the propeller.

The results of an investigation of the division of the forces and moments between a duct and a propeller of a ducted propeller are reported in reference 6. The investigation covered an angle-of-attack range and an advance-ratio range typical of the transition of a tilt-duct VTOL aircraft.

Figures 9.3.1-10a and 9.3.1-10b, reproduced from reference 6, present a comparison of the normal force, thrust force, and pitching moment on the propeller with the total model forces and moments, for an unstalled and a stalled duct, respectively. The unstalled configuration is the basic symmetrical duct shape modified by the addition of leading-edge fairings. These results show that the normal force and pitching moment acting on the propeller and spinner are relatively small in comparison with the total normal force and pitching moment of either the stalled or unstalle unit and that the duct is the primary source of normal force and pitching moment.

Figure 9.3.1-12, reproduced from reference 6, presents the variation of propeller thrust relative to total thrust with angle of attack for both the unstalled and the stalled duct configurations. In hovering ($V/nd_p = 0$), the propeller carries approximately 40 percent of the total thrust. At the highest value of the advance ratio tested, the propeller carries approximately 70 percent of the total thrust when α is near 0^o. For the unstalled operation, the propeller thrust ratio generally decreases with increasing angle of attack at a constant advance ratio. Beyond the stall the propeller thrust ratio increases with increasing angle of attack at a constant advance ratio. The increase can be attributed to the reduction in duct thrust caused by the lip stall.

Unpowered conditions correspond to a duct exit-velocity ratio of approximately 1.0. The exact value depends on the circulation about the duct. Annular wing reports, such as reference 2, may be used to estimate the forces and moments on an unpowered ducted propeller at angle of attack.

For convenience, the methods presented in subsequent Sections provide wind-axis aerodynamic force coefficients: conventional lift and drag coefficients normal and parallel to the free stream. The aerodynamic force and moment coefficients are referred to free-stream dynamic pressure.

Ducted propeller forces and moments are compared with those predicted by the Datcom methods in this and the following Sections. The experimental data represent a wide variation of duct and propeller variables over angle-of-attack and advance-ratio ranges typical of the transition range of a tilting duct VTOL aircraft. Experimental axial-thrust values have been used in the Datcom method calculations. A comparison of some of the pertinent geometric and aerodynamic parameter variations of the test configurations can be made by referring to the reference list of this Section and the reference list and table 9.3-A of Section 9.3. The Datcom methods are based on modifications to simple momentum theory and do not account for the possible wide variation in design parameters.

The lift predicted by the Datcom method of this Section compares favorably with test results throughout the range of the investigation. On the other hand, the pitching moment and drag predicted by the Datcom methods of Sections 9.3.2 and 9.3.3, respectively, vary noticeably from experimental results.

The method presented in this Section for the estimation of the lift of a ducted propeller is expressed as the sum of the lift components resulting from the internal and external mass flows. The internal-mass-flow component is estimated on the basis of simple momentum theory with empirical flow-turning corrections as a function of the duct aspect ratio and the duct exit-velocity ratio. The external-mass-flow component is estimated on the basis of empirical modifications of the data of references 1 and 2.

DATCOM METHOD

The method presented for the estimation of ducted-propeller lift coefficient is expressed as the sum of the components resulting from the internal and external mass flows. This approach is summarized by

$$C_L = \frac{L}{q_\infty S_D} = C_{L_i} + C_{L_e}$$

$$= \frac{\pi A_D}{2}\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right]\left(\frac{V_e}{V_\infty}\right)^2 \sin \delta_{1_f} + C_{L_e} \qquad 9.3.1\text{-a}$$

where

C_{L_i} is the lift coefficient resulting from the internal mass flow

C_{L_e} is the lift coefficient resulting from the external mass flow. It is obtained from figure 9.3.1-13 as a function of duct aspect ratio and angle of attack. Figure 9.3.1-13 is based on empirical modifications of the data of references 1 and 2.

δ_{i_f} is the net turning angle of the internal flow including power effects.

The basic approach to the solution of equation 9.3.1-a is as follows:

1. Determine the turning angle of the internal flow neglecting the effects of power.
2. Determine the exit-velocity ratio V_e/V_∞.
3. Determine the net turning angle of the internal flow including power effects.
4. Evaluate the internal-flow lift contribution using the terms obtained in steps 2 and 3 above.

The results of reference 2 indicate that the lift-curve slope of annular wings is twice that of plane unswept wings of the same aspect ratio. Based on simple momentum theory, the usual small-angle approximation, and the assumption of no lip separation, the turning angle of the internal flow, neglecting power effects, is

$$\delta_{i_o} \approx \sin^{-1}\left(\frac{C_{L_\alpha}\,\alpha}{\pi\, A_D}\right) \qquad 9.3.1\text{-b}$$

The unpowered, internal-flow turning angle relative to duct angle of attack is presented in figure 9.3.1-14 as a function of duct aspect ratio. Figure 9.3.1-14 is based on the unstalled test data of reference 2 and equation 9.3.1-b.

Addition of power causes further turning of the internal flow. This turning occurs forward of the propeller plane because of the closed boundaries of the duct. The flow is assumed to pass through the duct normal to the propeller plane, and the total velocity increase imparted to the internal flow (V_i) is assumed to be the difference between the duct exit velocity and the free-stream velocity. This results in the following expression for the net turning angle of the internal flow, including power effects (see figure 9.3-11b).

$$\delta_{i_f} \approx \sin^{-1}\left[\frac{V_\infty \sin\delta_{i_o} + (V_e - V_\infty)\sin\alpha_D}{V_e}\right] \qquad 9.3.1\text{-c}$$

The total lift contribution of a ducted propeller is obtained from the procedure outlined in the following steps:

Step 1. Determine the turning angle of the internal flow, neglecting power effects, by

$$\delta_{i_o} = \alpha_D\left(\frac{\Delta\delta_{i_o}}{\Delta\alpha_D}\right) \qquad 9.3.1\text{-d}$$

where $\frac{\Delta\delta_{i_o}}{\Delta\alpha_D}$ is obtained from figure 9.3.1-14 as a function of duct aspect ratio.

Step 2. Determine the exit-velocity ratio $\frac{V_e}{V_\infty}$ using

$$\frac{V_e}{V_\infty} = \frac{1 + \sqrt{1 + \frac{2T_i}{q_\infty S_e}}}{2} \qquad 9.3.1\text{-e}$$

where

S_e is the flow area at the duct exit plane $= \frac{\pi d_e^2}{4}\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right]$

T_i is the total internal axial thrust ($\alpha_D = 0$), obtained as the sum of the net axial thrust T_{net} and the external duct drag.

$$T_i = T_{net} + C_{D_e}\, q_\infty\, S_D \qquad 9.3.1\text{-f}$$

Estimation of the net axial thrust is a ducted-propeller performance problem and is consequently outside the scope of the Datcom. A propulsion engineer should be consulted for this parameter.

The external duct drag C_{D_e} is obtained from figure 9.3.3-4 at $\alpha_D = 0^\circ$, where $C_{D_e} = -C_{F_{x_e}}$

Step 3. Using equation 9.3.1-e, obtain δ_{i_f} with the δ_{i_o} and $\frac{V_e}{V_\infty}$ values from Steps 1 and 2 above.

Step 4. Determine the internal-mass-flow lift-coefficient contribution by

$$C_{L_i} = \frac{\pi A_D}{2}\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right]\left(\frac{V_e}{V_\infty}\right)^2 \sin\delta_{i_f} \qquad 9.3.1\text{-g}$$

Step 5. Obtain the lift coefficient C_{L_e} from figure 9.3.1-13 as a function of the duct aspect ratio and angle of attack.

Step 6. The total lift coefficient is given by equation 9.3.1-a

$$C_L = C_{L_i} + C_{L_e}$$

A comparison of test data with ducted-propeller lift coefficients computed by this method is shown in Table 9.3.1-A.

Sample Problem

Given: The ducted propeller configuration of reference 1

$d_e = 4.525$ ft $\quad d_{CB} = 1.208$ ft $\quad c = 2.75$ ft $\quad S_D = 12.45$ sq ft

Additional Characteristics

$V_\infty = 93.5$ ft/sec $\quad \alpha_D = 30^\circ \quad T_{net} = 635$ lb $\quad$ Sea level $\quad q_\infty = 10.4$ lb/sq ft

Compute:

Step 1. Determine the turning angle of the internal mass flow without power effects.

$$A_D = \frac{d_e}{c} = \frac{4.525}{2.75} = 1.645$$

$$\frac{\Delta\delta_{i_o}}{\Delta\alpha_D} = 0.830 \quad \text{(figure 9.3.1-14)}$$

$$\delta i_o = \alpha_D \left(\frac{\Delta\delta_{i_o}}{\Delta\alpha_D}\right) \quad \text{(equation 9.3.1-d)}$$

$$= (30)(0.830)$$

$$= 24.9 \text{ deg}$$

Step 2. Determine the exit-velocity ratio

$$C_{D_e} = -C_{F_{x_e}} = 0.022 \quad \text{(figure 9.3.3-4, at } \alpha_D = 0)$$

$$T_i = T_{net} + C_{D_e}\, q_\infty\, S_D \quad \text{(equation 9.3.1-f)}$$

$$= 635 + (0.022)(10.4)(12.45)$$

$$= 637.7 \text{ lb}$$

$$S_e = \frac{\pi d_e^2}{4}\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right] = \frac{\pi(4.525)^2}{4}\left[1 - \left(\frac{1.208}{4.525}\right)^2\right]$$

$$= 16.10 \quad (0.9295)$$

$$= 14.97 \text{ sq ft}$$

$$\frac{V_e}{V_\infty} = \frac{1 + \sqrt{1 + \dfrac{2T_i}{q_\infty\, S_e}}}{2} \quad \text{(equation 9.3.1-e)}$$

$$= \frac{1 + \sqrt{1 + (2)\dfrac{637.7}{(10.4)(14.97)}}}{2}$$

$$= \frac{1 + \sqrt{1 + 8.19}}{2}$$

$$\frac{V_e}{V_\infty} = 2.02$$

Step 3. Determine the net turning angle of the internal mass flow, including power effects.

$$\delta_{i_f} \approx \sin^{-1}\left[\frac{V_\infty \sin \delta_{i_o} + (V_e - V_\infty) \sin \alpha_D}{V_e}\right] \text{(equation 9.3.1-c)}$$

$$= \sin^{-1}\left[\frac{(93.5)(0.421) + (189 - 93.5)(0.50)}{189}\right]$$

$$= \sin^{-1} (0.4609)$$

$$= 27.45 \text{ deg}$$

Step 4. Determine the lift-coefficient contribution of the internal mass flow.

$$C_{L_i} = \frac{\pi A_D}{2}\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right]\left(\frac{V_e}{V_\infty}\right)^2 \sin \delta_{i_f} \quad \text{(equation 9.3.1-g)}$$

$$= \frac{\pi(1.645)}{2} (0.9295)(2.02)^2(0.4604)$$

$$= 4.53$$

Step 5. Determine the lift-coefficient contribution of the external mass flow.

$$C_{L_e} = 0.69 \quad \text{(figure 9.3.1-13)}$$

Solution:

$$C_L = C_{L_i} + C_{L_e} \quad \text{(equation 9.3.1-a)}$$

$$= 4.53 + 0.69$$

$$= 5.22$$

This corresponds to an experimental value of 5.40 obtained from reference 1.

9.3.2 DUCTED-PROPELLER PITCHING-MOMENT VARIATION WITH POWER AND ANGLE OF ATTACK

This Section presents a method for estimating ducted-propeller pitching moments as functions of power and angle of attack. The basic discussion in Section 9.3.1 is directly applicable to this Section, and the reader is referred to that discussion for a general description of the fundamental phenomenon.

DATCOM METHOD

The method presented for estimating ducted-propeller pitching moments is based on ring vortex and simple momentum theories with empirical modifications.

The pitching moment consists of three component parts:

(1) A circulation-induced moment which in effect causes a shift in axial duct forces (essentially a shift in thrust axis.)
(2) A moment due to the lift component
(3) A moment due to the negative drag component

The circulation-induced moment is always positive (nose-up) and increases with increasing power. The last two components also increase in magnitude with power but may be positive or negative depending upon the location of the ducted-propeller center of pressure. This method assumes the center-of-pressure location to be independent of power and angle of attack and to be on the duct axis at the unstalled center-of-pressure location of the undiffused annular wings of reference 2.

The pitching-moment contribution of a ducted-propeller configuration, based on the duct planform area and duct chord and referred to an arbitrary moment center, is given by

$$C_m = \frac{\pi A_D}{2}\left(\frac{V_e}{V_\infty} - \cos \delta_{i_f}\right) \sin \alpha_D + \frac{\bar{x}}{c}\left(C_L \cos \alpha_D - C_{F_x} \sin \alpha_D\right) \qquad 9.3.2\text{-a}$$

where the first term on the right-hand side is the circulation-induced moment as derived by Sacks in reference 1, modified by the empirical relation for the net turning angle of the internal flow, discussed in Section 9.3.1. The last two terms are the components due to lift and drag.

$\frac{V_e}{V_\infty}$ is the exit-velocity ratio, obtained from equation 9.3.1-e

δ_{i_f} is the internal-flow turning angle, including the effects of power, obtained from equation 9.3.1-c

C_L is the total lift coefficient of the ducted propeller, obtained from Section 9.3.1

C_{F_x} is the total negative drag coefficient of the ducted propeller, obtained from Section 9.3.3

$\frac{\bar{x}}{c} = \left(\frac{x_m}{c} - \frac{x_{cp}}{c}\right)$, the chordwise distance, in duct chords, from the reference center to the unstalled duct center of pressure, positive for the center of pressure ahead of the reference center

$\frac{x_m}{c}$ is the chordwise distance, in duct chords, from the duct leading edge to the reference center, positive aft of the duct leading edge

$\frac{x_{cp}}{c}$ is the chordwise distance, in duct chords, from the duct leading edge to the center of pressure of the unstalled duct, positive aft of the duct leading edge. It is obtained as a function of duct aspect ratio from figure 9.3.2-6.

A comparison of test data with ducted propeller pitching-moment coefficients computed by this method is shown in table 9.3.2-A.

Because of the number of variables involved in the ducted propeller problem and the design parameters not considered in the Datcom method, the comparison between theory and experiment cannot be analyzed by examining the isolated effect of one variable. However, it is felt that one important factor pertaining to the test conditions of the available data, namely scale effect, should be considered before assessing the accuracy of this method. The data presented in reference 1 of table 9.3.2-A are the only available test results of a large-scale ducted propeller in the non-axial flow regime. Although experimental data on similar models of different scale are needed for the proper evaluation of the scale effect, it is felt that the low Reynolds numbers of small scale tests will appreciably affect the stalling characteristics of the duct. Therefore, comparison of calculated and large-scale experimental results of reference 1 in table 9.3.2-A is more indicative of the accuracy of the method than comparison with the other reference data.

Sample Problem

Given: Same ducted propeller configuration as sample problem of Section 9.3.1. Some of the characteristics are repeated below.

$d_e = 4.525$ ft $\quad d_{CB} = 1.208$ ft $\quad c = 2.75$ ft

$A_D = 1.645$ $\quad S_D = 12.45$ sq ft

Additional Characteristics

$V_\infty = 93.5$ ft/sec $\quad \alpha_D = 30^\circ$ $\quad$ Sea level

Moment reference center at 0.49c $\quad q_\infty = 10.4$ lb/sq ft

Compute:

$\frac{V_e}{V_\infty} = 2.02$

$\delta_{1_f} = 27.45^\circ$

$C_L = C_{L_i} + C_{L_e} = 5.22$

(sample problem Section 9.3.1)

C_{F_x} = 3.455 (sample problem Section 9.3.3)

$\frac{x_{cp}}{c}$ = 0.266 (figure 9.3.2-6)

$\frac{\bar{x}}{c} = \frac{x_m}{c} - \frac{x_{cp}}{c}$

$= (0.49 - 0.266)$

$= 0.224$

Solution:

$$C_m = \frac{\pi A_D}{2}\left(\frac{V_e}{V_\infty} - \cos \delta_{i_f}\right) \sin \alpha_D + \frac{\bar{x}}{c}\left(C_L \cos \alpha_D - C_{F_x} \sin \alpha_D\right) \text{ (equation 9.3.2-a)}$$

$$= \frac{\pi(1.645)}{2}(2.02 - 0.8874)(0.50) + 0.224\left[(5.22)(0.866) - (3.455)(0.50)\right]$$

$$= (2.58)(1.1326)(0.50) + 0.224\ (2.792)$$

$$= 2.085$$

This corresponds to an experimental value of 1.899 obtained from reference 1.

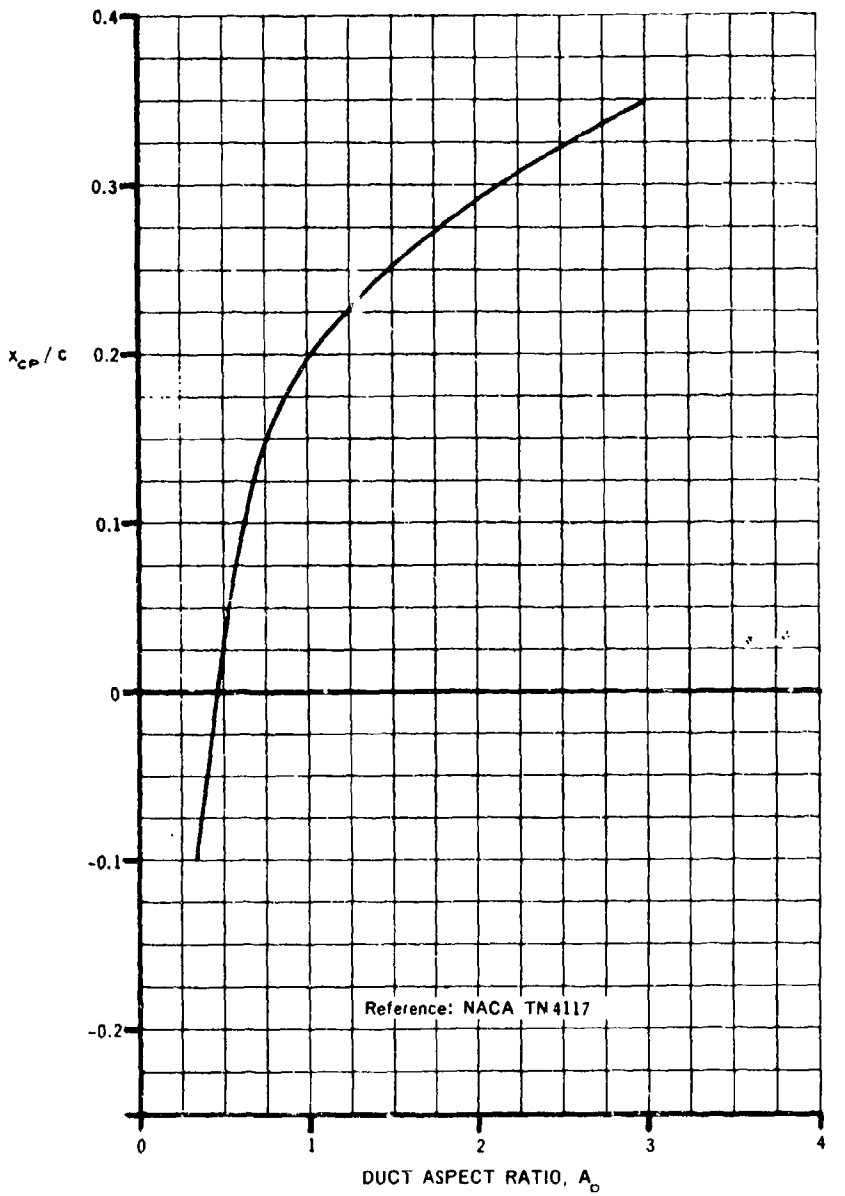

FIGURE 9.3.2-6 DUCT CENTER OF PRESSURE LOCATION

9.3.3 DUCTED-PROPELLER DRAG VARIATION WITH POWER AND ANGLE OF ATTACK

This Section presents a method for estimating ducted-propeller drag as a function of power and angle of attack. The basic discussion in Section 9.3.1 is directly applicable to this Section, and the reader is referred to that discussion for a general description of the fundamental phenomenon.

DATCOM METHOD

The method presented for estimating ducted-propeller drag is expressed as the sum of the components resulting from the internal and external mass flows. The theoretical basis of this method is the same as that of the Datcom lift-estimation method of Section 9.3.1.

The negative drag coefficient of a ducted propeller is given by

$$C_{F_x} = \frac{\pi A_D}{2}\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right]\left[\left(\frac{V_e}{V_\infty}\right)^2 \cos\delta_{i_f} - \left(\frac{V_e}{V_\infty}\right)\right] + C_{F_{x_e}} \qquad 9.3.3\text{-a}$$

where the first term on the right-hand side is due to internal flow and is estimated on the basis of simple momentum theory modified by the empirical relation for the net internal-flow turning angle, discussed in Section 9.3.1.

$\frac{V_e}{V_\infty}$ is the exit-velocity ratio, obtained from equation 9.3.1-e

δ_{i_f} is the net turning angle of the internal flow, obtained from equation 9.3.1-c

$C_{F_{x_e}}$ is the external negative drag coefficient, resulting from the external flow, obtained from figure 9.3.3-4 as a function of duct aspect ratio and angle of attack. Figure 9.3.3-4 is based on empirical modifications of the data of references 1 and 2.

A comparison of test data with ducted-propeller drag coefficients computed by this method is shown in table 9.3.3-A. The measurement of drag involves the difference between the components of the thrust force and the normal force and is inherently less accurate than the measurement of the lift force. At a tunnel velocity near that for steady level flight ($C_{F_x} = 0$), slight errors in drag measurement can result in test values with an opposite sign than that predicted by theory; and percent error becomes incalculable, although the actual magnitude of the difference may be less than that for lift. Consequently, a comparison of theory and experiment in this area may be misleading when presented in terms of percent error. Therefore, a summary of the results presented in table 9.3.3-A is presented as a weighted error.

Sample Problem

Given: Same ducted-propeller configuration as sample problem of Section 9.3.1. Some of the characteristics are repeated below.

$d_e = 4.525$ ft $\qquad d_{CB} = 1.208$ ft $\qquad c = 2.75$ ft

$A_D = 1.645$ $\qquad S_D = 12.45$ sq ft

Additional Characteristics

V_{∞} = 93.5 ft/sec — Sea level

α_D = 30° — q_{∞} = 10 lb/sq ft

Compute:

$$\left.\begin{aligned}\frac{V_e}{V_{\infty}} &= 2.02\\ \delta_{1_f} &= 27.45^{\circ}\end{aligned}\right\} \quad \text{(sample problem Section 9.3.1)}$$

$$\left[1 - \left(\frac{d_{CB}}{d_e}\right)^2\right] = 0.9295$$

$$C_{F_{x_e}} = -0.395 \quad \text{(figure 9.3.3-4)}$$

Solution:

$$C_{F_x} = \frac{\pi A_D}{2}\left[1-\left(\frac{d_{CB}}{d_e}\right)^2\right]\left[\left(\frac{V_e}{V_{\infty}}\right)^2 \cos\delta_{1_f} - \left(\frac{V_e}{V_{\infty}}\right)\right] + C_{F_{x_e}} \quad \text{(equation 9.3.3-a)}$$

$$= \frac{\pi(1.645)}{2}(0.9295)\left[(2.02)^2(0.8874)-(2.02)\right] + (-0.395)$$

$$= (2.41)(1.60) - 0.395$$

$$= (3.455)$$

This corresponds to an experimental value of 3.785 obtained from reference 1.
